(Dotted triangles, 40-in. tuberculated steel penstock; pipe factor, —0.79. Dotted circles, 12-in. smooth steel pipe; pipe factor, —0.85.)

Agreement of Reference Piezometers. As first installed, there were variations as high as 4 per cent among the four reference piezometers. In removing these discrepancies a great deal was learned about the action of square-edged orifices.

Burr. From a study of the results of runs Nos. 10 to 19, inclusive, Table 2, it is seen that orifices Nos. 2 and 3 actually changed 0.4 per cent due practically entirely to the removal of the burr, since the surfaces of these piezometers were little changed. This burr was not on the surface of the piezometer plug, i.e., projecting into the flow of the water, but overhung the hole of the orifice about 0.001 in., and was caused by the dragging effect of the file when the orifice plug was being dressed down to the pipe surface.

The presence of this burr was expected, but following the filing process a piece of hardwood that fitted very snugly was forced and twisted into the hole, and it was thought that the burr was removed by this treatment. To the unassisted eye the edge was smooth and square. The true state of the orifice edge was seen only under a microscope and was remedied with a fine rat-tail file.

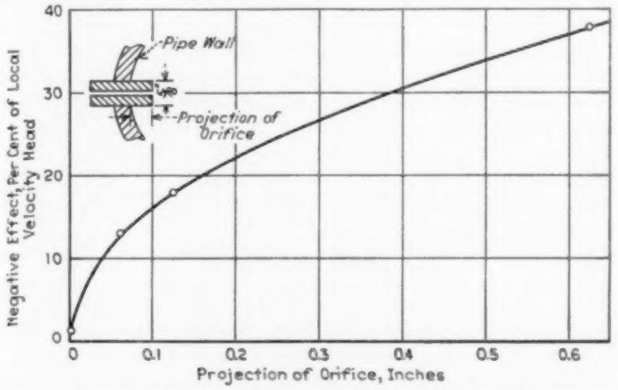

FIG. 9 EFFECT OF PROJECTION OF ORIFICE PLUG UPON PRESSURE READINGS

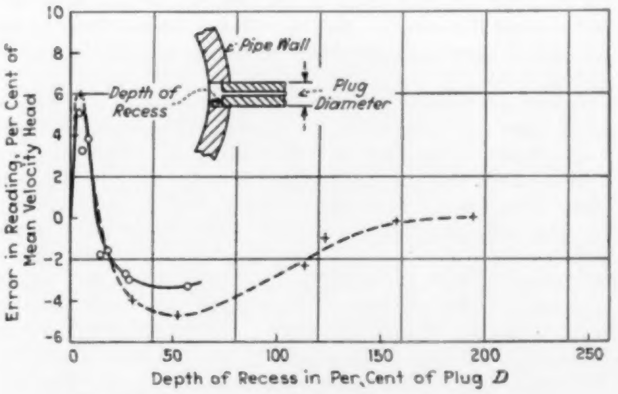

FIG. 10 EFFECT OF RECESSED PIEZOMETER PLUG

Surface Finish of Plug. In examining the reference orifices under a binocular microscope it was noted that the surface left on the piezometer plug by a smooth file was relatively rough. Therefore while the burr was removed from all square-edged orifices, the surfaces of piezometers Nos. 1, 2, and 4 were polished with crocus cloth and the surface of No. 3 was left untouched. In subsequent tests it was noted that No. 1 and No. 3 gave the same reading when in the same place. Since one was polished and the other was not, it would indicate that a piezometer plug is not sensitive to minute abrasions on its surface.

Projection of Plug. Probably the greatest source of error was that caused by the orifice plug projecting beyond the surface of the pipe. Orifices Nos. 12 and 13 were purposely projected $^1/_8$ in. and $^1/_{16}$ in., respectively, and the average error was found to be about —10.0 per cent and —7.4 per cent. In the first few runs orifice No. 4 had a —2.2 per cent error. This was later reduced to —1.1 per cent, but the reason for the improvement was not guessed at the time. Finally the true reason for the discrepancy was surmised. It was found that the center of the orifice plug projected 0.005 in. beyond the pipe surface. This surface was leveled as near as possible, and the error was decreased to —0.3 per cent. In Fig. 9 the negative error, expressed as a percentage of the local velocity head, is plotted against the projection in inches of the piezometer plugs. It will be noted that the curve at first rises rapidly from the origin. Then, in Fig. 10, the effect of allowing the piezometer plug to be recessed in the pipe wall is noted. Here again the curve rises very abruptly from the origin. This should emphasize the great importance of getting a piezometer plug or plate absolutely flush with the penstock wall.

Final Agreement of Reference Piezometers. When the known sources of error were removed, the four $^1/_8$-in. square-edged orifices checked each other to well within 1 per cent. Further, the discrepancies remaining are largely due to oblique or turbulent flow of the water since piezometers No. 1 and No. 3 check each other to 0.1 per cent when in the same place, i.e., when the pipe was rolled over, but there is a variation of 0.5 per cent between them on opposite sides of the pipe.

Size of Orifice. From a comparison of performance of piezometers Nos. 1 to 8 and including No. 5*A*, Table 2, it is seen that within the limits tested the error of a piezometer is not a function of the size of the orifice. All these piezometers mutually check within 0.7 per cent. The variation in size between the piezometer orifices was from $^1/_{16}$ in. to $^{27}/_{32}$ in. It may be noted, however, that a very small orifice, such as No. 5, which had a $^1/_{16}$-in. hole, may be overdamped and sluggish in action, leading to erroneous readings, since the operator assumes that the reading is correct because it is steady. Also the effect of a minute leak in the piping may cause a considerable error in the reading in the smaller piezometers.

Length of Straight Piezometer Tube. Referring to Fig. 10, another factor governing the performance of piezometers is brought out. In addition to illustrating the fact that the piezometer plug must be flush, this curve shows that the piezometer orifice that pierces this plug should be continued for over two diameters into the plug before its shape is changed. This fact is of great importance when piezometers are constructed in thin wall pipe.

Piezometers With Rounded Edges. Orifices No. 10 and No. 11 were made with $^1/_8$-in. holes and a radius of rounding on the edge of $^1/_{16}$ in. for No. 10 and $^1/_8$ in. for No. 11. It is seen that No. 10 checks the standard readings very consistently and accurately throughout. No. 11 has a positive error of 2.1 per cent. Piezometer No. 10 was rescraped because it looked rough under the microscope, yet the performance of the orifice was changed very slightly. The relatively large radius of rounding on the edge of piezometer No. 11 apparently allowed the water to eddy into the opening to give a small positive error. A rounding of $^1/_{16}$ in. and of $^1/_{32}$ in. on a $^1/_8$-in. hole gave the same results as the standard orifices. From these results, for a commercial standard, a piezometer having a $^1/_8$-in. hole and a $^1/_{32}$-in. radius of rounding is recommended for small pipes, while for larger pipes a piezometer having a $^1/_4$-in. hole and a $^1/_{16}$-in. rounding is recommended.

Effect of Pipe-Wall Roughness on Piezometers. In runs Nos. 22 to 39, inclusive the effect of various combinations of wall roughness on the piezometers was studied. In runs Nos. 22 to 25 inclusive a single tubercle made of tar, $1^1/_4$ in. in diameter and $^1/_4$ in. high, was placed $1^1/_4$ in. on center line in front of each of the test orifices. It will be noted that the effect of such a large tubercle immediately upstream from the piezometer was to cause a positive error of about 5 per cent. Various other arrangements of tubercles were tried, as will be noted in Table 2. However, the effect of adding rows of tubercles upstream from the piezometers, as shown in Fig. 11, is to reduce the error gradually until it becomes slightly negative. Leaving 3 in. of clean and smooth pipe wall between the orifice and any roughness or tubercles was sufficient in these tests to insure correct readings. In commercial practice, therefore, it would seem that if a strip of pipe wall about 6 in. wide and 12 in. upstream from the orifice was scraped smooth, correct results would be assured.

In runs Nos. 38 and 39 strips of $^1/_4$-in.-mesh wire screen were laid over all test orifices, as shown in Fig. 12, and the effect for the most part was a very slightly increased negative reading. This checked the action of a large number of tubercles in the pipe immediately upstream from the orifice.

Effect of Whirling Water. In runs Nos. 40 and 41 and Nos. 45 to 48, inclusive, the effect of whirling water upon the piezometers was studied. (See Fig. 13.) The reference orifice in this case was the so-called tea-ball piezometer, which was rated and held at the center of the pipe for these tests. The only conclusion that can be drawn is that under such conditions large positive errors can be obtained. Referring to Fig. 18, the effect of whirling water was tried upon the 12-in. by 6-in. venturi meter. In this case it will be seen that the coefficient of the meter was increased at low discharges and decreased at the high discharges.

Pressure Distribution Below a Butterfly Valve. In runs Nos. 49 to 51, inclusive, the effect upon the piezometers of a butterfly valve above the test section was studied. The valve was 12 in. in diameter and $2^1/_2$ in. thick, and modeled after the butterfly disks which are in common commercial use. The center line of the butterfly valve was located 0.5 ft., 1.0 ft., and 1.5 ft. above the center line of the piezometers. The pressure distribution found at the piezometer section during these tests was very different from that existing with smooth water-flow conditions. The errors are erratic and sometimes relatively large. The data available do not indicate any remedy for this condition except to take a greater distance between the butterfly valve and the piezometer section.

Inserted Tube. The inserted tube, which is shown in Fig. 14, was rated by placing it at the center of the pipe with its axis parallel to that of the pipe. The error was found to be 0.3 per cent, which is an exact check with the reference orifices. The error became —7.0 per cent, however, when the tube was rotated about 10 deg. out of its proper position. It is therefore evident that such a piezometer must be used with the greatest care.

A traverse was made across the pipe with this tube. The deviation was from —1.3 per cent to +1.3 per cent and directly proportional to the true position. This deviation is probably accounted for by the fact that the water flow was not absolutely smooth and axial. Quantitatively, the traverse indicated that the pressure head is constant all across the pipe.

Tea-Ball Piezometer. This type of piezometer, illustrated in Fig. 14, was rated at the center of the pipe and showed a large negative error. While it does not read the true pressure head, it is not sensitive to the direction of the water flow.

Conical Piezometers. As the name implies, this type of piezometer, illustrated in Figs. 15 and 16, consists of a cone which projects into the water flow, with the orifice located at the apex of the cone. Various angles of the side of the cone with the flow of the water from 0 deg. to 90 deg. were tried, both at the wall and mounted on a rod in various parts of the pipe. Very large negative effects can be obtained in this manner up to as much as 15 times the local velocity head acting at the apex of the cone. However, wherever one of these conical piezometers is used, it must be rated, as the amount of the negative effect cannot be

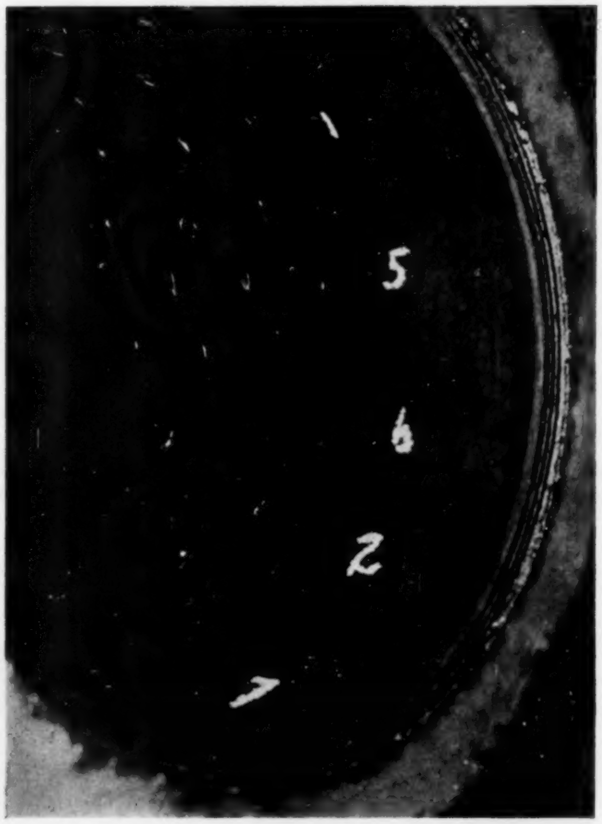

FIG. 11 TUBERCLES OF TAR ATTACHED TO PIPE WALL

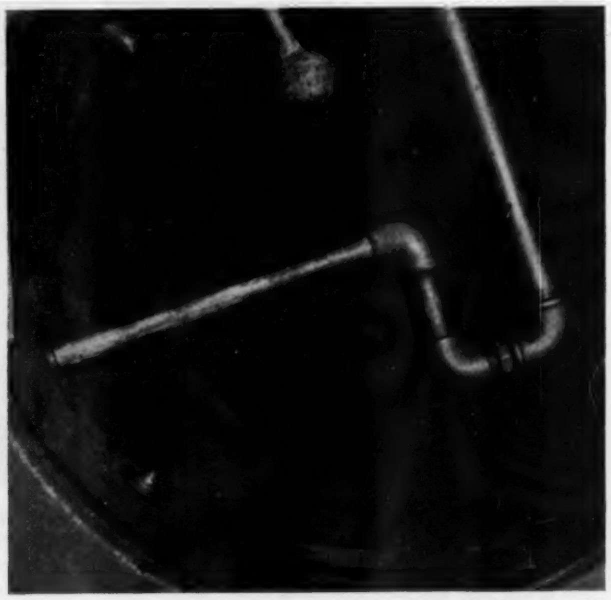

FIG. 14 INSERTED-TUBE AND TEA-BALL PIEZOMETERS

predicted. This is due to the fact that the flow past the tip is the resultant of the primary flow in the pipe and a secondary flow along the tip. This secondary flow is caused by the difference in velocities along the pipe traverse. The dynamic pressure of the water striking the side of the tip is directly proportional to the velocity of the water at that point. Inasmuch as the velocity is constantly changing in the traverse there is a difference in pressure from the bottom of the cone and the apex which is dependent upon the position of the cone in the pipe. Where there is a difference in pressure in a free fluid, there must be a flow which is the secondary flow referred to. Therefore it is seen that a conical piezometer will have a varying rating according to position in the pipe and also according to the distribution of velocities in the pipe.

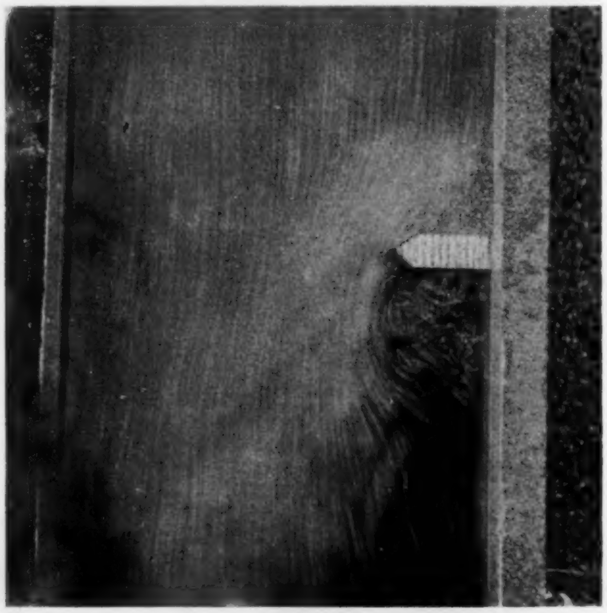

Fig. 15 Flow Past a Piezometer Mounted on a Rod

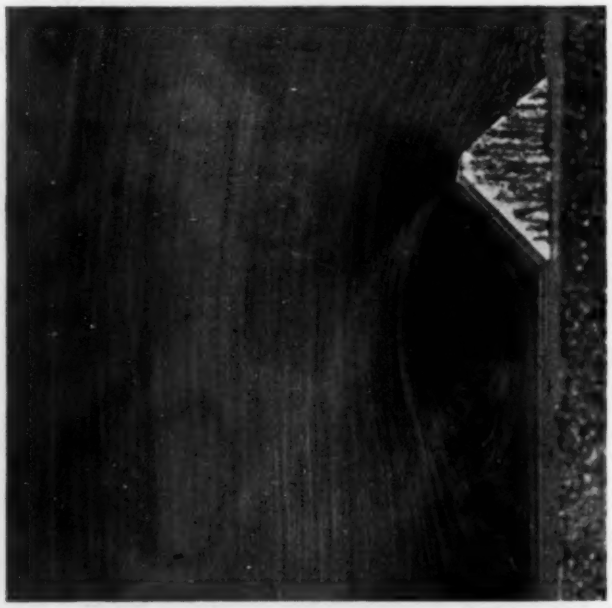

Fig. 16 Flow Past a 45-Deg. Conical Piezometer on the Wall of the Pipe

From the foregoing discussion it is seen that conical piezometers can be used to increase greatly the deflection in a water-gaging or venturi section and for other similar uses. However, due to its sensitivity to more than the ordinary number of factors, it should be used with great care and thoroughly rated.

TABLE 6 RECESSED PLUG

(Tests on Sept. 15, 1931)

Depth of recess, per cent of plug D	Deflection, per cent of mean H_v	Remarks
5.0	+6.0	[a]
30.0	—4.0	
51.5	—4.7	
113.0	—2.3	
123.0	—1.0	
158.0	—0.2	
194.0	0.0	
4.4	+5.1	[b]
8.8	+3.8	
13.3	—0.1

[f] Piezometer No. 13, run No. 53.

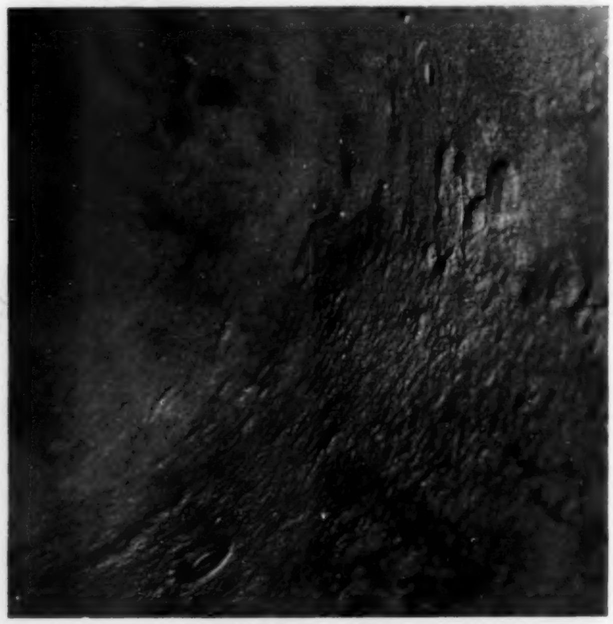

Fig. 17 Inlet Piezometers of Venturi Meter After Tubercles Were Removed

Venturi-Meter Study. During the piezometer investigation, the effect of wall roughness, whirling water, and improvement of meter-inlet piezometers upon the operation of the 12-in. by 6-in. venturi meter was studied. Fig. 17 shows the condition of two inlet piezometers after the tubercles had been removed and before the piezometer plugs were filed down smooth and flush. The results of these tests are shown in Figs. 18 and 19.

CONCLUSIONS

The following results were indicated by these tests on piezometer openings:

1 The error of a piezometer is a constant percentage of the local velocity head existing at the orifice.

2 The size of the opening has no effect within the limits tested, which were from $^1/_{16}$-in. to $^{27}/_{32}$-in. opening and mean velocities up to 7.3 ft. per sec. in a 12-in. pipe.

3 A true square-edged orifice is accurate, but very sensitive to slight changes in construction and position.

4 A standard piezometer plug or plate must be absolutely flush with the conduit wall.

5 A piezometer that projects beyond the pipe-wall surface has a large negative error.

6 The burr must be carefully removed from a square-edged orifice.

7 A piezometer plate or plug is not sensitive to minute abrasions on its surface.

8 A piezometer orifice must continue with parallel sides for over two diameters into the plug before its shape is changed.

9 The inside penstock wall should be scraped clean for at least 1 ft. upstream from a piezometer.

10 The piezometers to determine true pressure head should not be installed where there is any chance of the water whirling in the pipe or immediately downstream from an obstruction, such as a butterfly valve, a rivet head, or a plate joint.

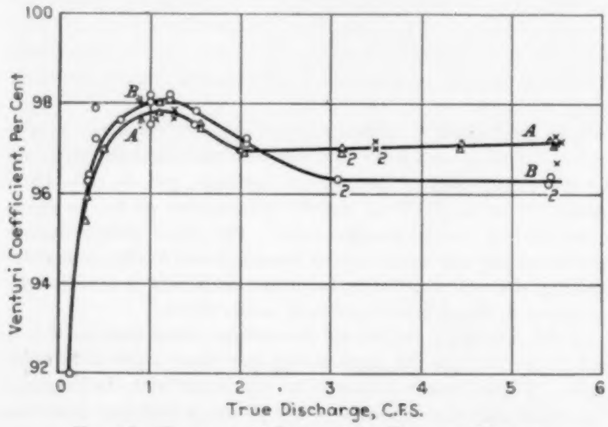

FIG. 18 TESTS OF 12-IN. BY 6-IN. VENTURI METER
(Curve *A*, with and without butterfly valve; curve *B*, with spinner. Circles, six-vane spinner in pipe, 5.3 ft. upstream; crosses, butterfly valve in pipe, 5.3 ft. upstream; triangles, calibration under normal circumstances.)

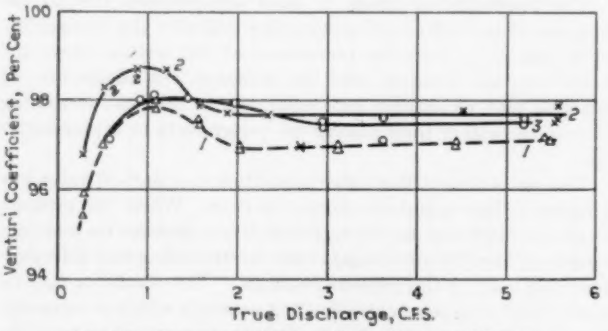

FIG. 19 TESTS OF 12-IN. BY 6-IN. VENTURI METER
(Order of tests: Curve 1, as used in piezometer study; curve 2, with tubercles removed; curve 3, with inlet piezometers improved.)

11 An inserted tube pointed on the upstream end and with piezometers on the side gives a correct pressure-head reading, but it is very sensitive to angularity.

12 A tea-ball piezometer has a large negative error, but it is not sensitive to the direction of flow of the water.

13 A conical piezometer has a very large negative effect, but must be used with extreme care and calibrated.

14 An orifice with a large radius of rounding has a small positive error.

15 An orifice with $^1/_4$-in. hole and $^1/_{16}$-in. radius of rounding is recommended for standard practice.

Discussion

ARTHUR L. COLLINS.[3] The work of the authors on piezometers has been made public at an opportune time, and the information should be a valuable guide to engineers who are interested in measurements where they must make use of pressures obtained through the piezometer.

The authors have stated that the object of this investigation was (1) to determine a stable type of piezometer suitable for use as a standard in commercial work and (2) to determine those factors which have the greatest bearing in obtaining correct results. It does not appear that the first object has been satisfactorily accomplished, because the data do not indicate how a piezometer can be constructed so that it will provide a means for taking a pressure measurement without the measurement being affected by the velocity in the pipe. It will be a matter of coincidence when such a piezometer is discovered. This is apparent since the reference orifices when first installed had variations as great as 4 per cent between them. Even then there was no way to prove that all four piezometers were not in error.

In some classes of measurements where the piezometer is depended upon, such as the pitot tube, orifice plate, and venturi, and where the low differential pressures are required in pipe-line tests for coefficient of roughness, these errors are very important.

Difficulty in obtaining an ideal piezometer may not be the fault of the design of the piezometer so much as it is the rolling action of the water at the pipe wall. Under a normal flow, where the velocity distribution is unaffected by various factors, the slope of the distribution curve has a tendency to follow the parabola. Under this condition the liquid probably strikes the wall in a direction oblique to the axis of the pipe.

The failure of the piezometer to function accurately has already had its effect upon many hydraulic problems. For example, it has prohibited to a large extent the use of the pitot tube, which should be one of the simplest and most accurate instruments that can be used for flow measurements in pipes. Also, the piezometer is bringing into disrepute in many cases measurements made by the orifice plate where it is used on the end of a pipe as a nozzle or between the flanges, and the taps for the piezometer are made by tapping into the pipe. In the orifice plate the way to minimize the effect of the piezometer on differential pressure is to have a high ratio of pipe diameter to orifice diameter. Of course, the objection to the high ratio is the loss of head and dissipation of energy through the restricted area.

The manufacturers of the deep-well turbine pump in California are the most extensive users of the orifice plate for field tests. It was introduced to them about 1920. The end orifice plate is generally used with a low ratio of pipe diameter to orifice diameter, in order not to build up a false head on the pump being tested. The piezometer is drilled in the field, and of course may create readings which are far from correct. Where the differential head is only a few inches and the initial pipe velocity is quite high, the measurement cannot be very reliable. However, innumerable acceptance tests are made with the orifice plate, and the results are not questioned, because some reliable company is credited with having calibrated the orifice plate under laboratory conditions and found it to be correct. Such tests mislead both the manufacturer and the buyer, and no doubt will be abandoned when better methods of water measurement are introduced.

A few examples of how the piezometer has affected the general information on pitot tubes will be called to attention. The A.S.

---

[3] Consulting Engineer, San Francisco, Calif.

M.E. Fluid Meter Bulletin, Part 1, 1924, pages 39, 40, and 42, illustrates by Figs. 17A, 17B, 18, 19, 21, and 23, types of tubes the reliability of which can now be judged by these piezometer studies. The A.S.M.E. Power Test Code of 1926 particularly recommends 17B. The coefficient for this tube is given as 0.98. No doubt the 0.02 correction is due to the piezometer, and the value may change depending upon various conditions. It is noted that in the revised Third Edition, Part 1, 1931, the 17B design is now shown on page 42, Fig. 17, and the coefficient has not been mentioned, but multiple piezometers are recommended.

The next example is the Testing Code, approved by the Machinery Builders Society, dated Oct. 17, 1917. Under Pitot Tubes it reads: "The static pressure over the cross-section shall be measured by from four to eight carefully constructed piezometers." . . ."and condition of piezometer orifices shall be such that no piezometer shall vary its readings by more than 10 per cent of the velocity head from the average of all piezometers." Then the code further states that after the measurement has been conducted the velocity is multiplied by 0.976 to correct for oblique or sinuous flow.

Inasmuch as an error in the piezometer due to the velocity means an error in the measurement, one is now also able to judge to a certain extent the risk taken in a pitot-tube measurement when the piezometer is used. It is quite noticeable that the pitot-tube coefficients are less than 1.00, which naturally favors the waterwheel manufacturer, inasmuch as a low measurement is in their favor. However, the pump manufacturer in a performance test is on the other side of the fence and favors the high-capacity readings, and should demand a tube coefficient of 1.00 plus, to be on the safe side.

In the writer's field experience with the pitot tube he has proved that the type of tube using the piezometer in the pipe wall will give readings which may be in error as much as 5 per cent. This error is not permissible, and since the method is specified in the Power Code, it practically prohibits the use of the system. In order to overcome the handicap offered by the piezometer, it is necessary to use a type of pitot tube where the piezometer feature has been eliminated.

There is another point worth mentioning along this same line. The pitot-tube traverses shown in the paper apparently were taken with the overhung type of tube which crowds the water to the opposite side. On one side of the pipe the velocity will be much higher than the velocity on the other side of the pipe, due to the insertion of the tube. For that reason the curve of velocity distribution does not indicate the true velocity in the pipe. As a matter of general information the writer would like to ask for a description of the pitot tube and its coefficients. Is the coefficient the same for the 12-in. pipe and the 40-in. pipe?

F. G. Switzer.[4] The measurement of pressure certainly seems a very simple thing at first, but it needed further investigation to bring out some of the difficulties. The authors deserve credit for a difficult job well done.

In the connections from the pressure tap to the pressure-measuring device such as a water or mercury column, it is customary to insert a valve, which is partly closed, to reduce pulsations. It should be noted that such practice may introduce errors which mount rapidly with increasing tendency to pulsation. Pulsations are usually not entirely eliminated, but merely reduced to a point where accurate observations of column height may be made. Hence there is flow back and forth through the throttling valve. Loss of head through this valve is proportional to nearly the square of the velocity. Velocities above and below the average will therefore be damped by different percentages. The average pressure on the manometer side will not be quite the same as the average pressure in the pipe under observation. While this difference may not be great, its presence may be noticeable in work of a high degree of accuracy. Some method of viscous damping is much to be preferred. One method of accomplishing this is to insert a bundle of fine wire into a short section of the connecting tubing. This makes the removal of air bubbles very difficult, no matter how the piping is arranged with air vents. It is not to be recommended unless extreme care is used in installation and observation. It is suggested that a more practical method of securing viscous damping be devised.

For measuring air pressures, an entirely different device has been used which apparently can be made to measure pressures in liquids also. No reference to this device can be cited. It consists of a tube with a large number of small holes drilled through the walls from all directions. Around that portion of the tube there is wound a closely coiled helix of fuzzy material such as twine used for tying up packages. This arrangement has been used in experimental work at Cornell University with great success. Its chief advantage is that it can be used anywhere in a flowing stream and is not directional, no matter in what direction the tube is placed with respect to the flow lines. This makes it possible to measure pressure distribution in any cross-section.

E. B. Strowger.[5] Although according to the writer's experience it has been customary to insist on rather rigid specifications for the installation of piezometer openings, yet to date there seemed to be available no definite information as to the errors introduced by various modifications. The paper quite definitely establishes the effects of various modifications in the piezometer opening, some of which may be either artificially or accidentally produced in the ordinary course of construction.

Of the conclusions stated by the authors, those numbered 8, 9, and 15 are perhaps the outstanding ones from a practical viewpoint. These three conclusions are concerned with the length of the orifice wall, the condition of the penstock wall just upstream from a piezometer, and the rounding of the orifice edge to prevent burrs. The results found will serve to preclude controversies on these points.

The possibility of errors in head measurement due to the vagaries of the individual piezometers indicates the advisability of having more than one piezometer at the section where the head is to be measured, and also indicates the advisability of bringing each piezometer pipe separately to the head-measuring instrument rather than joining the piezometers to a piezometer ring.

The use of a throttling valve in addition to a shut-off valve in a piezometer line is perhaps worthy of note. Where the pressure to be measured may have a variation in one direction for a certain length of time, the use of a gate valve for throttling may introduce a serious error in the pressure readings. This condition may be exemplified by a piezometer line to a penstock which is connected to a surge tank, a gate valve for throttling purposes being in the piezometer line. If the valve disk is nearly closed, it may become locked closed by the action of the changing pressure tending to deflect the disk over against the seat and thus cut off more or less completely the opening to the penstock. One precaution is to drill a hole through the center of the disk to insure a positive opening under all conditions of throttling.

It should be pointed out that the function of piezometers for use in connection with taking Gibson diagrams is somewhat different in principle from their function in measuring absolute pressure head. In the former case, the piezometer is used for transferring the supernormal pressures existing in the penstock by virtue of the water hammer produced by destroying the momentum of the water. Any slight modification of the piezometer opening while changing the absolute head reading for "steady state" conditions, in the case of the diagram, only results in altering the position of the "running line," the impulse area recorded being unaltered. This has been established by many experiments, using combinations of various piezometers located around the periphery of the pipe on the piezometer sections.

[5] Assistant Hydraulic Engineer, Buffalo, Niagara & Eastern Power Corporation, Buffalo, N. Y.

John W. Brasko.[6] Due to the care which must be exercised with piezometers, the writer is curious to learn what results, in the opinion of the authors, may be expected from the use of a piezometer consisting of a $^1/_2$-in. H pipe nipple screwed into a $^1/_2$-in. H coupling, which is welded over a $^3/_8$ drilled hole in the wall of standard thickness pipe.

We have adopted this method of pressure-tapping pipes as a much more satisfactory mechanical job than that of screwing a nipple into a tapped hole in the pipe. We feel, also, that the elimination of the problem of making the piezometer flush with the pipe wall and the consequent reduction of burr formations are strong points in favor of this method.

If such a piezometer gives inaccurate readings, is it reasonable to assume, in cases of flow measurement by orifice plate where the pressure differential across the orifice is to be measured, that the error in the one piezometer is cancelled by the same error in the other piezometer by reason of a manometer arrangement.

John. B. Drisko[7] **and Hunter Rouse.**[7] A short series of investigations similar to those performed by the authors, dealing with only five types of piezometer openings, was carried out in 1905 in Dresden, Germany, by Dr.-Ing. Paul Schuster.

Schuster's work[8] was essentially an investigation of flow through a Francis turbine. Preliminary tests of various pitot tubes and piezometer openings were carried out in the towing tank of the Uebigau Shipyard. The piezometer openings investigated were five in number:

(1) Square-edged hole with diameter of 1.75 mm. (0.069 in.).

(2) Hole with diameter of 1.75 mm., corners removed with 90-deg. countersink to a maximum diameter of 1.8 times the hole diameter

(3) Square-edged hole with diameter of 2.7 mm. (0.106 in.).

(4) Hole with diameter of 2.7 mm., corners removed with 90-deg. countersink to a maximum diameter of 1.5 times the hole diameter

(5) Hole with diameter of 2.7 mm., corners rounded on a radius of 0.4 times the hole diameter.

The five piezometer openings were mounted at intervals of 25 mm. in a vertical row on a brass plate 4 mm. thick. The plate, the leading edge of which was sharpened with the bevel on the back side, was mounted on the towing carriage exactly parallel to the direction of travel and was towed in still water.

The velocities of the carriage were recorded chronographically. Glass tubes of 6.5 mm. inside diameter containing the piezometer water columns were mounted on a board faced with millimeter cross-section paper, by means of which the column heights were determined. Test data are as follows:

Velocity		Piezometer error due to dynamic pressure head, in mm.				
m. per sec.	ft. per sec.	(1)	(2)	(3)	(4)	(5)
0.76	2.49	—1	—1	—2	—1	—1
0.84	2.76	—1	—1	1	0	0
1.02	3.34	—2	—2	0	—1	1
2.05	6.72	0	—2	0	—1	0
2.57	8.42	—10	—8	—10	—8	—4

Schuster concludes that the suction effect of moving water is best avoided and hence the pressure is indicated most accurately by the use of a well-rounded opening. He gives the following approximate values for the error of piezometer column heights due to the velocity effect:

Square-edged opening, —3 per cent of velocity head
Countersunk opening, —2.5 per cent of velocity head
Well rounded opening, —1 per cent of velocity head

Similar errors as found by Allen and Hooper are:

Square-edged orifice, 0 per cent of velocity head
Round-edged orifice No. 11, 2.1 per cent of velocity head

Allen and Hooper arbitrarily chose square-edged orfices as references; hence rounded orifices have a positive error. Schuster found the rounded openings more nearly correct, which would give the square-edged openings a negative error. A comparison of the foregoing tables indicates that in both cases the well-rounded orifice gave higher readings.

The values of "piezometer error in per cent of mean velocity head" from Allen and Hooper are probably smaller than if based upon actual velocity, inasmuch as they were figured for mean pipe velocity and not for the lesser velocity actually existing near the piezometer openings in the pipe wall. The corresponding Schuster values were figured for a velocity which actually existed close to the piezometer openings and are hence somewhat larger than the former values.

The fact that Schuster's piezometer openings were set into a flat plate and that those of Allen and Hooper were set into a cylindrical surface may account for some of the discrepancy noted.

It is barely possible that some of Schuster's work was done in water quiet enough to give laminar flow conditions. In general, it is found that the first one or two runs made in a towing tank after the water has been undisturbed for some time, as for instance overnight, are unsatisfactory because the water has become quiescent and conditions correspond to those of laminar flow. Once having been disturbed, the water in the tank may be said to be turbulent, and gives corresponding results. Since the flow with which Allen and Hooper were working was undoubtedly turbulent, the possible dissimilarity of flow conditions under which the two series of investigations were done may be given as a remote source of difference in the results.

It is to be regretted that the wide range of piezometer inlets discussed in the paper did not include various forms of openings leading to tubes set at angles differing from 90 deg. with the pipe wall. The fact has long been known that a tube pointing slightly against the direction of flow, however flush it may be with the pipe surface, will give values above the actual pressure head, because of the additional effect of a component of the velocity head—similar conditions causing a decreased reading for a tube pointing somewhat downstream. In addition to having quantitative data on the influence of such angularity, it would also be interesting to know whether the proposed rounding of the opening would tend to reduce this effect.

The danger of inaccuracies due to this cause, especially in cases where openings must be drilled by hand with no means of procuring absolutely normal holes, may be fully understood only through such careful tests as are contained in this paper. One of the writers recently conducted a series of experiments involving 75 hand-drilled piezometer connections on the side of an open flume for measuring the effect of curving flow; as the pressures were often below the atmospheric and the velocities correspondingly high, many of the tubes were rendered useless by their imperfect construction, despite great care in finishing the openings at the wetted face.

[7] River Hydraulic Laboratory of Massachusetts Institute of Technology, Cambridge, Mass.

[8] Published in 1910 by the Verein deutscher Ingenieure, "Mitteilungen über Forschungsarbeiten," Heft 82.

Allen and Hooper's ingenious method of arranging the gage box brings to mind a number of gage forms which have proved satisfactory in various laboratories for very delicate setting. It is claimed of the gage point lowered from above that small particles of dust or drops of water will cause the springing of the meniscus before the metal point is actually in contact with the water surface. This difficulty is overcome by the hook gage immersed in the water, but the latter is often sharply pointed and the contact noted from above when the surface is punctured; needless to say, this instant of contact cannot be observed with great accuracy from above the surface, while the sharpness of the point makes it equally difficult from below.

The apparatus used at the Worcester laboratory apparently includes a gage whose point is not so acute as to involve the latter difficulty. A slightly arched chisel edge has been used at the Walchensee experiment station of the Forschungsinstitut of Bavaria, with which one may measure without great difficulty to within 0.02 mm. (0.0008 in.). A small lamp illuminates the hook, whose reflection is sharply visible in the under side of the water surface; the hook is raised until it apparently just touches its reflection above, but without quite puncturing the surface.

Many experimenters believe that the glass gage pipe should be from $1^{1}/_{2}$ to 2 in. in diameter, not only to insure a flat portion of the water surface between the meniscus curves at the sides of the glass, but also to overcome the lag due to capillarity, and the variable capillary rise if the pipe varies slightly in diameter. This usually makes the tube large enough to serve both as stilling box and gage glass, and hence lessens the effect of changing volume as the gage is raised or lowered.

H. S. Bean.[9] The paper is the most comprehensive study of pressure measurements with a piezometer that has come to attention. Since K. Büchner[10] published the results of his observations, and possibly before, there have been many references to more or less causal observations on the use of piezometers, but in all cases these observations have been incidental to the attainment of some other objective.

The effects of the various designs and flow conditions that were tried and the conclusions drawn are very much what would be expected. It is gratifying to see that the piezometers used in the Chicago tests, by the A.G.A. Committee on the Measurement of Large Volumes of Gas,[11] conformed exactly to the recommendation of the authors.

The authors do not specifically state whether they used other sizes of lines than those shown in Fig. 1. Presumably they did not. Also, they recommend the use of a piezometer with a $^{1}/_{8}$-in. hole and a $^{1}/_{32}$-in. radius of rounding for small pipes, while for larger pipes a piezometer with a $^{1}/_{4}$-in. hole and a $^{1}/_{16}$-in. rounding is recommended. However, they have not suggested a dividing line between "small" and "larger" pipes. It will be very helpful to know what their recommendations on this point would be.

John R. Freeman.[12] The paper interests me, because about 55 years ago I had a hand in a much more fundamental and more precise research on piezometers. The principal results of this research were published in the *Transactions* of the American Academy of Arts and Sciences in Boston in the year 1878, pages 28 to 53, and illustrated by four plates of drawings and diagrams.

These researches were carried on by Mr. Hiram F. Mills, Chief Engineer of the Essex Water Power Company at Lawrence, Mass., who was one of the most eminent hydraulic experimenters in America in the epoch of 50 years ago. They were made as a preliminary to a long series of other experiments on the flow of water in pipes, only a few of which have ever been published.

These researches on piezometers by Mr. Mills, unfortunately, have remained almost unknown to the engineering profession, because presented to a society which at that time contained relatively few engineers in its membership.

The writer had the rare good fortune to be one of Mr. Mills' young assistant engineers at the time these experiments were made, and soon afterward became his principal assistant, and continued in that capacity for about 10 years in a great variety of hydraulic work, including much of an experimental nature.

These experiments by Mr. Mills were much more fundamental than those of Allen and Hooper because they compared the piezometric level with that of a free water surface flowing in an open channel, whereas Allen and Hooper's experiments simply compare one piezometer with another, and have all their piezometric orifices arranged around the same cross-section of a closed pipe flowing full of water under pressure. Thus they simply show the errors which may be introduced in such measurements by the careless projection of a burr on the inside of the piezometric orifice or the lowering of the water column caused by carelessly permitting the end of a connecting pipe to protrude inside of the channel, which errors are, however, often permitted by those who fail to realize the truths brought out by Professor Allen's experiments.

The precision of measurement in the Mills experiments was also greater inasmuch as the micrometer gages used in the comparisons were all carefully read to about 0.0001 in., under excellent conditions for measuring head in the piezometer chamber, whereas the limit of measurement in the Allen-Hooper experiments was 0.01 in. For most practical purposes this difference of precision is unimportant.

Mr. Mills' experiments aimed to accurately determine once and for all the truth about a moot point in physics which had been raised by Darcy in a statement in his monumental work "Recherches Hydraulique," published about 75 years ago, which (translated) reads: "Piezometers do not indicate the entire head of a conduit at the point where they are attached, but the head diminished by a certain amount, the diminution being due to the velocity at the base of the piezometers, where the water by its cohesion acts on the manometric column, the height of which it lowers."

Darcy also stated that in a piezometer attached to a reservoir of large diameter, feeding a pipe in which water was flowing, the lowering of the piezometric column by suction would be less than in a piezometric column attached to the pipe.

The idea at the bottom of this piezometer question in physics is that water has a definite cohesive strength (which with proper apparatus may be measured as a tensile strength amounting, as I remember it, to about 75 lb. per sq. in.). And it appeared not unreasonable to Darcy and others to suppose that this cohesion would lower the piezometric column when water was flowing rapidly past the orifices.

Dubuat, ablest of the hydraulic experimenters of 120 years ago, had erroneously concluded that water would press against the side of an open conduit in which water was flowing, with a pressure less than that due to its depth by the amount of pressure that would produce its mean velocity. Mr. Mills stated that although Navier in 1819 had controverted this idea, Dubuat's conclusion had been commonly presented in treatises on hydraulics up to the time of Darcy.

[12] Consulting Engineer, Providence, R. I. Mem. A.S.M.E.

Mr. Mills therefore sought the origin of this wrong idea of Dubuat, that the piezometric height would be less than the true height, by connecting certain of his piezometers to a pipe with an open end, which could be projected through the wall of the conduit; and he found, just as Allen and Hooper have now found, that the water column in the piezometer chamber was thereby lowered proportionately to the velocity of the water passing the end of the projecting pipe, because of the deflection of the current by this projection.

The apparatus designed by Mr. Mills for the purpose of definitely settling this question of whether or not there was a lowering of the piezometric column by suction, when connected to an orifice truly in the plane of a conduit wall, comprised in brief an open trough, nearly 30 ft. in length, about 1 ft. in depth, and about 4 in. in width of channel, constructed of clear, well-seasoned pine wood with greatest care by an uncommonly expert mechanic, within the walls of which about 20 orifices of different forms were cut, on opposite sides of the trough, of various sizes and shapes and having various inclinations.

We are now chiefly concerned with the results of the three series of experiments:

(A) With orifice in the plane of the wall of the flume and with the connecting passage at right-angles to that wall
(B) With orifice truly in the plane of wall of the flume, but with passage leading from the orifice to piezometer inclined at an angle to wall
(C) With orifice in end of pipes which projected into the conduit by various amounts.

Nearly 6000 separate observations were made, covering velocities all the way from about $^1/_2$ ft. per sec. to about 9 ft. per sec. The flume was frequently emptied and inspected for possible changes in shapes due to swelling of the wood, by means of steel straight-edges, some short and some long, under conditions of lighting so arranged that deviations of 0.001 in. in or out from the plane of the orifice could readily be perceived. Some of the orifices were in smooth brass plates carefully inserted in the conduit wall.

The piezometric water columns were measured in small reservoirs averaging perhaps 6 in. in diameter, constructed of tin boxes, attached to the side of the flume, with great precautions to prevent leakage.

The principal cause for possible errors in measurement of comparative heights lay in the "wrinkles" in the surface of the water in the open conduit when flowing at high velocities. Notwithstanding the care taken to maintain a constant level at the entrance of the flume, this surface at higher velocities became somewhat "wrinkled" along its course by small diagonal standing waves.

Every practicable precaution was taken to obtain accuracy. To eliminate the personal equation, the observers at the several stations along the trough, all of whom were skilled and experienced in such experiments, frequently shifted their location.

As a result of this elaborate series of experiments, Mr. Mills concluded that the height of the water shown by piezometers of class A was the same as the height of water at the middle of the stream flowing in the trough, as nearly as it was practicable to measure, and that there was no lowering of the piezometric column by suction or cohesion of the water flowing past the piezometric orifice.

For class B, by experiments on four orifices he found, notwithstanding the edges of the orifice coincided as nearly as practicable with the plane of the conduit wall, that when the connecting passage was inclined 45 deg. facing upstream, the effect was to slightly raise the piezometric column, and when inclined downstream to slightly lower it, probably because of some slight sinuosity in the current past the orifice.

For class C, with orifices in the end of a pipe, Mr. Mills found, as Allen and Hooper have found, a definite lowering proportional to the velocity head of the water flowing past the end of the pipe.

As the final result of nearly 6000 observations on about 20 different orifices, Mr. Mills concluded his paper with the words: "From these results, it is evident that it is entirely within the practicable limits of construction to make piezometers that will indicate the true height of the stream, within the practicable limits of observation."

During the 10 years or more following these experiments, in my work for Mr. Mills in measuring water used by the factories at Lawrence, Mass., and Manchester, N. H., in various turbine tests, and in a great variety of experiments on the flow of water in conduits, great care was always taken when setting up piezometers for water-measuring apparatus to make sure that the piezometric orifice was truly in the plane of the surface of the pipe, and in order that there could not be any possibility of a burr or projection, the edges of the orifice were always very slightly rounded. Great care was taken when a pipe was screwed into a conduit wall that by no possibility should it project inside the surface of this wall.

I am prompted to make a few further comments relative to the precautions necessary to obtaining the greatest practicable accuracy in piezometric observations.

First, as to the size of the glass tubes for observing the height of water, I assisted Mr. Mills in a long series of experiments on this matter, using glass tubes of many sizes up to 2 in. in diameter, with water of various temperatures, with the water surface in the reservoir rising in some cases, falling in others, and in experiments in which the actual mean level in the reservoir did not change, but was simply agitated, as by small waves. Unfortunately, no description of these experiments was ever published.

My recollection is that we found it necessary to have our glass tubes at least 1 in. in internal diameter, in order to fully avoid the effects of surface tension, or capillarity, from the inner walls of the glass tubes.

We found this degree of surface tension and error which existed in the small tubes of, say, $^1/_2$ in. internal diameter, varied with both temperature and with the degree of cleanliness of the inner wall of the tube.

Subsequent to these experiments, in all of our precise work, care was taken to have tubes not less than about 1 in. in diameter. With these and proper apparatus of loop-vernier index, proper lighting, and accurate scale, the height can quickly be measured with certainty to within about 0.001 in.

Another matter which commonly does not receive sufficient attention, in precise work, and which may have led to a lack of precision in Professor Allen's experiments, is that the conduit channels between the piezometric chamber and the pipe should be such that water should flow just as easily in one direction as in another; otherwise a sort of check-valve action occurs which, if there are pulsations in the water of the conduit, may materially affect the accuracy of the piezometric measurement.

In the Mills' experiments previously discussed, great care was taken to have the orifices in the walls of the conduit and the connections to the piezometric chamber so shaped that the coefficient of contraction at all edges of the connecting channel should be the same for inward flow as for outward flow.

Another matter which Professor Allen has touched on is the importance of avoiding even the faintest leakage in piezometric connections. I have had frequent occasion to observe that the importance of this precaution is often not appreciated. It is of highest importance for precise experimentation that there be no leakage whatever. Possibly the fact that water possesses slight velocity may be at the bottom of this possible source of error.

Long tubes and tubes of small diameter in many cases present opportunities for error in piezometric observations by reason of air bubbles released from solution which collect in these tubes.

On one occasion, perhaps 25 or 30 years ago, in some experiments in the large hydraulic flume and measuring weir in the hydraulic laboratory of Cornell University, I found that the hook gage in the still-box measurements of depth over the weir, supposed to be "absolutely correct," was about 1 in. in error, as determined by holding an ordinary leveling rod, first on the crest of the weir and then at the water level of the weir box, using an engineer's Y-level under such conditions as to insure accuracy.

This test was made with a foot or more in depth flowing over the weir in order that any effect from settlement under the weight imposed by operating conditions should be discovered. The experienced engineer at that time in charge of Cornell's hydraulic flume could hardly believe his eyes when this amazing error was revealed. Probably it was due to an air trap or an accumulation of small bubbles in the connections.

In our many water experiments and measurements at Lawrence 50 years ago, under Mr. Mills, we learned to take the utmost care to arrange our piezometric connections so that they could be flushed out by a swift current, immediately before beginning observations, also at frequent intervals, and, moreover, found it necessary to carefully avoid slopes in connecting pipes which might interfere with the free rising of bubbles, and also found it necessary at intervals of half an hour more or less, in many cases, to hammer our rubber-tube connections in a way to produce violent pulsations of the water column, for the purpose of loosening air bubbles disengaged from solution in the water, while it stood in the connection.

Precise experimentation in hydraulics involves an everlasting setting of traps to guard against unconscious error of many kinds.

AUTHORS' CLOSURE

Arthur L. Collins: In answer to the statement which Mr. Collins makes that "it does not appear that the first object of the investigation has been satisfactorily accomplished," may we call attention to the work of Mr. Hiram Mills referred to in Mr. John R. Freeman's discussion. Results of his work, which was done in an open flume where the actual elevation of the free-water surface was checked against the piezometer heads, check the work described in this paper very closely. In addition, the four reference piezometers, when properly installed, check within 1 per cent of the mean velocity head of each other, and later four other piezometers, Nos. 5A, 6A, 11B, and 12B, were installed according to the specifications developed in the paper, and they checked the reference piezometers within 1 per cent of the mean-velocity head.

In regard to the use of pitot tubes in this investigation, the static piezometers of the tube referred to as No. 11A and shown in Fig. 14 were compared as to performance with the reference piezometers, and in this case checked very well. However, a pitometer was used in making the traverses in the 12-in. and 40-in. pipes, the curves of which were printed in the paper, and the indicated velocities were corrected for the change in area occasioned by the presence of the rod. Pitometers have been carefully calibrated recently in the 12-in. line and in the 16-in. throat of a 36-in. by 16-in. venturi meter against weighing-tank measurements, and the value of the coefficient was the same in both cases. A pitot tube should not be in error as much as 5 per cent if it is carefully calibrated under hydraulic conditions similar to those in which it is to be used.

F. G. Switzer and E. B. Strowger: The damping devices referred to in the discussions of Professor Switzer and Mr. Strowger are probably satisfactory, but at the Alden Hydraulic Laboratory it is customary to pinch a rubber hose to give the desired degree of damping. This system, we believe, has merit on account of its simplicity, flexibility, and availability. In the first place, it is very easy to obtain full discharge in the pressure line for the elimination of dirt or trapped air, or to change the water in the line because of temperature conditions. Secondly, the channel of approach to the throttling section is just the same on both sides. Then, if the hose is pinched so that the water column or pressure gage is just alive, it is probable that the flow through the throttling section is viscous. And finally the throttling is very readily changed to meet the pressure conditions.

John W. Brasko: Fig. 10 of the paper shows that a $^3/_8$-in. hole must have parallel sides for $^3/_4$ in. before any change of diameter of the piezometer tube occurs. Therefore, for a large number of cases where the pipe-wall thickness may be considerably less than $^3/_4$ in., this form of piezometer will undoubtedly be in error. Also the importance of removing the burr from the inside edge of the piezometer opening cannot be overemphasized.

John B. Drisko and Hunter Rouse: With reference to the tests of Dr. Ing. Paul Schuster in 1905, it is evident that the hydraulic conditions of the two investigations are so dissimilar that comparisons are probably of little value.

H. S. Bean: If reference be made to the results of tests on piezometers Nos. 5A and 12B, it will be seen that they give the same results. Hence the choice of the size of the orifice depends upon other considerations than accuracy.

John R. Freeman: With reference to Mr. Freeman's statement of relative accuracy of Mr. Mills' and this work, it should be understood that the error given in this paper was an over-all figure (about 1 per cent), whereas the figure given for Mr. Mills' work really applies only to the measurement of the elevation of the water surface in the piezometer stilling pots. Referring to Plates Nos. 3 and 4 of Mr. Mills' paper, it will be found that there are a number of points which lie more than 2.0 per cent of the mean velocity head away from the smooth curve of all the points, and each of these points is the average of ten readings. The determination of the free-water surface, a very difficult thing to measure accurately, introduced errors which makes the two papers comparable as to accuracy.

It is to be regretted that Mr. Mills' paper on piezometers was so thoroughly hidden that the material therein was practically unknown to the engineering profession for so long. The authors were unable to obtain a copy of his paper until after the present paper was written, but find, fortunately, that his work and the results of this paper practically check.

HYD-54-2

Hydraulic Butterfly Valves

By ROSS L. MAHON,[1] SAN FRANCISCO, CALIF.

This paper describes some of the special features of design found in the modern butterfly valve and which have been adopted within recent years, during which this type of equipment has been developed to meet some of the unusual requirements existing in many modern hydroelectric projects. Means for making this type of valve more effective in limiting leakage are discussed in some detail and attention is given to general considerations affecting the design of disks and bodies. Some interesting types of operating mechanisms are outlined, and various kinds of protective and auxiliary equipment are described. Recent applications of butterfly valves for free-discharge service have broadened their useful field, and the suggestion is made that valves of this type might well find future use for other purposes than those existing in the hydraulic-power industry.

The butterfly type of valve as developed in the hydraulic-power industry during recent years has such a wide field of application and finds such general use in modern hydroelectric installations that information in regard to it will be of interest. As the size of hydraulic-power units has increased, more attention has been given to the design of auxiliary equipment for the modern hydroelectric plant, such as governors and valves. It is only by making a careful study of modern operating requirements and by cooperating with the engineers of the large public utilities that the turbine designers have been successful in meeting the needs.

Much has been published during recent years on hydraulic turbines, but little has appeared regarding the valves used in the pipe lines or penstocks to control the large quantities of water delivered to the units. During those earlier years when the unit capacities were limited and the penstocks and turbines were small, the penstock valve was usually of a standard type, such as was built by valve-manufacturing concerns for ordinary waterworks service, and little attention was given to developing special designs. As the turbine units increased in size and higher heads were utilized, more attention was directed by the designers to those factors that make for efficiency and safety, and the development of suitable penstock valves began to receive the same careful attention as the turbine units themselves.

It was during this period that the butterfly valve was recognized as being admirably adapted for hydraulic service. Its simplicity, its low cost, and its dependability brought it into general use in hydroelectric work. Although the butterfly valve covers a wide range of engineering conditions and is suited to many types of installation, it should not be understood that it is used to the exclusion of other types of valve. For example, under extraordinarily high heads, special types of gate valves are used. For installations having special requirements, and particularly where valves of very large diameter are needed, balanced needle valves with hydraulically operated internal plungers find their application. The Larner-Johnson valve is a fine example of this type of equipment.

The modern butterfly valve, in its essentials, shows little change from the original conception. A cylindrical or tapering valve body is provided with flanges or riveting necks for attaching to the pipe line and carries two large bearings placed diametrically opposite each other. These support a transverse shaft on which is mounted the circular disk. An external operating mechanism rotates the disk about 90 deg. to move it from full-closed to full-open position. The support of the disk on a central axis results in a hydraulically balanced condition at either the closed or open positions; hence makes possible the use of a comparatively simple operating mechanism.

The first butterfly valves were used with small turbine units and the heads were low. Even though they were equipped with no special means for reducing leakage, the comparatively small size and the low spouting velocity encountered did not make water tightness of great moment. Such water as did pass through the valve when closed was usually taken care of by a drain located in the penstock or turbine casing downstream from the valve.

As butterfly valves of larger size came into common use and as they were employed under higher heads, the problem of properly handling the leakage became a difficult one, and those engaged in the manufacture of this equipment began to give attention to some means for reducing the clearance between the closed disk and the body. The castings which form the body of a large butterfly valve may be machined to an accurate fit with the disk in the shop of the valve manufacturer but, after being installed in a concrete foundation and subjected to the stresses that are set up, they can deform to such an extent that a close fit with the circular disk cannot be maintained. Furthermore, even if a proper fit between disk and body can be assured when such a valve is installed, ordinary water wear may cause an enlargement of the clearances, with a resulting increase in leakage.

It thus became evident that some sort of adjustable device was needed, not only to permit proper setting of the clearances between disk and body when the valve was installed, but to permit periodic readjustment. As a result a number of ingenious devices have been developed by the different valve manufacturers, some of which are described.

As the valves became larger in diameter and the heads under which they were used were increased, it became necessary to develop more powerful operating mechanisms. In many cases purchasers' specifications required that these operating mechanisms be sufficiently powerful to close the valve while normal full water flow was passing through it. For some installations it was even specified that the valve be capable of closure under full spouting velocity, such as might occur in the event of a rupture in the turbine casing or penstock below the valve, and today it is quite

---

[1] Vice-President and General Manager, Pelton Water Wheel Company. Mem. A.S.M.E. The author was born in Detroit, Mich., on April 16, 1890, and received his education at the University of California and the University of Michigan, being graduated from the latter in 1912 with the degree of B.S. in Engineering. Following graduation he was with Charles Butters, a mining engineer, for one year, joining the organization of the Pelton Water Wheel Company in 1913 as sales engineer. During the World War he held the rank of Captain in the Engineer Corps, serving with the 91st Division in the A.E.F., and now has the rank of Major in the Engineer Reserves. In 1926 he was appointed assistant sales manager for the Pelton company, and in 1929 was advanced to his present position.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

usual to require that the operating mechanism for a large valve be arranged to close it automatically whenever the water velocity exceeds a predetermined maximum. A description of the different types of operating mechanisms now in common use will therefore be of interest.

The butterfly valve finds its application not only at the lower end of the penstock adjacent to the turbine, but at the upper end of the pipe line where it emerges from the surge tank, tunnel, or forebay; and large butterfly valves, because of their low first cost and ease of operation, are being frequently used in diversion dams on large power projects to serve as head gates.

So much has been done to improve butterfly-valve design that it is believed the field of application is much broader than has been realized. This is true in connection with condenser systems and in pumping plants and pipe lines, particularly where the valves are of large diameter.

Design of Disks and Bodies

Hydraulic-turbine design has been developed to a point where unusually high efficiencies are obtained, and the valve manufacturer must build his equipment so as to minimize hydraulic losses within the valves themselves. Every effort is made in designing a modern butterfly valve to reduce friction and velocity losses, as well as those resulting from unnecessary turbulence or irregular flow conditions.

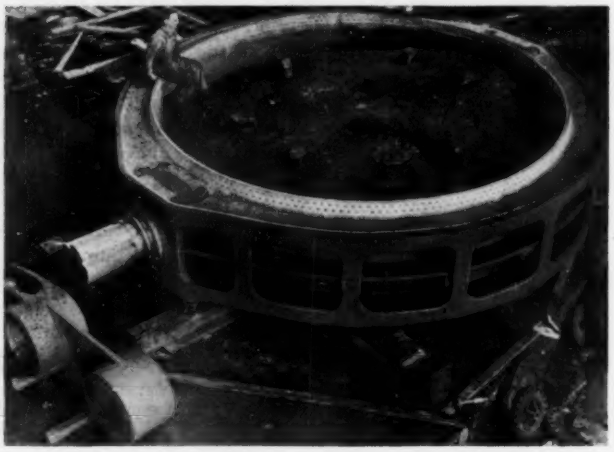

Fig. 1 Butterfly Valve 17 Ft. in Diameter for 180-Ft. Head
(Parting plane between halves passing through center line of valve shaft.)

It is therefore important that a smooth velocity curve be maintained as the water passes through the valve body and around the disk. If the velocity must increase, as is often the case when the valve is located adjacent to the inlet of a turbine casing, the water should be accelerated as gradually as possible. Proper determination of the water passage areas within the valve itself, as well as in the adjacent portions of the penstock and connecting pipes, will accomplish this result.

It is now the generally accepted practice to make the internal surface of the valve body and its connecting pipes as smooth as possible. Rivets with countersunk heads on the inside are used in fabricating joints, and sudden and abrupt changes in the area of the water passage are avoided.

The disk of one of these valves must be designed for heavy bending moments as, when it is closed against full penstock pressure, it will act as a rigid beam supported at its central point. The necessary strength is obtained by introducing heavy ribbing into the disk casting. In the modern valve these ribs are placed within the disk, which of course is hollow, and its outer surfaces are made as smooth as possible in order to present the least resistance to water flow. A characteristic streamline cross-section is found in almost all of the larger modern valves.

When the size of a valve body or disk is such as to make it impossible or inconvenient to transport it on standard railway equipment or to handle it easily with the derrick or crane facilities at the point of installation, recourse is had to sectionalization. The body can be made in two or more sections, with radial, flanged, bolted joints. In certain cases shrink keys have been used, as shown in Fig. 1. Disks of unusually large diameter are likewise made in two or more sections. Those comprising two sections may have the parting plane between the halves either at right angles to the axis of rotation, as shown in Fig. 2, or passing through the center line of the valve shaft, as shown in Fig. 1.

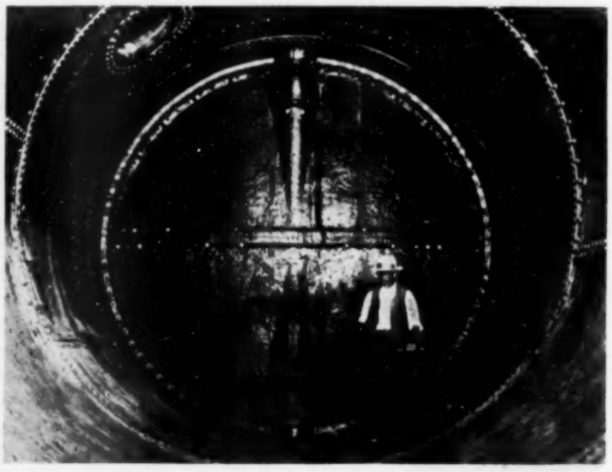

Fig. 2 Butterfly Valve 14 Ft. in Diameter for 40-Ft. Head
(Parting plane between halves at right angles to axis of rotation.)

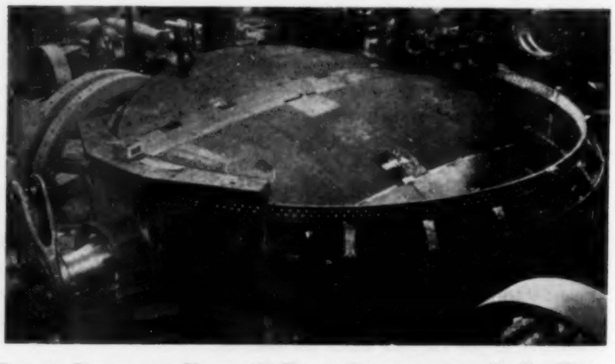

Fig. 3 Butterfly Valve 27 Ft. in Diameter for 89-Ft. Head
(Three-piece disk, with the two parting planes parallel to disk axis.)

When a three-piece disk is used, the two parting planes are preferably located parallel to the disk axis, as shown in Fig. 3, and the center section is made to carry the principal bending moments. Bolted joints are used in assembling the sections and may be located either internally or externally to suit the design. The internal joint has the advantage of leaving the outer surface of the disk free from irregularities, although the same result can be obtained by covering an externally bolted joint with a steel plate, welded or otherwise firmly attached to the face of the disk.

The bearings, which are located in the valve body and which carry the main valve shaft, are of conservative design, with large areas to transmit properly the enormous forces from the disk to the body structure without causing excessive bearing pressures.

It is quite common practice to design these bearings so that they can be removed from the body without disturbing the disk or shaft. Renewable bronze bushings are usually fitted to the bearings, and means are provided for ample lubrication, usually grease, forced into the bearings under high pressure.

Means for Reducing Leakage

Probably the most common method of insuring a practically watertight joint between the closed disk and the body of a butterfly valve is the use of metal seal rings. These are usually made of bronze or some similar non-ferrous metal and can be attached either to the body or the disk, or to both. Their design involves a means for adjusting the seal-ring position on the body or disk in order to make it match accurately the surface against which it seats.

When the ring is attached to the disk, it is usually made of comparatively thin cross-section and often sectionalized into several pieces with overlapping joints. It may be provided with a series of jackscrews or adjustable wedges, located in the disk as shown in *A*, Fig. 4, and by means of which it can be moved out radially in order to bring it into contact with the internal bore of the valve body or body-seat ring. Suitable clamping bolts make it possible to hold it firmly in its proper position after the adjustment is made. If both the adjustable seat ring on the disk and the seating surface in the body are made with a tapering or inclined contact surface, it is possible to have the disk at right angles to the axis of the valve body when it is in its tight closed position, and this is oftentimes desirable. The seating surface in the body may be machined on the body casting itself, although it is frequently desirable to attach a stationary bronze seat ring to the internal bore of the body, thus making it possible to renew the ring should excessive wear occur.

Another type of adjustable disk-seat ring is similar to that described, except that it fits into a slot in the edge of the disk and is so arranged that when the disk is moved into the closed position, pressure water in the penstock from the upstream side of the disk is used to force the seat ring firmly against the seating surface in the body. This construction is shown in *B*, Fig. 4.

In still another type where the closed position of the disk is at an angle of several degrees with the axis of the valve body, as shown in *C*, Fig. 4, the seat ring is loosely held by screws in a slot in the edge of the disk. As the disk comes to the closed position, the seat ring is brought into contact with the cylindrical machined surface in the valve body and is forced back into the disk against a special packing ring placed in the bottom of its groove, and in such a way as to serve not only as a flexible backing for the seat ring, but likewise as a gasket to prevent leakage.

Another very effective arrangement, shown in *D*, Fig. 4, consists of an adjustable bronze ring attached to the internal bore of the valve body. Radial movement of this ring is effected by means of jackscrews and bolts, all of which are adjusted from the outside of the valve body. A renewable ring may or may not be attached to the outside periphery of the disk itself.

One of the most ingenious, simple, and effective sealing devices is the rubber-tube seal ring, shown in *E*, Fig. 4. This is particularly well adapted for use on very large butterfly valves, and in its usual form consists of a heavy rubber tube set in a groove or slot in the valve body at the point where the disk seats. This tube is connected with a pressure system capable of supplying water at a pressure somewhat in excess of that which exists within the valve and penstock. As the disk of the valve is moved into the closed position, this tube is deflated, and after it reaches the closed position, pressure water is admitted to the tube, causing it to expand and to make a tight contact with the machined periphery of the disk adjacent to it. This arrangement has given very satisfactory service, and can be varied by placing the rubber tube in the outer edge of the disk instead of on the valve body.

The fact that these methods of obtaining a tight joint between disk and body are effective in reducing leakage is evidenced by data obtained from the various butterfly valve manufacturers and indicating the leakage that took place under actual test for valves of different diameters under a wide range of test pressures. All of these valves were fitted with special sealing devices to reduce leakage. (See Table 1.)

Valve-Operating Mechanisms

No attempt will be made to describe all of the different types of valve-operating mechanisms that have been devised for the operation of the many kinds and sizes of butterfly valves in use. There are, however, a limited number of typical arrangements that find general application and during the last few years there have been a few unusual installations that merit some mention.

For the smaller-sized butterfly valves, operating under low and medium penstock pressures, a mechanical operating stand consisting of gearing (which may be of the spur, worm, or bevel type) is well suited. Such a mechanism is ordinarily actuated by means of an electric motor arranged for push-button control from some convenient point adjacent to the valve, and the gearing operates a threaded nut that engages with a spindle or stem connected to a lever on one end of the main butterfly-valve shaft. An operating stand of this type is normally placed above the valve, and the electric motor is usually provided with limit switches and a solenoid brake to prevent overtravel and to permit centering the butterfly disk in its exact closed position. Auxiliary hand control is provided for by a handwheel and some type of clutch device that will permit throwing either the electric motor or the handwheel into mesh with the gearing. A mechanism of this kind has the advantage of being self-locking in any position and is comparatively simple to design, where the forces involved in the operation of the valve disk are not excessive. Figs. 5 and 6 are typical of this class of equipment. A threaded spindle attached at its lower end to a lever on the main valve disk engages with an oscillating nut in the operating stand. Fig. 7 shows a somewhat different type of operating rig in which a vertical threaded lead screw raises or lowers a trunnion nut connected to the main valve lever by means of links.

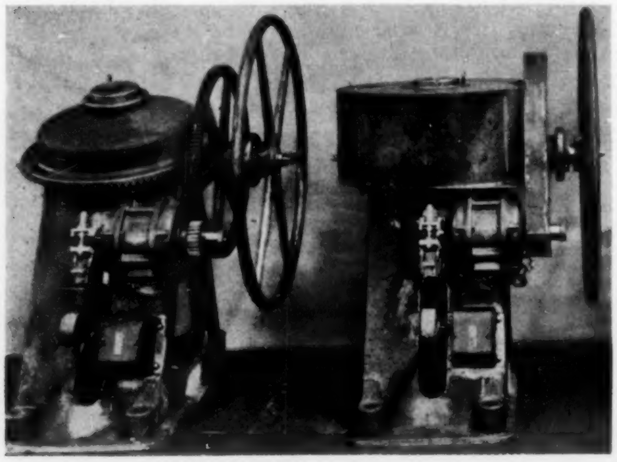

FIG. 5 ELECTRIC-MOTOR-DRIVEN OPERATING STANDS

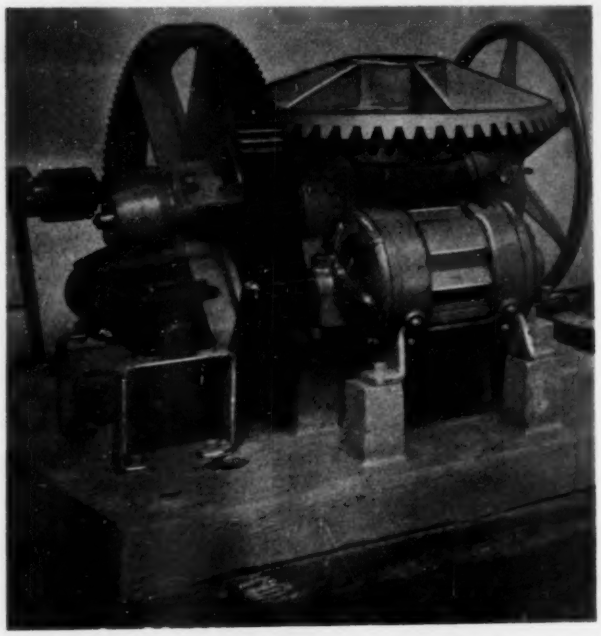

FIG. 6 OPERATING MECHANISMS WITH ELECTRIC-MOTOR DRIVE

There is a definite limit, however, to the amount of power that can be generated by this type of operating gear without involving the use of excessively large and cumbersome machinery. This limit is often exceeded with some of the equipment in use today, and for the larger butterfly valves, as well as those that operate under high heads, some form of hydraulic operating mechanism can be employed to advantage.

Where the penstock pressure is relatively high, a hydraulic cylinder receiving pressure water directly from the pipe line provides an effective means for operating the butterfly-valve disk. Water is admitted to either end of the cylinder, which may be of the vertical or the horizontal type, through a small control valve, which can be actuated by an electric motor or a solenoid arranged for remote control.

As penstock valves are not ordinarily required to remain in other than the full-closed or full-open positions, there is no necessity for having the mechanism self-locking at intermediate points. However, if this self-locking feature is desired, a simple restoring mechanism may be added to the operating cylinder that will hold the valve disk in any mid-position desired. A mechanical safety lock is sometimes provided at each end of the piston stroke so that the disk may be securely held in either the closed or the open position. The operating cylinder used with this type of mechanism may be of the oscillating type, mounted on trunnions, or of the stationary type, with a separate connecting rod and crosshead; it may also be of the trunk-piston type.

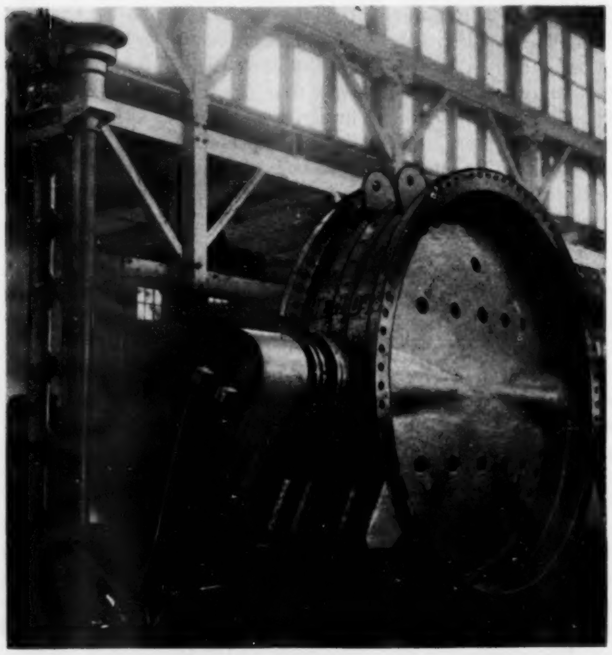

FIG. 7 BUTTERFLY VALVE 10 FT. 9 IN. IN DIAMETER WITH OPERATING MECHANISM

For the operation of very large butterfly-valve disks under low penstock pressures, an operating cylinder, using water from the pipe line, becomes excessively large and unwieldy. In such a case it is customary to use an operating cylinder of comparatively small dimensions, which is supplied with high-pressure oil from an accumulator or pressure tank, charged by a pump driven by an electric motor. An arrangement of this kind is particularly advantageous where several large butterfly valves are located adjacent to each other and where pressure oil can be delivered to all of them from a single source of pressure-oil supply.

An interesting new type of hydraulic mechanism that has been used on large butterfly valves built within the past few months is illustrated in Figs. 8 and 9. The hydraulic cylinder utilizes oil at about 1500 lb. pressure, supplied to it by means of a special high-speed multi-cylinder reversible displacement pump, mounted directly on top of the cylinder itself and direct-connected to an electric motor. No pressure tank or accumulator is needed, as the pump is connected directly to the cylinder and simply transfers oil from one side of the piston to the other. Instead of the usual limit switches, special flow motors are used at each end of the piston stroke to break automatically the electric-motor circuit and to bring the mechanism to rest. At the end of its stroke in either direction the piston comes in contact with a rigid mechanical stop, the oil pressure behind the piston builds up to a point in excess of its normal operating pressure, and it is then discharged through an adjustable pressure relief valve into the flow motor, closing an electric contact and shutting down the electric motor driving the pump. To prevent accident when work is being done within the valve or penstock, special shut-off valves with safety locks are located in the high-pressure oil pipes at either end of the cylinder. A handwheel that can be thrown into mesh with the pump provides a means for auxiliary hand operation. The upper side of the operating cylinder is cast to form a small tank, which provides a source of auxiliary oil supply to make up any leakage that may occur through the piston-rod glands of the operating cylinder.

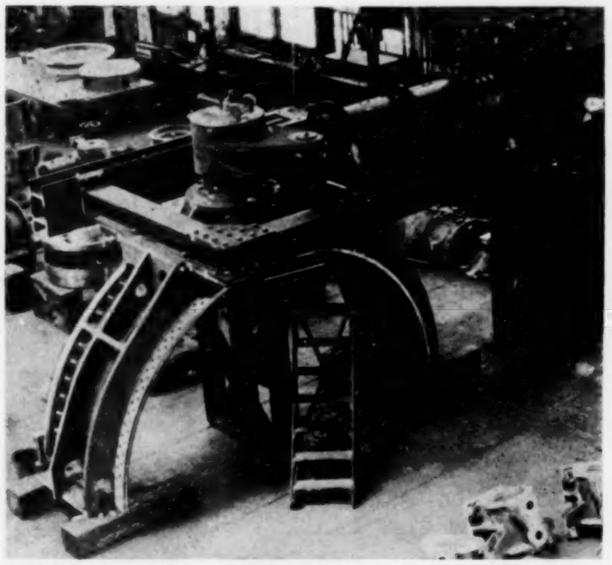

Fig. 8 Upper Half Body of 14 Ft. Diameter Valve With Operating Mechanism

Automatic Features and Bypasses

When a butterfly valve is located at the upper end of a penstock serving a modern hydroelectric plant, it is often required that it be so arranged as to close automatically should the velocity of the water column exceed normal—as, for example, in the case of a rupture in the pipe line below the valve. Such provision will insure prompt action in reducing the flow of escaping water down the penstock grade and will protect the power house and penstock supporting structures in the event of a break.

One device that has been thoroughly effective in accomplishing this automatic closure consists of two pitot tubes inserted within the penstock, adjacent to the butterfly valve, and connected by means of brass or copper tubing to a special diaphragm type of control valve that is extremely sensitive to pressure changes. The control valve can be connected up to actuate the operating mechanism of the butterfly valve, whether it be of the mechanical type driven by an electric motor or of the hydraulic type. If the butterfly valve or the penstock adjacent to it is designed to provide some venturi effect, piezometers can be used as effectively as the pitot tubes.

Another device often used and one that is less expensive than the mechanism just described consists of a vane or paddle located within the penstock and adjacent to the valve, and mounted on a lever that carries an adjustable balancing weight at its outer end. The weight can be set in such a way as to make the vane sensitive to any desired water velocity within the penstock, and by means of a suitable tripping device cause the operating mechanism on the butterfly valve to move its disk to the closed position when excess velocity occurs.

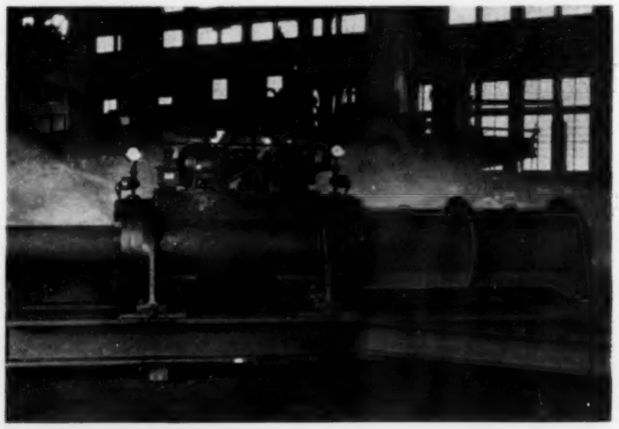

Fig. 9 High-Pressure Operating Cylinder With Pumping Unit

There are many cases on record where similar devices to cause automatic closure have been used with butterfly valves located at the lower ends of penstocks and adjacent to hydraulic-power units and for the purpose of protecting the power-hour structure and equipment in case of a ruptured turbine casing.

Another safety device that has been applied to many valves now in actual service makes it impossible to open the main valve until the pressure on both sides of the closed disk has been equalized. This is of use in preventing disastrous penstock pressure surges that can easily result from the sudden opening of a large valve, permitting the entry of a large volume of water under high pressure into an empty pipe line or turbine casing. Very little expense is involved for the addition of this automatic protection to practically any kind of valve-operating mechanism, and its use definitely eliminates the human factor in making certain that bypass equipment, almost always installed with high-head butterfly valves, will be used in the proper manner.

Bypass valves are of many types, depending on the conditions under which they are installed, and they may be connected directly to openings provided in butterfly-valve bodies, as shown in Figs. 10 and 11, or placed in piping that connects to the penstock above and below the butterfly-valve body. Under high heads and because the bypass is inherently a free discharge valve, the present-day trend is toward the special needle type, as a bypass valve of this construction is more certain to be free from vibration and to insure ease of operation than is an ordinary gate valve. This same needle type of bypass is also well suited for quick automatic opening.

Butterfly Valves for Free Discharge

A description of the modern butterfly valve would not be complete without mention of its comparatively recent use for free-discharge service.

For many of the sizable dams constructed during recent years it has been necessary to provide for the discharge of comparatively large quantities of water that must be bypassed at certain seasons of the year to supply the needs of power plants, irrigationists, and owners of riparian rights located below the dams. Due to the fact that the water level in a storage reservoir usually varies within wide limits, it is necessary to locate the discharge valves in the dam well below the high-water elevation, and the valves will be required at times to operate under relatively high heads. Daily or monthly variation in the quantity of the discharged water, coupled with the fact that the head on the valves changes with the water level, has made it necessary to develop a special type of valve known as the discharge regulator. This is so designed that its orifice can be readily and quickly adjusted for any required discharge up to its maximum and that no excessive wear or cavitation will result, although the valve be operated at partial opening for long periods.

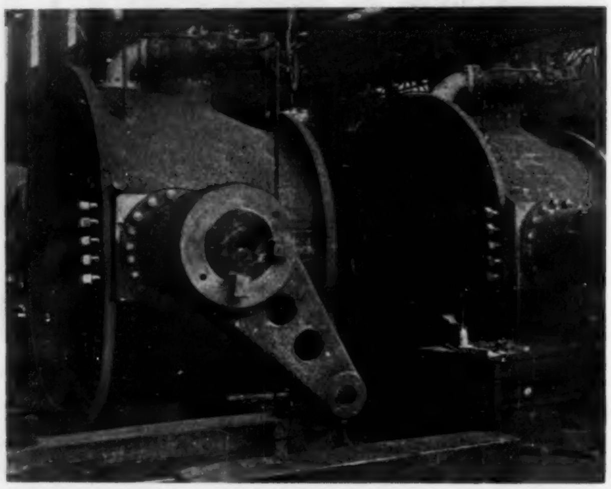

Fig. 10 Two Butterfly Valves Each 9 Ft. in Diameter for 836-Ft. Head

Early free-discharge valves used under very low heads were often ordinary slide gates, with circular or rectangular orifices, but as higher dams and greater discharge pressures were encountered, they proved unsatisfactory for continuous service, although still used in some installations as emergency sluices. In order to eliminate the difficulties experienced and as pressures were continually increasing, new forms of discharge regulators made their appearance, and the needle type of valve soon demonstrated its superiority over the slide gate.

However, with the increase in size and pressure, the forces required to move the needles assumed large proportions, and required the use of powerful operating mechanisms. This led to the development of the modern large needle type of free discharge regulator known as the Larner-Johnson valve, and in which the needle forms part of a hydraulic plunger, moving within a cylinder located inside the body of the valve, and actuated by pressure water taken from the conduit. Many of these valves have been operating for years, under conditions that would make impossible the use of any of the older types of equipment. Water wear and vibration have been eliminated, and mechanisms that are both simple and reliable are used to control the hydraulic forces that actuate the plungers or needles.

When the total water quantity that must be discharged through a dam is no more than can be passed through a single valve, the Larner-Johnson regulator fulfils all requirements, and will operate just as effectively at positions of partial opening as at full capacity. Of recent years, however, dams of such size are being constructed, and the required discharge is in many cases of such magnitude, that a single free-discharge regulator will not suffice, and a battery of these units becomes necessary. If these are all of approximately the same size and have about the same capacity, only one of them need be a regulator, capable of operating at fractional openings, and the remaining valves may all be of a type that is required to function only in the wide-open position, and hence may be of much simpler and less expensive construction than the regulator.

It is for this type of auxiliary free-discharge service that the butterfly valve has already proved itself well adapted and thoroughly dependable, even under fairly high heads. Actual tests, performed both in the laboratory and in the field, have enabled the designer to determine accurately the forces imposed on the disk as it is moved between open and closed positions in the discharging water column, and to design an operating mechanism that will provide plenty of power and insure freedom from vibration.

The shape of free-discharge valve bodies and disks now in use differs very little from those of butterfly valves in penstock service, although research work now in progress may indicate the desirability of adopting special features permitting the discharging jet to break clear of the valve structure at a sharp edge and admit air at certain points to prevent the formation of a vacuum, and the resulting tendency toward cavitation.

At the present time there are no less than ten butterfly valves, up to and including 84 in. in diameter, rendering eminently satisfactory service under free-discharge conditions; some of these operate under heads well in excess of 200 ft. Even under the most severe conditions, vibration is entirely absent and no difficulties have been experienced. Some of these have actually seen use as discharge regulators and have been operated for considerable periods in a position of fractional opening, even though not originally intended for this kind of service. Unless their continued use under these conditions causes cavitation and wear not yet apparent, it seems reasonable to predict that the butterfly type of valve may well fulfil all the requirements for an economical and dependable free-discharge regulator.

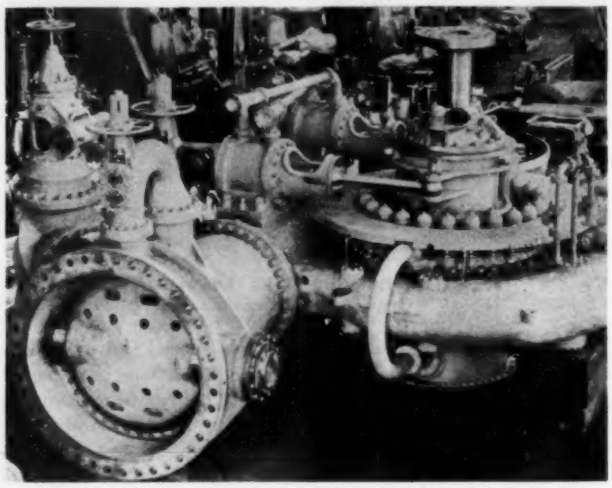

Fig. 11 Butterfly Valve 79 In. in Diameter for 940-Ft. Head (Located at inlet of large turbine casing.)

Butterfly Valves for High Heads

Among the butterfly valves now installed and operating under extremely high heads are those built for the Pigeon River Plant of the Carolina Power & Light Company, each 9 ft. in diameter. Two of them are shown in Fig. 10. The normal static head under which they are installed is 836 ft., but in order to take care of possible pressure rise in the penstock, it was considered necessary to design them for a maximum head of approximately 1215 ft. They are located at the lower end of their penstocks, adjacent to turbine casings, and the operating mechanism for each of them, not shown in the illustration, is of the hydraulic type, consisting of a cylinder and piston actuated by penstock-water pressure that is admitted to the cylinder through an electric-motor-operated control valve. Each butterfly valve is provided with a bypass valve by means of which the turbine casing below can be primed or filled with pressure water before opening the disk of the butterfly.

Provision is also made in the design of the control valve so that the main butterfly-valve disk will close automatically in case the pipe line or turbine casing below it is broken and the velocity through the butterfly valve increases beyond normal. In this case each of the valve bodies was made of tapering construction in order to eliminate the use of a separate taper section. Each of the disks is equipped with a special bronze seal ring in order to reduce the leakage to a minimum.

In the Oak Grove Plant of the Portland General Electric Company on the Clackamas River near Portland, Ore., there are two 79 in. diameter butterfly valves installed under an operating head of about 940 ft., and both serving as main inlet valves for large reaction turbine units. One of these valves is shown in Fig. 11 and is operated either by means of an electric motor or by an impulse water motor taking its supply directly from the penstock. The other is operated by means of a hydraulic cylinder with control valve and likewise takes its water supply from the penstock. Both valves have their disks equipped with bronze seal rings to eliminate leakage, and renewable bronze rings are likewise placed in the valve bodies at the points where the disks seat when in the closed position. Bypass valves are included. Both valves were subjected to a hydrostatic test at the manufacturer's works under a pressure of 1400 ft., or about 615 lb. per sq. in. Each of them has a tapering body, which is more or less characteristic of the high-head type of butterfly valve.

Butterfly Valves of Large Diameter

Probably the largest diameter butterfly valves ever built are those installed at the Conowingo Development of the Susquehanna Power Company, located near Philadelphia. These are each 27 ft. inside diameter and work under a head of 89 ft. Figs. 3 and 12 give a conception of their general construction and show the manner in which, because of their large size, it was necessary to sectionalize each body and disk. In this case each disk has a vertical axis of rotation and is operated by means of a hydraulic cylinder, using pressure oil supplied from a central oil-pressure system with accumulator tank. Aside from their large diameter, these valves are of particular interest because of the rubber-tube seal rings located in the valve bodies.

At the Calderwood Development of the Knoxville Power Company, where the head is 213 ft. there are three 16 ft. diameter butterfly valves that also are equipped with rubber sealing tubes, but in this case the tubes are placed in the periphery of the disk.

In the Diablo Plant of the Seattle City Lighting Department on the Skagit River near Seattle, two 14 ft. diameter valves are being installed under a head of 330 ft. In this case each of the disks rotates on a vertical axis, and both the bodies and the disks are sectionalized. Each disk is equipped with an adjustable bronze seal ring, seating against a stationary bronze seat ring set into the valve body. Operation of the disk is effected by means of a high-pressure hydraulic cylinder, shown in Figs. 8 and 9, and using oil supplied from a pump driven by an electric motor. Provision is made for automatic closure in case of excess velocity.

Fig. 2 shows a 14 ft. diameter butterfly valve with vertical spindle and adjustable bronze seal ring installed in the diversion dam at the upper end of the tunnel that supplies water to the Chelan Power House of the Washington Water Power Company. This valve is actuated by means of an electric motor and gearing located directly above it.

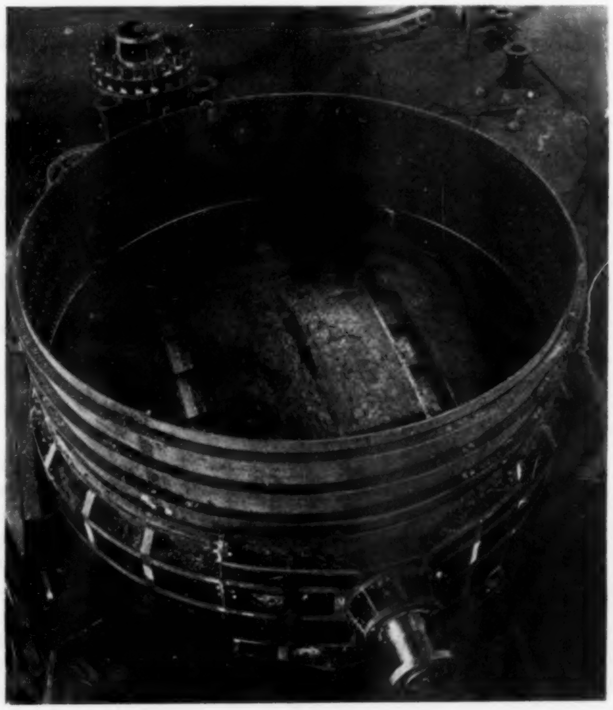

Fig. 12 Butterfly Valve and Connecting Pipe 27 Ft. in Diameter for 89-Ft. Head

At the Ariel Power House of the Northwestern Electric Company on the Lewis River near Portland, Ore., a 17 ft. diameter butterfly valve with a horizontal spindle is located at the inlet to the turbine casing where the head is 180 ft. This valve is shown in Fig. 1, and is at the lower end of a large penstock which passes directly through the lower part of the dam, the power house being located adjacent to the dam itself. An adjustable bronze seal ring is attached to the periphery of the disk. Operation is by means of a high-pressure hydraulic cylinder with an oil pump driven by an electric motor, of the type shown in Fig. 9, and excess velocity causes automatic closure.

Conclusion

Certain of the more important features of modern butterfly valves have been described in order to give a conception of the progress that has taken place during recent years. Difficulties accompanying the use of these valves under unusually high pressures have been successfully overcome, effective means have been devised practically to eliminate leakage, and by adopting special types of construction it has been possible to build them of very large size. New types of operating mechanisms have been developed capable of applying tremendous forces to the valve disks. Automatic operation has been brought to a state of dependability and perfection considered impossible several years ago, and the large number of these valves that are today in successful operation bears witness to the ingenuity and skill of the engineers responsible for their development.

The widespread use of butterfly valves for controlling water flow in large pipe lines proves their fitness and adaptability to this type of service.

The outstanding development in butterfly-valve design in the past four years is its adaptation to free-discharge service, with water velocities that are 10 to 20 times those produced in the average penstock.

There is reason to believe that this type of valve, because of its simplicity of design, its reasonable cost, and its inherent flexibility, has by no means reached the limit of its possibilities.

Acknowledgment

In the preparation of this paper and in the collection of descriptive matter and engineering data the author has received valuable assistance from the following organizations, in addition to his own, and to whom he acknowledges his thanks: Allis-Chalmers Manufacturing Co., Milwaukee, Wis.; Joshua Hendy Iron Works, San Francisco, Calif.; I. P. Morris & De La Vergne, Inc., Philadelphia, Pa.; Newport News Shipbuilding & Drydock Co., New York City.

Discussion

D. J. McCormack.[2] The paper tends to widen the scope of use of butterfly valves. There is a distinct field for installing butterfly valves in pipe lines under normal heads where the velocities are relatively low—that is, at the upper ends of pipe lines or even at the lower ends before the penstock is reduced in size, but far enough away from the turbines so that the disturbance set up by the valve is not carried into the turbine. Many recent tests have shown that such a disturbance carried into the wheel results in a much greater loss than the actual head loss as measured from end to end of the valve. The valve should be set sufficiently away from the turbine to permit the flow to be straightened out before reaching the turbine casing.

Under high heads, say over 600 ft., the disk becomes so thick at the center, to accommodate the spindle and to obtain sufficient strength of all parts, that the velocity through the valve is unduly increased, and the diameter of the valve should be correspondingly increased and made larger in diameter than the pipe. However, this is seldom done. Instead, the butterfly valve is generally installed at the lower end of the pipe line, just where the pipe is reduced to a smaller diameter, and the reduction in area is effected in the valve by necking it down very decidedly. The velocity in the smaller pipe between the valve and turbine, of 25 to 35 ft. per sec., necessarily sweeps the disturbance caused by the valve into the turbine before it can be smoothed out. For this purpose, a valve providing a flush passage through it is the proper thing to use. It is more than justified, since there is practically no head loss through it and no disturbance set up to affect the results of the turbine.

Due to its design characteristics, a butterfly valve is not suitable for free discharge work. In order to eliminate vibration, the disk has to be held rigidly in any position, which is almost impossible with a butterfly valve, because the forces are transmitted from the disk, through a stem and lever, to the operating mechanism. The deflection and lost play in the disk, stem, lever, and operating mechanism do not permit of this. Experience in trying to use a 9-ft. butterfly valve for free discharge under 200-ft. head has proved that some other form of valve should be used for this work. The vibration is terrific.

In 1913 the writer was granted a patent on a flexible sealing ring for a butterfly valve and thought at that time that it was a wonderful thing to make such a valve tight. However, since then, experience has materially changed his ideas. Seal rings in the periphery of the disk, unless they are rigidly and positively held tight without any possibility of loosening up, are a dangerous thing. It is much better to use a babbitted or flexible seat rigidly attached to the housing. There is very little, if any, leakage for the greater part of the periphery of the disk at top and bottom. Most of the leakage occurs at the corners where the stem passes through the housing. A detachable seal ring is of no benefit in reducing this leakage.

When discussing butterfly valves for a wider scope than ordinarily used, as brought out in the paper, it is proper to mention the Dow type of valve, which has some advantages for this work not inherent in a butterfly design of valve. Due to the inclination of the disk in the valve housing, one-half of the disk will be pressed up tightly to its seat by the water pressure on the upstream side. The other half of the disk in a butterfly valve is free to deflect away from its seat. However, in the Dow valve a connecting rod attached to the outer edge near the middle of the disk and designed with a toggle-joint action, takes up any such deflection and provides an absolutely tight periphery on that half of the disk. In the wide-open position, the disk is rigidly held in the fixed position without any lost motion occurring through the stem, lever, etc., which would be the case with a butterfly valve. Around the trunnions special adjustable glands are provided to seal off the ordinarily large amount of leakage between the disk and the housing and at the four corners where the stem passes through. The thickness of the disk does not have to be so great, because the stem need only be designed to take care of bending. Therefore, the head loss through the Dow valve is appreciably less than through a butterfly valve. The Dow valve does not need a bypass, but can easily be cracked open slightly to fill the penstock or turbine casing below. It has been used extensively for free discharge work and stands up remarkably well, with practically no vibration.

Author's Closure

The discussion brings out a few points which have often been discussed by hydraulic engineers and in regard to which some further information will undoubtedly be of interest.

Under high heads, in order to get sufficient bearing area to support the spindle or shaft of a butterfly valve, the bearings and shaft must be of comparatively large diameter, thus requiring a fairly thick disk. In practically every case, however, the butterfly-valve shaft, when designed of proper diameter to carry the load on the disk when it is in the closed position, is more than sufficient to give the necessary torsional rigidity for outside operation by means of a lever instead of using any type of connecting rod attached directly to the disk itself and inside the pipe. Properly proportioned water passages can be obtained through these high-head butterfly valves by using a valve body diameter somewhat larger than the connecting pipes on both sides, adopting a proper curvature for the inside of the butterfly-valve body, and using suitable designed taper sections at one or both ends of the valve body to connect it to the line.

A large number of these high-head butterfly valves are in successful use today, and as far as is known, they have not shown any vibration whatever, even at the partially closed position with full velocity flowing through them. In fact, as stated in the paper, some of these butterfly valves are operating under unusually high heads. Two free-discharge valves are installed under a head of

---

[2] Sales Manager, S. Morgan Smith Company, York, Pa. Mem. A.S.M.E.

280 ft., and there seems to be no reason for not going to even higher heads and obtaining successful operation from the butterfly type of valve under free-discharge conditions.

Many years ago hydraulic turbines were equipped with wicket gates with "inside gate operating mechanism." In other words, the links and pins which connected the turbine gates to the gate-shifting ring were placed inside the water passageway, and therefore subject to cavitation, oxidation, water wear and erosion from grit, etc. As improvements were made in turbine design, it became standard practice on the part of hydraulic engineers to remove all possible mechanical connections from the water passages, and the present form of turbine guide vanes, with spindles extended on one or both ends through stuffing boxes and operated by means of levers on the outside, became the accepted method of accomplishing the desired results. This change resulted in no trouble from vibration, even though the turbine guide vanes closely resembled free-discharge valves in their function and the velocity of the water passing through them is in many cases very high.

The butterfly type of valve, as described in the paper, is sometimes called a wicket valve or pivot valve, and in principle of operation is exactly like the modern form of turbine guide vane or wicket gate which has been accepted and standardized by all of the large hydraulic turbine manufacturers without exception. It seems reasonable, therefore, to expect the butterfly type of valve to perform successfully as a free-discharge valve, even though the water passing through the valve and over the disk may be traveling at a comparatively high velocity.

In selecting the proper type of valve, either for pipe line or free-discharge hydraulic service, the engineer should consider which of two general types of design is better suited to his needs. In the true butterfly type of valve he has the outside operating mechanism with a streamline form for the valve disk, together with tapering body, etc. to insure undisturbed flow and practically constant velocity with the least possible obstruction from the disk. All of the operating mechanism is outside of the valve, and therefore is subject to inspection at all times and easily arranged for thorough grease lubrication.

On the other hand, he will have available a type of valve similar to the butterfly, but having the disk operated by means of a connecting rod which attaches to the disk itself near the periphery on the downstream side. This connecting rod must in turn connect to a crosshead located some distance downstream from the center line of the main butterfly-valve spindle or shaft. This, of course, results in a longer body for this type of valve than for the true butterfly. With the disk of this type of valve in the open position, the connecting rod forms an obstruction to the water flow and is at right angles to the shaft of the butterfly-valve disk. In order to prevent unnecessary water wear on the pins and connections between this connecting rod and the disk, a housing of some form is usually built around it, which still further increases its cross-sectional area, and therefore reduces the size of the water passage. In some cases this additional obstruction will more than offset the saving which could be effected by making the disk any thinner than is necessary for the true butterfly type of valve.

It may also be interesting to note that adjustable seal rings, both of the metal and rubber types, have been successfully used for many years, and if properly designed, will not loosen up, nor are they dangerous in any sense of the word. Within the author's experience, there has been no case reported of properly designed seal rings causing any trouble whatever through becoming loose, and the adjustable feature of these seal rings will always permit of their being accurately placed in such a way as to prevent leakage due to the distortion of the disk from pressure on its upstream side, from settlement of the concrete foundation, and from distortion of the valve body or any other part of the mechanism.

It is quite common practice in modern hydroelectric work to use a large butterfly valve, sometimes under a high head, without a bypass. An instance of this is the case of two large 14-ft.-diameter true butterfly valves with outside operating mechanisms, located at the main inlet of two turbines operating under a head of about 330 ft. Filling of the turbine casing is accomplished by means of cracking open the main butterfly-valve disk.

It is believed that engineers engaged in the design and operation of waterworks systems, particularly where they involve piping of comparatively large diameter, can well afford to investigate the advantages of the butterfly type of valve. Due to the inherent low cost of this type, it should find an application in large city networks where it can be used as a quick closing, sectionalizing valve to close automatically in the case of a break in the water main, which without such protection could easily do a great amount of damage to large buildings and their foundations, subways, etc. Automatic closure of these butterfly valves can be accomplished in any one of a number of different ways, such as sudden drop in pressure, sudden increase in velocity, etc. The butterfly type of valve, being inexpensive, would seem to be quite applicable to service as a check valve in waterworks lines where space is limited and cost is a primary consideration. It is believed that a study of modern butterfly-valve design on the part of the waterworks engineer will unquestionably develop some interesting facts.

Research Institute for Hydraulic Engineering and Water Power

Description of the Latest Project of the Kaiser Wilhelm Society for the Promotion of Science at Obernach, Near Munich, the World's Largest Open-Air Hydraulic Experiment Station

By HUNTER ROUSE,[1] CAMBRIDGE, MASS.

HISTORY

TO Oskar von Miller, founder of the renowned Deutsches Museum at Munich and responsible for the development and perfection of the Bavarian power system, is given first credit for the movement that has led to the creation of the world's largest open-air hydraulic experiment station. In an address before the Kaiser Wilhelm Society for the Promotion of Science early in 1924, Dr. von Miller proposed the establishment of an institute of such size that hydraulic models could be studied at practically full scale. Engineers and investigators, for decades the sponsors of experiments on an exceedingly small scale, had begun to realize the limitations and possibility of error in model study requiring complete dependence upon the theory of similitude, and turned hopefully to a means of vindicating theory and practice in a more conclusive manner.

In April, 1926, there was organized the Research Institute for Hydraulic Engineering and Water Power, latest of the many branches of the Kaiser Wilhelm Society. Contrary to the usual custom of placing the laboratory management under the staff of a technical university, the new institute was made an integral organization, financed by such bodies as the National Government and the State of Bavaria, the City of Munich, and a number of private power and industrial concerns, in return for the privilege of experimental investigation. Though the Kaiser Wilhelm Society is concerned principally with purely scientific research, the services of the institute were to be available to all who applied for them, the only charges being the actual cost of labor, material, and time.

Generally speaking, the institute was planned to serve the twofold purpose of the supervision of a permanent outdoor laboratory with equipment to carry on large-scale and full-scale model experiments and the training of a staff of engineers who could conduct investigations in various parts of the country at the actual sites in question. Prior to the completion of the station, the institute carried on experiments on the Ampelsbach near the Achensee in Tyrol, at two points on the Isar River north and south of Munich, and finally assisted in a series of flow measurements on one penstock of the Walchensee Power Plant in which four standard methods were used simultaneously.

The search for a desirable location for the new station was governed by several factors: constant water supply in sufficient quantity to provide for all future needs; large unobstructed land area to permit favorable layout of the long canals and river channels; and proximity to both the Munich headquarters and as many of the larger hydraulic works as possible. The region just to the south of the Walchensee, a lake some 50 miles from Munich at the foot of the Bavarian and Tyrolean Alps, was finally selected as that fulfilling these requirements to the greatest degree. Actual construction was begun in 1928, and by the spring of 1930 the installation of the basic equipment had been completed and preliminary rating experiments were under way.

ORGANIZATION, PURPOSES, AND METHODS

At Loristrasse 2, Munich, are the executive headquarters of the research institute, composed of an office for the leaders, with ample space for group consultations, a smaller secretarial room, and large quarters for six or eight men who do the drafting and computation of results.

Two former assistants of Dr. Thoma's laboratory in the Munich technical university are at present responsible for the leadership of the institute: Dr.-Ing. Otto Kirschmer (now Professor of Hydraulics at the Dresden Technische Hochschule) as director, and Dipl.-Ing. B. Esterer as supervisor of experimentation. On the permanent staff are one diplom-ingenieur and five young graduates of technical trade schools for mechanical engineering. During the time of experimentation all are on constant duty at the station, several returning afterward to the Munich office for the work of calculation; additional assistants are employed when occasion demands.

Labor for construction work is easily secured at the nearby villages, and as there are new projects in building throughout the summer, there is usually a force of from 10 to 20 men at work.

In a laboratory where the models are of very small scale, an assistant is generally able to take complete charge of a single experiment and without help carry to completion both the actual handling of the model once it is built and the resulting computation. Here at Walchensee the work is on so great a scale that it requires the combined efforts of from three to ten experienced men, more than one series of experiments seldom being in progress at a given time. Since accuracy is dependent upon weather conditions, once these are favorable the experiment is carried through to completion without stop, often requiring uninterrupted work in shifts for 20 or 30 hours.

While each assistant makes himself familiar with all the apparatus and experimental methods, several of them have perfected themselves in certain systems of flow measurement and represent the institute at construction sites or power plants where their services are requested. In close cooperation with the research institute is the laboratory of Dr. Thoma, where most of the staff have at some time or other supplemented their practice with small-scale study. Throughout the winter, when outdoor work is practically impossible, projects are continued indoors at the Munich technical university, and there is a hearty feeling of collaboration between the two. It is hoped that the other laboratories in the country will sense the value of this attitude, those at Dresden and Berlin having already made steps toward

Contributed by the Hydraulic Division to the Transactions of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

substantiating their small-scale results by further study through the institute.

An all-too-prevalent belief is that the Walchensee laboratory is attempting to establish the falsity of the theory of similitude. The error of this assumption cannot be too highly emphasized. Its work is on the contrary the proof that the theory of similitude is really a dependable tool, once its factors of conversion have been experimentally determined, and the general study of these conversion relations. In the past there has been little opportunity to vindicate the blind reliance upon similitude in the accurate study of water flow where the scale is reduced often a hundredfold and more, and until this is clearly illustrated by experiments upon the same structures with models varying from very small to practically full scale, many engineers will continue to mistrust small-model study.

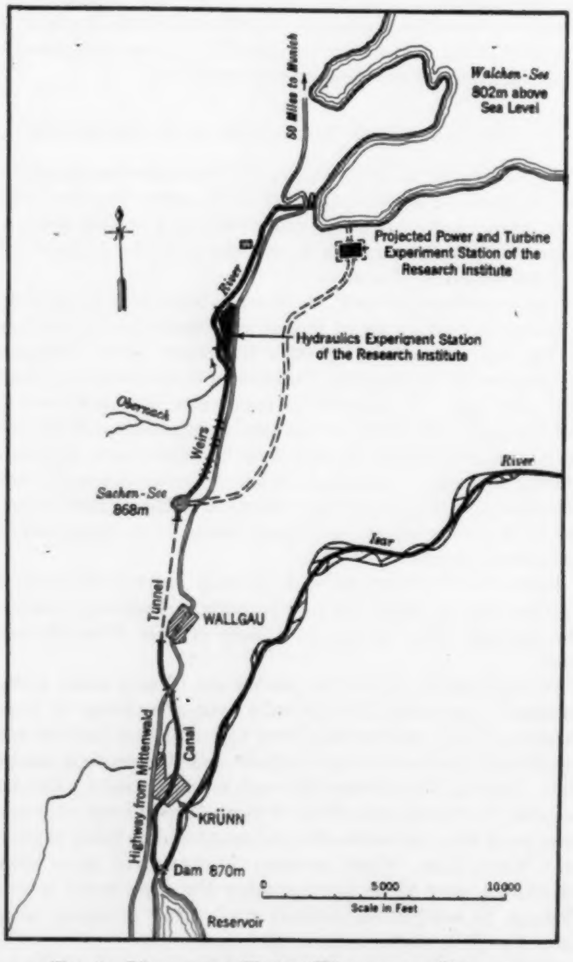

Fig. 1 Map of the Krünn-Walchensee Region

(Showing Isar diversion canal, location of the experiment station, and the projected power plant and turbine research station. Distance above sea level in meters.)

Sponsors of the latter type of research hold quite justifiably that such methods allow greater accuracy in measurement and permit thoroughness of study in a short time and with an economy that is impossible on larger structures. The research institute is not endeavoring to displace the small laboratory, but to give it new value in the eyes of the engineering world; for its directors realize as well as any that small-scale study holds a place in the experimental field which no other method can usurp. On the other hand, there are demands which only a station of the Walchensee type can meet—perfection of flow-measurement methods for commercial use, tests of canal forms and linings, siphon experiments where the atmospheric conditions cannot easily be reproduced to scale, and other experiments of a like nature; and though other experimenters hold that small-scale indoor equipment provides the greatest accuracy, it is claimed by the leaders of the institute that increasing the size as they do involves little sacrifice of exactitude in measurement and that this is offset by greater proximity to actual conditions. In brief, outside of time and financial considerations, the relative advantages and disadvantages of both systems practically compensate each other. Where they have been proved dependable, small-scale experiments are the more desirable, except under circumstances requiring actual or nearly actual proportions.

THE EXPERIMENT STATION

From its source in the Alps of Tyrol near Innsbruck, the Isar River flows over the German border and takes a northerly course toward Munich. Just before the village of Krünn, somewhat more than 5 miles above the Walchensee, the Isar valley forks, and the river takes the deeper route to the right so that it passes completely around the eastern side of the Walchensee. This lake, roughly triangular in shape, $3^1/_2$ miles long and 640 ft. in depth, has a mean surface level 660 ft. higher than that of the Kochelsee, little more than a mile to the north. The Walchensee Power Plant takes complete advantage of this excellent site, and not only draws the entire discharge from the Walchensee, but also diverts the normal Isar discharge of from 15 to 25 cu. m. per sec. (530 to 880 sec-ft.); in winter a minimum of 5 cu. m. per sec. (175 sec-ft.) is reached.

This borrowing of water from the Isar is accomplished as follows: At the valley fork near Krünn, as is shown in Fig. 1, a small regulation reservoir has been constructed, so that in dry seasons the total flow of the river may be diverted through a concrete canal and tunnel system into a small pond, the Sachensee, $2^1/_2$ miles from the Walchensee, and thence a mile farther through an open-cut channel to the point where the Obernach stream enters the valley. Here the channel ends, and its discharge joins that of the Obernach and flows through the latter bed to its outlet at the Walchensee. Just below this juncture, the Obernach bends away from the highway, circling back parallel to it again at a point $^1/_2$ mile farther downstream. This bend, with the highway on the other side, encloses a flat section of land of about 10 hectameters (25 acres), which was chosen by the institute as the most nearly ideal station site in the region. Here is ample space for development of large-scale layouts and a constant water supply large enough for all purposes.

Due to a steady fall in the valley, amounting to 66 m. (217 ft.) from the Sachensee to the Walchensee, future expansion of the Bavarian power system calls for a new plant at the southern end of the Walchensee making use of this head by means of still another diversion canal, with a branch of the institute station at this lower point for turbine and other high-head experiments. In this way the laboratory will have grounds, equipment, and water-supply facilities that surpass as a whole any existing in the world.

Station Layout

At a point some 60 ft. above the weir where the Isar River diversion channel (with a maximum flow of 25 cu. m. per sec.) discharges into the Obernach waters is the intake canal for the entire laboratory supply, as is shown in Fig. 2. The flow is regulated by two hand-driven or electrically driven vertical gates 3.5 m. (11.5 ft.) in width and rising to a maximum height of 2 m. (6.56 ft.), admitting from 8 to 12 cu. m. per sec. (280 to 425

sec-ft.) depending upon the Isar discharge. This water is carried about 350 ft. through the concrete canal, parallel to the highway, and is then discharged freely into the concrete stilling basin at the upper end of the supply basin. (See Fig. 3.) Since this basin may serve as many as four or five future side-channels to separate experiments, it has been given a capacity of 2500 cu. m. (88,250 cu. ft.), with a 10-m. (32.8-ft.) constant-head weir and a 1-m. drainage gate at the west end, wasting into the Obernach. This basin is unlined, with a side slope of 1 to $2^1/_2$, the coarse gravel and clay in the soil withstanding the erosion to a fair degree. A single gage pit, of type A, described later, is used for observation of the water level.

In the original construction a single experimental canal was constructed, for a maximum flow of 4 cu. m. per sec. (141 sec-ft.). Plans have been made for a similar channel for double that discharge to be built alongside at a later date, but this is considered at present as unnecessary. This existing main canal runs almost due north from the mid-point of the outer bank of the supply basin for a distance of 575 m. (1889 ft.); inflow is regulated at the upper end by a single vertical gate 3 m. (9.85 ft.) in width, giving an opening 2 m. (6.56 ft.) high. This gate has been calibrated for discharge versus gate opening. As the canal is unlined at this end, the entrance is protected for a distance of 15 ft. by coarse wire screening over stone riprap on sides and bottom. To allow experimentation on various conditions of channel flow, and at the same time to avoid following directly the pronounced downward slope of the valley, this canal has been divided into four sections of different lengths, with a temporary wooden spill

(Scale is not exact. Elevations are mean height above sea level in meters.)

and stilling basin at the ends of the first two. Each of the individual sections has a 0.03 per cent slope. (See Fig. 4.)

The first three sections, approximately 280, 475, and 230 ft. in length, respectively, have the same trapezoidal cross-section, 9 m. wide at top, 3 m. at bottom, 1.5 m. deep. (See Fig. 5.) At first all three were simple earth canals, but the first and second have since been given a lining of tar-bound gravel of grades varying at intervals.[2] The first two spill sections have been made of coarse timbers to allow for future modification and a height of weir to vary with the discharge. The stilling basin at the end of the third earth canal has been made of concrete, extra large to give sufficient energy reduction at the beginning of the fourth section.

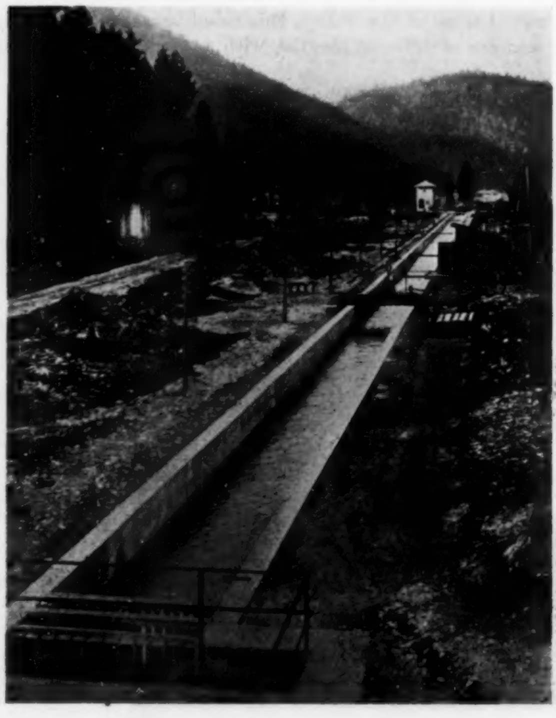

FIG. 6 FOURTH (CONCRETE) SECTION OF EXPERIMENTAL CANAL
(View from titration scaffold looking north; salt-velocity shack at right, control house in distance.)

It is in this fourth section, illustrated in Fig. 6, that the principal flow research of the institute has been conducted. Sides and bottom are of concrete (see Fig. 7), unfinished except for the stripping of the wooden forms, and provided at frequent intervals with boarded-in stop-log grooves for temporary bulkheads in the seepage tests, weir insets, and stilling screens. The entire length is provided with numerous standpipes embedded in the concrete, and gage pits just outside the channel, for the two different systems of water-level observation. Outflow at the lower end is

---

[2] Prior to the winter of 1930–1931 both the first and second canal sections were surfaced with various bituminous preparations in an effort to develop an inexpensive and efficient method to protect earth channels from erosive action. This investigation included not only a study of proper materials, but also of a practical means of application. Twelve different kinds of lining were tried in consecutive sections, consisting of hot- and cold-water emulsions, of tar, and of asphalt. These were applied by spraying to a thickness of 0.5 to 1.0 mm., by soaking to a thickness of 2.0 to 5.0 mm., and finally by a poured paving operation similar to that used for city streets. Further experiments have been conducted with what is called "asphalt-beton," crushed stone with a bituminous binder. All twelve kinds of lining were submitted for nine months to constant discharge through the canal, with the accompanying frost action. It was found that the light covering was soon disrupted by the frost, but the heavier forms were uninjured. The institute has succeeded in producing mechanically an economical and practical surfacing now ready for use; the light covering is applicable to temporary channels, while the thicker lining is suitable for all other conditions. The costs are lower than those for concrete, while the asphalt has the further advantages of being elastic, watertight, and easily repaired.

measured by a sharp-crested suppressed weir adjustable to various elevations. Here the flow discharges into a forebasin with a capacity of 96 cu. m. (3390 cu. ft.) below the outlet sills, plus 72 cu. m. (2543 cu. ft.) with outlets closed. There are two outlets to the forebasin, symmetrically arranged and controlled by two Tainter gates to turn the discharge into either the waste channel leading back into the Obernach or into the large measuring basin. The gates are of steel, 3.5 m. (11.5 ft.) wide and opening 1.0 m. (3.28 ft.), swinging on a 1.80-m. (5.91-ft.) radius. The measuring basin has a usable capacity of 1500 cu. m. (52,900 cu. ft.), is of finished concrete, and has recently been given a $^1/_4$-in. to $^3/_8$-in. coat of bituminous waterproofing to eliminate all seepage. The outlet from this basin is into the waste channel through a single vertical gate.

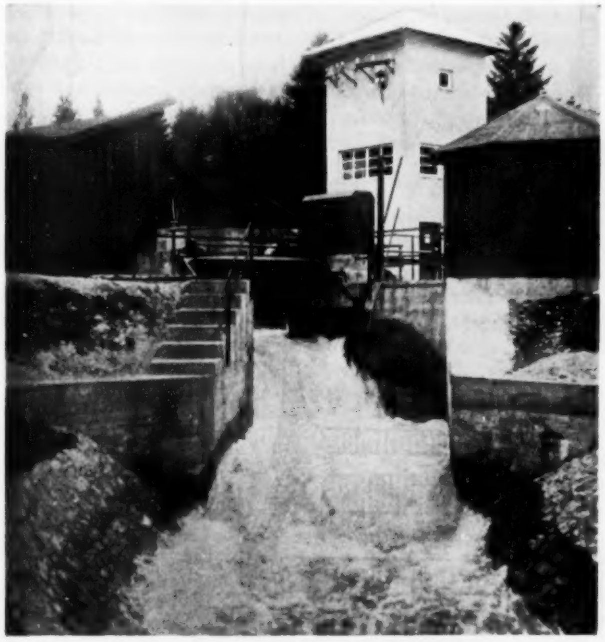

FIG. 8 DISCHARGE FROM FOREBASIN INTO WASTE CHANNEL
(Scale shelter at left, control house center, and gage house right.)

There are at present three permanent buildings on the station property: the headquarters cabin and the workshop between the highway and earth canal at the supply-basin end and the control house at the lower end of the concrete canal. There also are small shelters for the salt-velocity pump near the beginning of the concrete canal, for weighing scales at the forebasin, and for the gages at the measuring basin.

In the headquarters cabin there are rooms designed for executive purposes and for drafting and for chemical analysis, a photographic darkroom, and a kitchen and sleeping quarters for several assistants. The workshop is completely equipped with forge and metal-working machinery and carpentry tools, so that the station can build practically all its apparatus on the site of experimentation.

The control house is of concrete, with windows on three sides commanding a complete view of the canal and measuring basin. In the basement are transformers reducing the potential of the main supply from 6000 v. to either 380 v. three-phase or 220 v. single-phase, convertors to direct current, and storage batteries. In the first floor are further electrical connections, consisting of a switchboard for direct current varying in potential from 2 v. to 40 v., an electric clock sending impulses every second to all parts of the station, and a telephone. Here are also the controls for the gates leading from the forebasin and measuring basin, time of movements being recorded chronographically. Instruments for recording current-meter turns and the salt-velocity curves may be operated here as well. (See Fig. 8.)

The entire plant is connected by telephone so that all points are in communication throughout experimentation, and electric lines the length of the major canal provide current for both lighting and electrical measuring methods. Since this original canal parallels the main highway, there is ready access to all points by wagon or truck; bicycles and motorcycles owned by the assistants allow rapid travel to and from the more distant points without loss of time.

Though still only partially cleared of timber, the remainder of the land in the institute's possession offers possibilities of expansion through many years to come. (See Fig. 9.) Aside from the downward slope of the valley, the section is comparatively flat and admirably suited for large-scale model development; due to its elongated shape, discharge into the Obernach is possible at practically every point with only short waste channels.[3]

FIG. 9 VIEW OF NORTHERN END OF STATION
(Measuring basin on extreme left, with Obernach bed in foreground; practically entire tract owned by the institute is visible.)

VOLUMETRIC MEASURING BASIN, APPARATUS, AND TECHNIQUE

Claims by the institute directors of an experimental accuracy equal to that of any of the small-scale laboratories have their

---

[3] The adaptability of the main concrete canal for model experiments was illustrated in the study of a round-crested spillway in the fall of 1930 at a scale of 1 to 4.375 for the Preussische Versuchsanstalt für Wasserbau und Schiffbau. The latter had already tested models

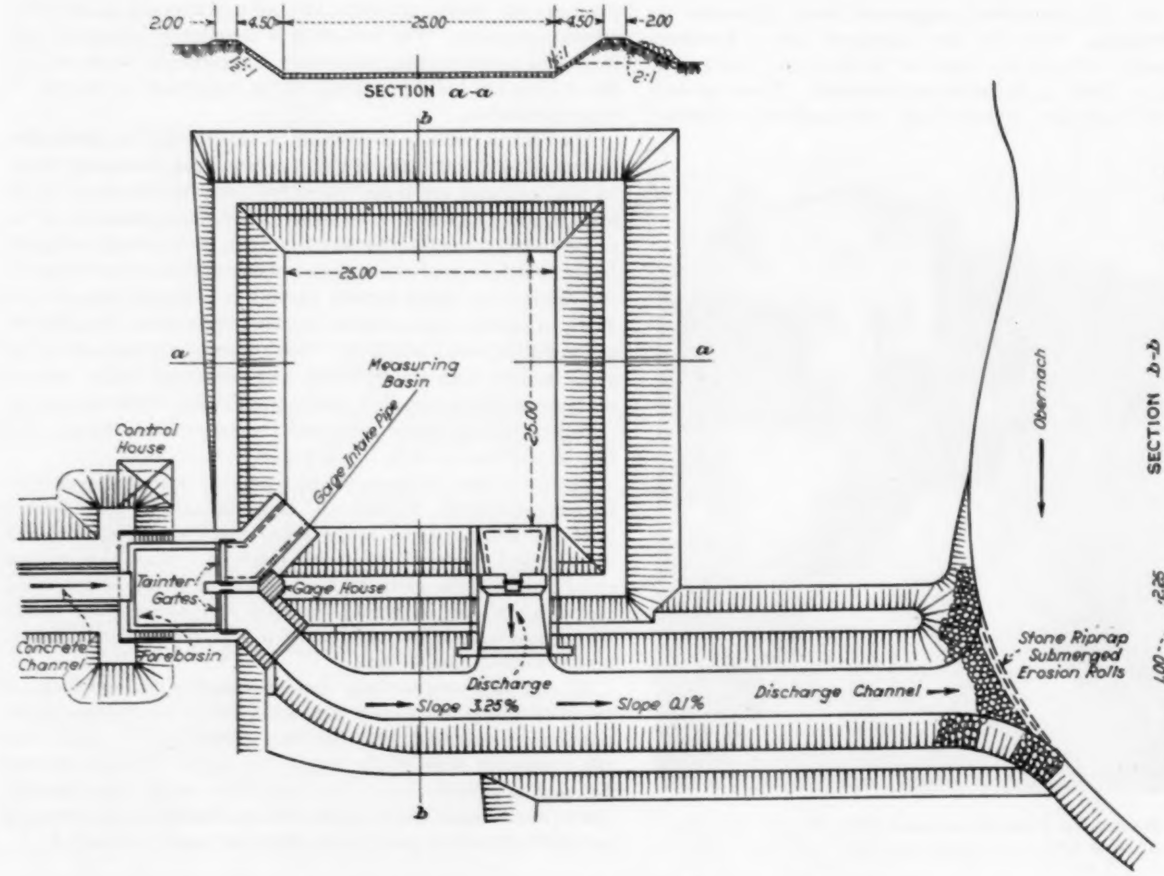

FIG. 10 DESIGN OF FOREBASIN, MEASURING BASIN, AND WASTE CHANNEL
(Dimensions are in meters.)

foundation in a thorough, painstaking planning of each experiment before the run is started; the use of instruments that are probably among the finest that have ever been developed for this purpose; and a patient, capable analysis of and compensation for all unavoidable error. Care and foresight in the arrangement of all detail of layout and procedure have produced an exactitude that is extraordinary in such large-scale work.

Measuring Basin. The principal factor in the accuracy of the results, that upon which all other computations are based, is the actual volumetric record of discharge given by the large measuring basin at the lower end of the main canal. (See Fig. 10.) Whereas most other laboratories depend for their standard upon the mean value of a number of comparative methods of measurement, the research institute measures volumetrically the water that passes through its canals during active experimentation, with apparatus that is even more accurate than conditions require—a calculated and proved error of ±0.1 per cent is the maximum that is present.

Before the measuring basin was used in the first series of experiments, two comparative rating curves were plotted—one from careful measurement and geometrical computation of its capacity with relation to depth of water, and the other by actual tabulation of gage readings as quantities of water, measured by weight, were successively introduced. The concrete canal was boarded up at the lower end and allowed to fill, the forebasin also being filled level with the sills of the Tainter gates. Water was then pumped from the canal into the balance tank, weighed, and discharged into the forebasin. Gage readings were made for each different water stand in the forebasin, and when the latter was filled to capacity, its contents were discharged into the measuring basin, and the process was repeated until the measuring basin had been rated to depths varying from 0 to 2 m. (6.56 ft.). The balance used has a capacity of 3000 kg. (6620 lb.), sensitive to 0.0013 per cent.

For experiments in the concrete canal with built-in models requiring only a small flow, the forebasin alone is used as the measuring tank. A temporary steel chute carries the discharge from the canal over the sill of the Tainter gate leading to the waste channel, the closing of the one gate being sufficient to direct the water into the basin during time of filling. Under these circumstances the basin may be filled only to a point somewhat below the sill level, so that the basin had to be rerated to cover this lower range of 1.25 m. (4.1 ft.).

Error in recording the actual time of filling the measuring basin has been practically removed by the absolutely symmetrical construction of the forebasin and the Tainter gates. (See Fig. 11.) The two gates are coupled so that both begin or cease to move at the same instant, one closing at the same rate that the

---

at scales varying from 1 to 75 to 1 to 8.75, but a discrepancy between performance in nature and in a small-scale model necessitated further experimentation at greater scale. The model was built into the main canal with cement mortar and a rubble bed, the canal floor being raised about 2 ft. for a length of perhaps 300 ft. by a temporary wood planking bolted in place. Temporary stilling screens were built in, and measurements were made with the usual gages along the canal wall and the forebasin at the end converted into a smaller measuring basin. A needle weir at the end of the canal regulated the tail water.

other opens, and vice versa. Electrical contact is made when each gate reaches or leaves its lowest position and is recorded automatically in ink on a paper ribbon that contains a simultaneous double chronographic record. (See Fig. 12.) Hence for a single filling of the basin, four points in time will be indicated on the ribbon: t_1 marking the instant the basin gate A begins to open, and t_2 about 3 seconds later indicating the instant the waste gate B from the forebasin is entirely closed; t_3 some 3 or 4 minutes afterward gives the instant B once more begins to open, this interval depending upon the rate of flow in the canal, and t_4 the instant A is again completely shut, after which no more water flows into the basin. Either the time t_1 to t_3 or t_2 to t_4 is used as the time of filling.

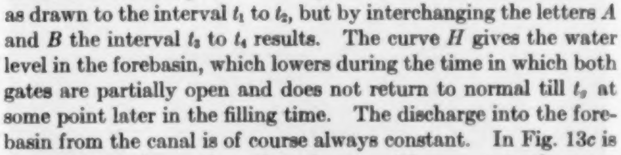
(Fig. 13c Curve of total discharge from forebasin versus time.)



(Fig. 13d Curve of discharge into measuring basin versus time.)

FIG. 13 GRAPHS OF MOVEMENT OF GATES

A proof of the mathematical accuracy of this method is as follows:[4] The gates in every case open well above the water surface, so that there is free discharge under them even under maximum conditions. In Fig. 13a is shown the elevation of the bottom edge of gates A and B with respect to rate of motion. (It is to be borne in mind that the curves are only general and that this in no way affects the accuracy of the proof.) Curves A and B in Fig. 13b show the respective gate openings during the interval of motion, plotted now against time. These curves refer as drawn to the interval t_1 to t_2, but by interchanging the letters A and B the interval t_3 to t_4 results. The curve H gives the water level in the forebasin, which lowers during the time in which both gates are partially open and does not return to normal till t_g at some point later in the filling time. The discharge into the forebasin from the canal is of course always constant. In Fig. 13c is shown the discharge through each gate with respect to the same time axis in curves Q_A and Q_B, and the summation of the flow through both gates in $Q_A + Q_B$; the latter varies in accord with the curve H in Fig. 13b.

Between the times t_1 and t_g the total flow into the forebasin is exactly equal to its total discharge; that is, the total volume of water passing through the forebasin is equal to the area enclosed between the basic time axis in Fig. 13c and the horizontal line of normal flow Q; but since the actual summation of discharge through both gates is the area between the time axis and the

FIG. 16 TYPE A GAGES IN GAGE HOUSE NEXT TO MEASURING BASIN

(Lighting facilities, small reading mirrors, capillaries, and connections are visible.)

curve $Q_A + Q_B$, then the positive area X must equal the sum of the negative areas Y and V_g. Expressed mathematically:

$$\int_{t_1}^{t_g} (Q_A - Q_B)dt = Q(t_g - t_1)$$

From the diagram it is clear that

$$V_A + V_B = Q(t_2 - t_1) + V_g$$

and

$$V_g = Q(t_g - t_2) - \int_{t_1}^{t_g} Q_A dt$$

From these relations there may now be constructed the diagram of discharge into the measuring basin as shown in Fig. 13*d;* the V_B in the last interval of time is obviously the same as the V_B of the first interval, except that it now designates flow through gate A during its period of closing. In other words, the level and discharge curves at the second gate action are identical with those at the first change, except that the letters A and B must be interchanged and t_3, t_4, and t_g' substituted for t_1, t_2, and t_g.

The flow into the measuring basin during each interval may be tabulated as follows:

Time interval	Inflow
t_1 to t_2	V_A
t_2 to t_g	$Q(t_g - t_2) - V_g$
t_g to t_3	$Q(t_3 - t_g)$
t_3 to t_4	V_B

The total flow given by the addition of these factors is:

$$V = V_A + V_B + Q(t_g - t_2) - V_g + Q(t_3 - t_g)$$

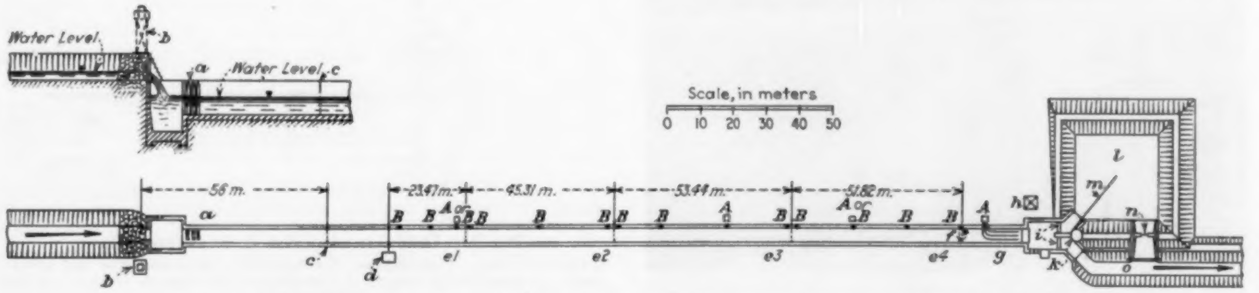

FIG. 18 PLAN OF CONCRETE CANAL, GIVING LOCATION OF MEASURING INSTRUMENTS AND APPARATUS

(Legend: *a*, stilling racks; *b*, titration injection apparatus; *c*, sampling pump for titration; *d*, salt-velocity injection pumps; *e*, salt-velocity electrodes; *f*, current-meter bridge; *g*, measuring weir; *h*, control and observation house; *i*, Tainter gates; *k*, gage house; *l*, measuring basin; *m*, gage inlet pipe; *n*, outlet gate; *o*, discharge canal; *A*, pit gage, type A; *B*, standpipe gage, type B, electrical.)

Through substitution of the equivalent value already found for $V_A + V_B$ this becomes:

$$\begin{aligned} V &= Q(t_2 - t_1) + Q(t_g - t_2) + Q(t_3 - t_g) \\ &= Q(t_3 - t_1) \end{aligned}$$

Hence the method itself is entirely correct, and whatever inaccuracy is involved can come only through unsymmetrical motion of the water in the forebasin, leakage through the gates and basin structure, unfavorable weather conditions, and the personal error involved in reading the gages.

The influence of possible unsymmetrical flow is practically negligible. The interval during which the gates are in motion is constant for a given run, but may be varied for different runs, with a minimum length of 2 sec. at the beginning or end of filling. A very small error during only these 2 sec., as compared to the total filling time of at least 180 sec., thus becomes actually $^1/_{90}$th as large.

Under each Tainter gate in its closed position seeps a small quantity of water; a depression has been left in the top edge of each sill to collect this discharge of perhaps 0.2 liter per sec., so that the seepage under the closed gate may be conducted through a short length of pipe to join the discharge through the open gate. Valves in these pipes are regulated by hand during the interval of gate movement (see Fig. 14) so that the seepage is turned into the measuring basin during time of filling and thereafter once again into the waste channel. Seepage under the outlet gate from the measuring basin is collected in the same way and run into a concrete container, from which a small propeller pump, running continuously, returns it to the basin.

Errors resulting from weather conditions and the reading of the gages will be discussed in the following section.

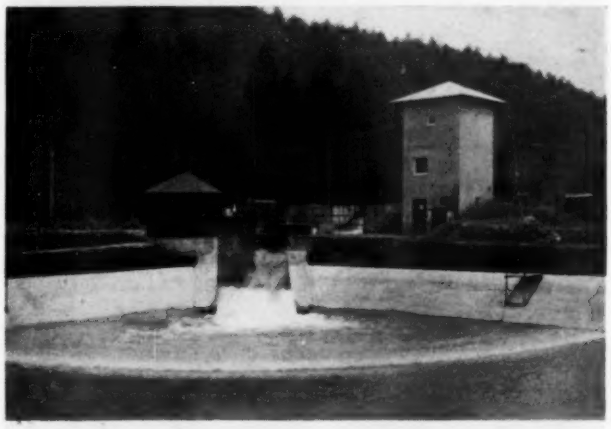

FIG. 17 DISTURBANCE IN MEASURING BASIN AT START OF FILLING

Hook and Point Gages. In the gage house for the forebasin and measuring basin is a remarkably fine set of instruments, arranged to allow the utmost convenience in setting and reading, and so exact in their results that they give an unavoidable error of less than 0.1 mm. (0.00033 ft.). These gages are nine in number, three giving readings for the forebasin and covering a range of 600 mm. (1.97 ft.) and six for the measuring basin with a range of 400 mm. (1.31 ft.), overlapping some 3 cm. on the readings of that gage above and that below. (See Fig. 15.) All are arranged around a narrow spiral stairway leading to the main control valves at the bottom of the concrete pit, and may be set and read from a sitting position on the nearest step. A large glass standpipe with floating pointer covers the entire range of readings, from which the gage to be used is determined.

From the screened inlet at the center of the basin floor, a 3-in. pipe runs across the floor and through the walls into the bottom of the gage pit. Here, following the shut-off valve, are the connections for the pipes leading to the six vernier gages and the standpipe. (See Figs. 16*a* and 16*b*.) Connections to the three forebasin gages are identical. All nine instruments are similar, consisting of a glass standpipe 4 cm. (1.58 in.) in diameter, easily removable for cleaning, with a main inlet tube that can be closed after the water has reached its approximate level, pressure then being transmitted through a glass capillary tube 2 mm. (0.079 in.) in diameter, to avoid momentary fluctuations. The tube extends past the rubber fittings above and below so that both ends will remain free of air bubbles and sediment, as is shown in Fig. 15.

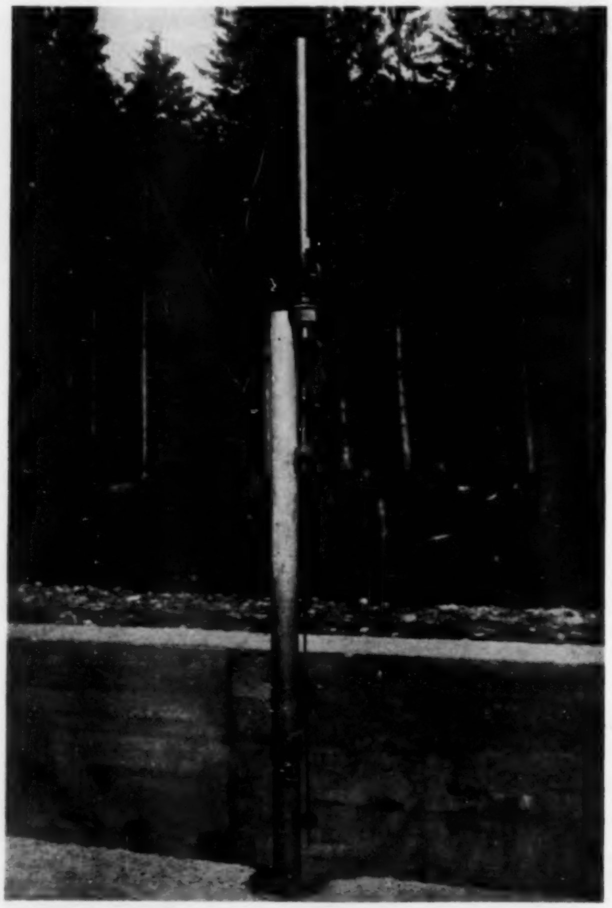

Fig. 19 Standpipe Gage, Type B

(With pointed extension rod hanging outside; note insulator balls and headphone connections.)

Surmounting the standpipe is a centimeter scale with vernier attachment reading directly to tenths of a millimeter (0.0039 in.); three of the instruments read to fiftieths of a millimeter—an accuracy greater than is necessary. The finer adjustment is made by means of a worm gear, with a cone release to permit rapid preliminary setting. The point, of the general hook type, has a fairly broad, arched knife edge to give further accuracy. A movable mirror at the side, set just below the level of the water, gives a simultaneous picture of both the knife edge and its reflection in the water surface above, permitting a very easy and delicate adjustment. Two small electric bulbs illuminate the vernier and the reflected image of the hook below. Both the setting of the instrument and the reading of the results can be accomplished rapidly and without undue change of position.

As is the custom of the institute, results are directly plotted against time of day on graph paper, wherever possible, rather than tabulated in notebooks. This serves to eliminate practically all gross errors, and in the case of the measuring-basin readings, the instrument man can see from his plotting the effect of weather and the resulting length of time necessary for a record from which a satisfactory average may be drawn. Before filling, the basin is never quite empty, a zero reading being made with enough water left in from the last run to require the use of either gage 1 or gage 2. Readings are made at the rate of one every minute, for at least 15 minutes, or in case of wind disturbances until the plot gives a definite average line. Since the sides of the basin are not perpendicular, wind has a pronounced effect upon the readings, giving results that are slightly low. For this reason a wait of almost an hour is necessary after filling, so that the surging due to inflow may quiet down before final readings are begun. (See Fig. 17.) The latter are plotted on the same sheet as the zero curve, but often last as long as one or two hours in severe cases. So delicate is this method that rain or undue seepage makes the records worthless, and the run must be repeated.

Fig. 21 Reading Water Elevation Electrically With Type B Gage

(Electrode 3 visible in foreground.)

At various points along the concrete canal (marked *A* in Fig. 18) are hook gages identical with those at the measuring basin, but located in individual pits beside the canal. The last gage downstream gives readings at the right and left of the weir alternately by a simple valve action. Pressure is transmitted to all gages through small pipes leading from the center of the channel. The inlets are somewhat above the canal floor, the pipes pointed upstream, plugged at the end, and perforated with small holes on the sides. Within each pipe is a capillary tube 3 mm. (0.118 in.) in diameter to eliminate the effect of waves in the water.

The type B gage has the same inlet connections, but differs in form and accessibility. Set in the west canal wall are iron standpipes 2 in. in diameter rising about 4 ft. above the ground. Pointed metal rods of known length are inserted in these pipes, insulated from them by wooden balls fitted tight on the rods, but sliding easily through the pipes. Each rod is hooked to a metal scale reading by vernier to 0.1 mm. and lowered till it touches the water surface in the standpipe. Contact is given electrically through a pair of headphones, current coming from the line along the canal and passing through the circuit formed by the rod and pipe as terminals and the water between as conducting medium; a sharp buzz is heard the instant the point touches the water. (See Figs. 19, 20, and 21.) Readings are made to 0.1 mm., but the water level is so variable due to flow disturbances that constant reading is necessary to give a satisfactory average record. Often four or five gages are read in turn by one assistant, who carries a single scale and headphone from one standpipe to the next.

The gage pits and standpipes were originally located to serve the needs of the first series of experiments, but are at the same time so evenly distributed along the main channel that they are in favorable positions for practically all future needs. For general purposes the standpipe system gives all necessary accuracy, with the pit gages at the several points for use where the flow is stable enough to allow more care in observation. Additional pits and standpipes are built in as occasion demands. A recent improvement has been the enclosing of the usual standpipe with a cylinder of steel 20 cm. (7.9 in.) in diameter, so that the increased volume of water thus contained will further dampen momentary fluctuations.

In two lines, 10 m. on either side of the channel axis, are pipes for the determination of the groundwater level to be used in connection with the correction for seepage through the floor and sides of the canal and measuring basin. Readings are made either electrically or by inserting a rod and then measuring to the wetted point. At intervals during experiments with the concrete canal, the latter is divided into five sections by watertight stoplogs, the channel is filled to capacity, and the lowering of the water surface due to seepage is read from the gages over a period of from 36 to 72 hours. These data, together with those from the groundwater readings, furnish the correction for each section in question to be applied to the flow measurements; the same correction was made for the measuring basin prior to its waterproofing.

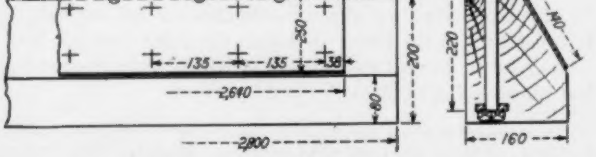

FIG. 22 DESIGN OF MEASURING WEIR AT END OF CONCRETE CANAL

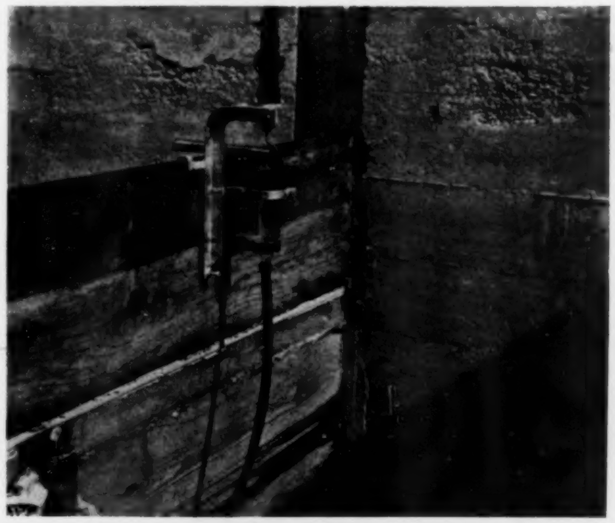

FIG. 24 GAGE AND RIDER USED FOR ACCURATE SETTING OF WEIR CREST
(Hook gage set to crest elevation by spirit level as shown, and then lowered into water in glass standpipe; rubber tube leads to type A gage in nearest pit.)

INITIAL MAJOR EXPERIMENTS AT THE STATION

Simultaneous measurements of flow through the concrete canal by means of the four leading European and American methods composed the first series of studies by the research institute. The sharp-crested suppressed weir, the Allen salt-velocity, the chemical or titration, and the current-meter methods of calculation of discharge were tested for five different rates of flow, all based upon the volumetric record taken at the measuring basin several times during each run. This used to fullest advantage the original installation on the station grounds and at the same time investigated basic practice with an accuracy that never before had been attained.

Sharp-Crested Weir

A steel weir crest of the standard form (see Fig. 22) was bolted to a wooden beam so that it might be raised or lowered in the stop-log groove at the lower end of the concrete canal, the space below being boarded in and calked to watertightness. Thin boards set into the grooves above the crest preserved the smoothness of the walls and at the same time gave free passage of air to the steel ventilation sheet at the downstream side of the crest. An open U-piezometer served as a check upon the completeness of ventilation. (See Fig. 23.)

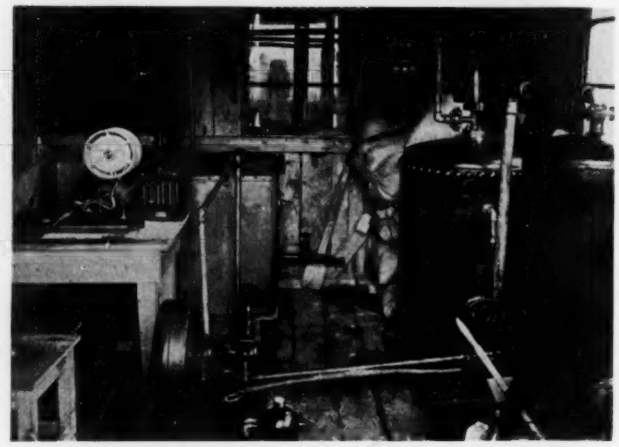

Fig. 25 Pump and Pressure Tanks for Salt-Velocity Injection
(Chronograph at left records current-meter turns during titration sampling.)

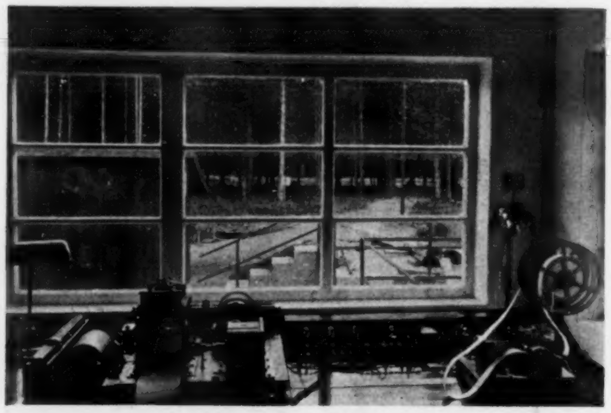

Fig. 26 Chronographs in Control House
(At left, the spark recorder for salt-velocity curves; at right, the six-pen instrument for current meters and forebasin gate movements; electric switchboard between.)

The weir crest was first set roughly by surveyor's level, and then accurately by means of a rider and standpipe hook gage connected by a rubber tube to the gage in the last pit. Since the latter gage read to a precisely known elevation, the water coming to the same level in both standpipes allowed accurate calculation of the crest level till the desired point was reached, the hook on the rider gage being checked to the crest by means of the usual spirit-level method. (See Fig. 24.)

Throughout the run the heads on the weir at the right and the left sides were read at the pit gage alternately at 1-min. intervals, the results being plotted directly against time of day. The gage intakes were located about 3 m. (9.85 ft.) upstream from the weir, 0.4 m. (1.31 ft.) from the side walls.

Allen Salt-Velocity Method

Apparatus for the injection of the salt solution was located under shelter about 60 m. from the head end of the canal. This consisted of a 640-liter (22.6-cu. ft.) tank in which a saturated solution was mixed, a 1.2-hp. gasoline pump and compressed-air tank, and a third container in which the solution was held under a 10-atmosphere pressure prior to injection. (See Fig. 25.) Injection was made through spring valves on the upstream side of the pipe system.

Electrodes, each consisting of six galvanized iron pipes $^3/_8$ in. in diameter, were set in sockets in the canal bed at four points below the injection apparatus (see Fig. 21); each pipe was about 42 cm. (1.4 ft.) from the next, so connected electrically as to give opposing terminals alternately across the section. The electrical recording was made on a chronograph in the control house near the measuring basin, by which the time curve was reproduced in ink on a paper ribbon and the graph of current intensity burnt into the paper by a spark gap to insure certain action. (See Fig. 26.) The record of each succeeding electrode was intensified to give approximately similar ordinates for all curves. Unfortunately with the larger discharges the third electrode had to be omitted to prevent overlapping of curves, only one recording instrument being available.[5]

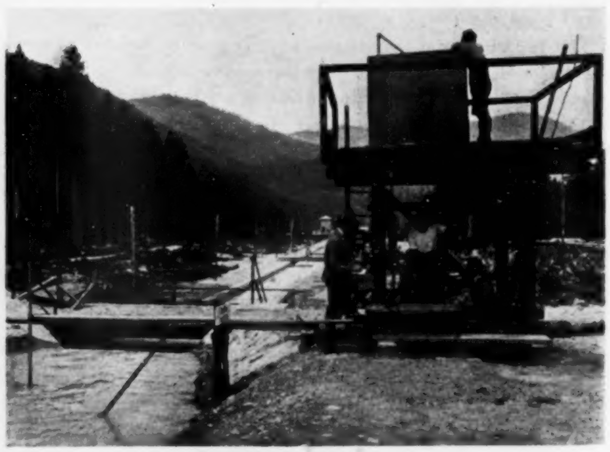

Fig. 27 Titration Injection Apparatus
(Mixing tank on scaffold, constant-head system just below, and calibrated rating tank on ground.)

---

[5] Considerable effort was made to determine the effect of length of injection, location and number of injection valves, injection pressure, and location and number of electrodes in the cross-section upon the resulting curves. The injection was varied between 0.5 sec. and 5.0 sec. under a pressure both increased and diminished 100 per cent, through a single valve at one side of the canal, through two valves symmetrically arranged, and finally through six. The electrodes were varied from several in number to an entire network of points over the cross-section. All these changes showed no influence whatever on the resulting measured discharge, the salt clouds in the canal spreading visibly over the cross-section within 10 to 15 m. (33 to 50 ft.) from the injection valves, depending upon the velocity of the water. The injection decided upon was from 42 to 45 liters (quarts) of solution over an interval of 1.5 sec., through two valves; this was later enlarged to a six-valve system.

For the purpose of determining the center of gravity of the areas enclosed by the curves, the latter are enlarged and reproduced to scale on sheets of cardboard, cut out, and the centers found by free suspension in the air; this was found to give more rapid results than mathematical methods, without loss of accuracy.

It is interesting to note that the Allen method was practically unused in Germany until its study by the research institute in 1928.

Chemical Salt-Dilution, or Titration Method

The principle of flow measurement, through chemical analysis of discharge before and after the introduction of a salt or similar solution, has in the past taken a number of various forms,[6] all apparently highly complicated and requiring considerable time and trouble and the assistance of a trained chemist. The experience of the institute is that, of all four methods tried, the titration gives the most accurate results in the shortest time, although handled entirely by a mechanical engineer, and is well adapted to measurements where all other methods are practically impossible.

For the injection of the salt solution at the station, the scaffold and system of tanks shown in Fig. 27 were constructed just above the end of the last earth channel. A saturated solution is mixed in the 2-cu. m. (70.6-cu. ft.) tank on the upper platform; below the outlet pipe from this tank is a constant-head apparatus, the excess solution flowing over the inner circular crest A (Fig. 28) into the narrow space B between the inner and outer cylinders. Discharge from this outer tank is governed by a small orifice giving practically constant flow yet maintaining a head in the outer tank. The ratio between the head h' on the crest A and the waste head h is arbitrary; in these experiments it was approximately 1 to 300. Consequently, a small variation in the discharge head H causing a change in overflow at A is greatly magnified by the variation in h. Hence by a slight regulation of the valve on the mixing tank to hold h fairly constant as shown by the gage, the variation in h' is thus rendered inappreciable.[7]

A swinging funnel below the orifice allows the discharge to be diverted into either the rating tank or the pipe leading to the canal. At the beginning of the run, the flow is regulated until the conditions become constant; the discharge, 0.5 liter (quart) per sec., is then directed into the calibrated tank for about 3 min., next into the injection pipe throughout the run (20 to 25 min.), and at the end once again into the calibrated tank. In other words, not only is a practically constant head maintained, but the flow is measured volumetrically twice during the run.

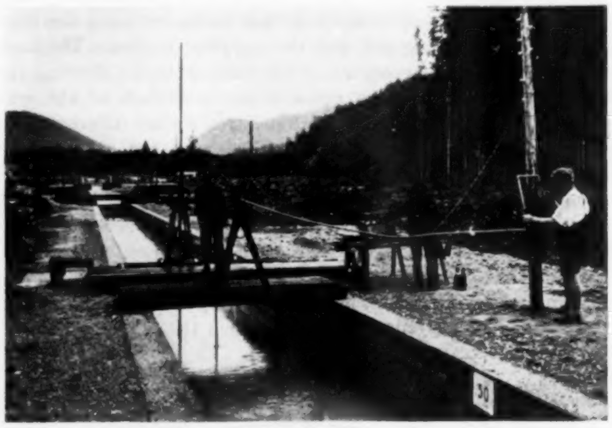

Fig. 29 Pump System for Withdrawing Stream Samples for Titration

(Current-meter carriage is seen just upstream from sampling bridge.)

The injection takes place just upstream from the large concrete tumble-bay, which gives a good mixture of the solution with the canal water. Just below the tumble-bay are three wooden stilling screens at the beginning of the concrete canal. Samples are taken at a point about 56 m. (184 ft.) downstream from the injection point by means of a hand pump and a long pipe whose intake can be placed at any point in the channel cross-section. (See Fig. 29.) Samples were taken for these runs at 15 points

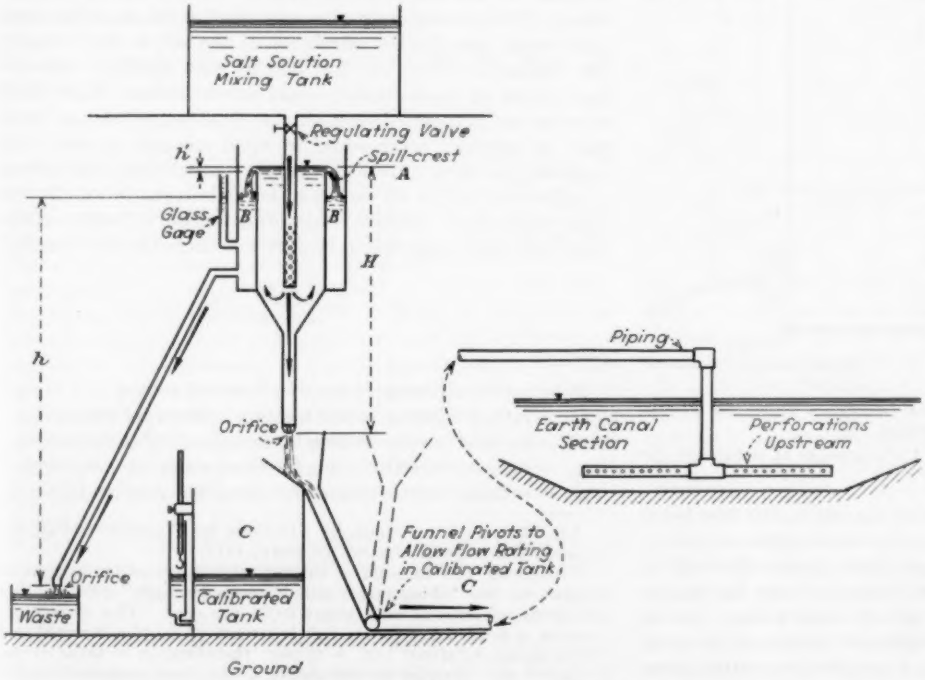

Fig. 28 Diagram of Titration Injection Apparatus

---

[6] "Chemi-Hydrometry," by B. F. Groat, A.S.C.E. paper No. 1366, 1916. "Saline Method of Water-Flow Measurement," by W. D. Peasley, *General Electric Review*, Feb., 1916, p. 132.

[7] A mathematical proof of the principle (printed by permission of the Forschungsinstitut für Wasserbau und Wasserkraft) is as follows:

The discharge of excess solution over crest A is $q = a \cdot h'^{3/2}$, where a is a constant. The same discharge expressed as flow through the waste tube is $q = b \cdot h^{1/2}$, where b is also a constant.

Differentiating and equating:

$$dq = \frac{3}{2} a \cdot h'^{1/2}\, dh' = \frac{1}{2} b \cdot h^{-1/2}\, dh$$

$$\frac{dh'}{dh} = \frac{b}{3a \cdot h'^{1/2} \cdot h^{1/2}}$$

Since $a = q/h'^{3/2}$ and $b = q/h^{1/2}$, then $dh'/dh = h'/3h$. Hence, as h during the experiments at the station was 500 mm. and h' was 5 mm., the ratio dh' to dh reduces to 1 to 300. A variation in h of 20 mm. gives a change in h' or H of 0.07 mm., or a matter of ±0.00175 per cent error when H is one meter.

(5 points each in 3 horizontals), during which electrically recorded current-meter readings were made 2 ft. upstream at each point simultaneously. The following samples were taken for each run in 1-liter capped bottles, first washed carefully in the solution to be sampled: 3 bottles of canal water before injection; 1 bottle of concentrated solution at beginning and 1 bottle at end of run; 15 bottles of canal water plus injected solution.

For the purpose of gaging small streams, a portable constant-head discharge apparatus has been devised. (See Fig. 30.) The tank is of light steel construction and may be carried easily on a wheelbarrow, the only other materials necessary being the bags of bulk salt, a mixing pail, and the sampling bottles. The tank is air-tight, with the exception of the inlet at the top through the narrow tube leading to a point about two-thirds of the way down, and the outlet at the bottom fitted for six different-sized orifices. The tank is completely filled with the concentrated solution, the inlet pipe is screwed in place, and the orifice is opened at the bottom. Within about 10 sec. the air inside has reached a negative pressure equivalent to the head of water above the lower end of the inlet, and air from outside flows in through the pipe at exactly the rate that the solution is discharging through the orifice. Since the inlet pipe is always thereafter filled with air, the only head acting upon the orifice is that between the lower end of the inlet and the orifice, the flow hence remaining constant till the water level in the tank has dropped to the end of the inlet. The smallest orifice gives a discharge of about 27 cc. (1.65 cu. in.) per sec. for nearly an hour; the largest, about 300 cc. (18.35 cu. in.) per sec. for some 5 min. All six orifices have been carefully rated with both water and the saturated solution. The jet from the tank is made to enter the stream preferably at a fall or rapids to ensure good mixing. Samples are taken by hand at a distance downstream depending upon the degree of turbulence.

Fig. 30 Section Through Portable Injection Tank for Titration Method

($H - h$ = constant head on orifice. Under-pressure at O balances the variable head h.)

This portable apparatus makes the method highly suited to gaging in mountainous country, where current meters are of little value. Several small streams in the Bavarian highlands were rated by the institute to try the method, with such success that two of the assistants spent three months in the fall of 1930 rating streams in the Austrian Alps for the Tauernwerk power project of the A.E.G. (Allgemeine Elektrizitäts Gesellschaft) by this method.

Fig. 31 Portable Injection Tank

(Measuring the flow from a melting glacier.)

Fig. 31 illustrates stream-rating with the portable injection tank for the titration method. There is a discharge of 250 liters (quarts) per second from the Karlinger glacier. The measurements are for the projected Tauernwerk in the Grossglockner territory, Austria.

Mellet's system of chemical analysis[8] has been adopted by the institute for the determination of flow values from the samples taken. This system deals with only relative values rather than with actual quantitative calculation of the salt in each sample. The various solutions are first diluted with distilled water so that all are of approximately equal concentration. Equivalent volumes are evaporated over an electric stove, potassium chromate as indicator being added in equal amounts to each concentrate, and silver nitrate of constant concentration added from a calibrated burette till each solution is brought to exactly the same reddish hue. Burette readings are reduced to 1-liter equivalents, and these numerical values are substituted in the formula:[9]

$$Q_2 = Q_1 \frac{n_1}{n_2 - n} - Q_1$$

in which:

Q_2 = rate of discharge of canal in liters per second
Q_1 = rate of injection of salt solution in liters per second
n_1 = reduced burette reading for sample of injected solution
n_2 = reduced burette reading for canal water after injection
n = reduced burette reading for canal water before injection.

---

[8] R. Mellet, Mitteilungen der Abteilung für Wasserwirtschaft des Schweiz. Dept. des Innern no. 10, Bern, 1917.

[9] Although this formula is theoretically incorrect, it is that in general use (see "Wasserkraft und Wasserwirtschaft," 1928, s. 101) and gives an error of only about 0.001 per cent. The correct expression is derived as follows: Salt in stream ($Q_2 \cdot n$) plus injected salt ($Q_1 \cdot n_1$) equals total salt $[(Q_2 + Q_1)n_2]$; therefore, $Q_2 = Q_1(n_1 - n_2) \div (n_2 - n)$. (Printed by permission of the Forschungsinstitut für Wasserbau und Wasserkraft.)

The steps in analysis may be summarized as follows:

1 Accurate volumetric dilution and measurement of samples
2 Evaporation almost to dryness and addition of equal volumes of potassium chromate
3 Titration with silver nitrate, always to the identical slight reddish tinge of the first sample
4 Reduction of all burette readings to 1-liter equivalents
5 Substitution in the formula.

Accuracy depends upon absolute cleanliness both in the securing of samples and throughout the analysis; the use of the same pipette, burette, and reagents, of approximately similar volumes of samples, and of equal-sized evaporation dishes for each individual run; and the judging of the color similarity and the reading of the burette by the same person under the same light conditions.

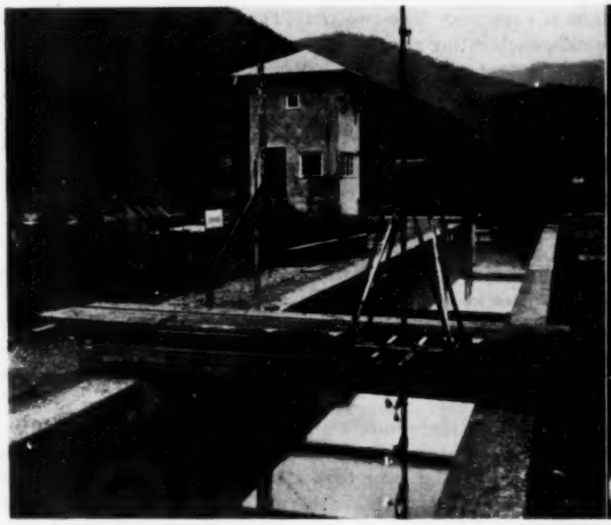

Fig. 32 Bridge and Carriage for Current-Meter Measurements

(Gage pit type A for weir readings is seen just behind and to left of carriage.)

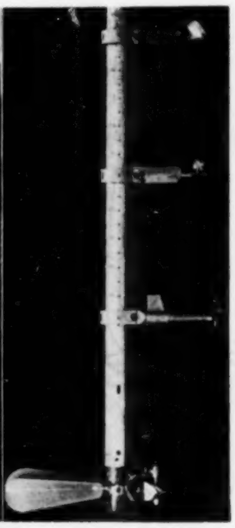

Fig. 33 Near View of Rod Supporting Current Meters

Current Meter Method

A small wooden bridge with wheel grooves was built across the concrete canal 21 m. (68.9 ft.) upstream from the end weir, to carry the steel meter carriage. The meter is bolted to a streamline shaft adjustable vertically by crank and windlass, so that the meter may be moved to any point in the canal section. The carriage is of such weight as to be easily movable by one person, yet stable enough to remain in the set position. The different meters were always used in succession in each run. Three could also be used simultaneously, so that by a single shift of the shaft either five or six horizontals were covered. The meters were in such positions, depending upon the discharge, that points as near as possible to the surface and bottom were reached, the others lying at even intervals in between. The verticals used were approximately 0.1, 0.3, 0.7, and 1.25 m. from either wall of the 2.50-m. canal. (See Fig. 32.)

Electrical leads ran to the control house, where a six-pen Ott chronographic recorder registered automatically the count of turns. The top and bottom pens marked the seconds directly from the clock, three kept track of the meter count, and the last was connected to the gate contacts for taking the filling time of the measuring basin. A spring mechanism moved the paper ribbon forward at the rate of 1 cm. per sec. An assistant on duty at the recorder marked on the paper ribbon the date, time, and location of meter at each change, signaling by buzzer to the carriage operator for movement of carriage or shaft as soon as the instrument had registered successfully a sufficient number of turns.

A similar bridge exists on the concrete channel leading from the Isar diversion canal to the supply basin. The apparatus for the meter readings accompanying the taking of samples for titration is identical, except that the recording is done in the salt-velocity pump house.

In these first experiments, efforts were made to compare the action of several different types of meter, a number of vane and propeller Ott instruments, 12 and 18 cm. (4.73 and 7.09 in.) in diameter, and an old-model Price (Gurley, 1903), each receiving identical tests. (See Fig. 33.) As the Price meter was 27 years old, only the results of the other meters were published. When the current meter was used for the determination of velocity distribution for other methods, that is, for titration and weir, three meters of the same type were used together on the same shaft.

Procedure of Experimentation and Computation

Five different rates of discharge, varying from 0.5 to 4.0 cu. m. (17.7 to 141 cu. ft.) per sec., were selected for study, the head gate on the canal being set at the beginning of each run to give as nearly as possible the discharge determined upon. A period of two hours was allowed for the flow to become constant, after which readings on the various gages along the length of the canal and at the measuring weir were begun and continued throughout the run. The current meters were first used, the measuring basin being filled during this time and the salt-velocity method immediately following the filling of the basin; the titration completed the sequence. This procedure was carried through three times for each run.

In the event of rain, the run was stopped, and then continued as soon as weather permitted. At the termination of each run, the results of the weir discharge and the measuring basin records were rapidly computed, so that in case of appreciable error the run might be immediately repeated under the same flow conditions. Approximately a month was required for the five runs.

All data were then taken to the Munich offices, and the calculation of results was carried out by a staff of six assistants in a period of about six weeks. A high degree of accuracy was sought throughout the period of experimentation and computation, often far more than would be thought necessary. This was done for a number of reasons: to reduce all error to a minimum, to make records of each step so complete as to obviate reproducing the same step at some time in the future, and in some cases to prove that certain influences had no appreciable effect upon the gross results—that is, canal seepage losses, rate of fall in water level of the measuring basin during gage reading extended as correction over filling time, etc.

The measuring-basin record was drawn from the large rating graph, and carefully marked as to time of day of filling. Seepage records for each section were also graphed, as seepage versus depth of flow. At the end of the calculations for each individual experiment, the results were corrected by use of the following routine chart, using for example the titration method:

1 Date
2 Titration number
3 Water depth at each seepage section
4 Seepage in each section from graph
5 Total seepage of all sections
6 Titration results: (*a*) by mixture of equal volume from each sample; (*b*) by weighting each sample for velocity
7 Mean head at weir h_t during titration
8 Mean head at weir h_m during filling of basin
9 $\Delta h = h_t - h_m$
10 $\tan \alpha$ (from basin rating curve)
11 $\Delta Q = \tan\alpha \cdot \Delta h$
12 Q from basin measurement •
13 Q from titration $= Q_t \pm \Delta Q$
14 Departure from basin results.

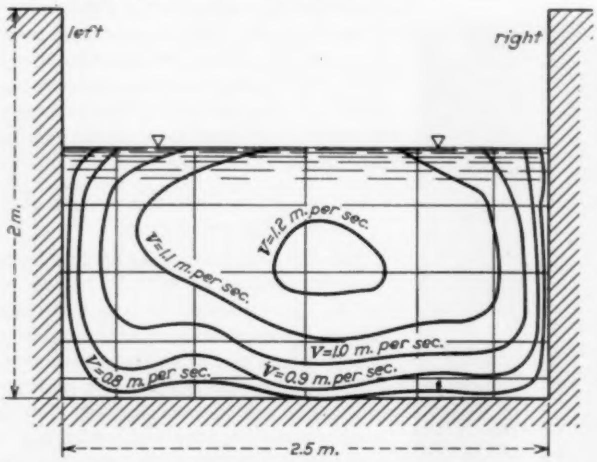

FIG. 34 VELOCITY DISTRIBUTION 20 M. (65.6 FT.) ABOVE WEIR DURING EXPERIMENT NO. 26
(Q = 3.3405 cu. m. per sec. (118 sec.-ft.); depth of water = 1.28 m. (4.2 ft.).)

RESULTS OF INITIAL EXPERIMENTS

Accuracy of weir measurements depends upon two interrelated qualities: the existence of uniform flow conditions with a weir of standard dimensions in good condition and the use of a reliable formula for discharge computation. Since the weir used was constructed as carefully as possible and flow conditions were as uniform as could be made (Fig. 34), the assumption that the first qualification was met leaves only a comparison of the resulting discharge values with those given by the accepted formulas.

In Fig. 35 are plotted curves of Bazin, Frese, S.I.A. (Swiss Society of Engineers and Architects), and Rehbock, together with the institute discharge results as given by the volumetric data of the measuring basin. The formulas[10] are as follows:

$$\text{Bazin (1888)}: \mu_0 = \left(0.6075 + \frac{0.0045}{h_0}\right)\left[1 + 0.55\left(\frac{h_0}{p + h_0}\right)^2\right]$$

$$\text{Frese (1890)}: \mu_0 = \left(0.615 + \frac{0.0021}{h_0}\right)\left[1 + 0.55\left(\frac{h_0}{p + h_0}\right)^2\right]$$

$$\text{S.I.A. (1924)}: \mu_0 = \left(1 + \frac{1}{1000h_0 + 1.6}\right)\left[1 + 0.5\left(\frac{h_0}{p + h_0}\right)^2\right]$$

(where $Q = \frac{2}{3}\sqrt{2g}\cdot\mu_0\cdot l\cdot h_0^{3/2}$ and p = crest height above canal floor, all dimensions being in meters)

$$\text{Rehbock (1929)}: \mu_0 = \left(0.6035 + 0.0813\,\frac{h_0}{p} + \frac{0.00009}{p}\right)\left(1 + \frac{0.0011}{h_0}\right)^{3/2}$$

(from $Q = \left(1.782 + 0.24\,\frac{h_e}{p}\right)\cdot l.h_e^{3/2}$ where $h_e = h_0 + 0.0011$ m.)

The crest height p of the plots in Fig. 35 is 523 mm. (1.716 ft.); experiments were also made with a height p of 850 mm. (2.795 ft.) with similar results.

Both were tested previously as models at a scale of approximately 1 to 7, giving results that checked almost perfectly with the Rehbock 1929 formula.

Since the four accepted formulas were derived from experiments conducted in laboratories to scale, the outcome of the institute tests seems to substantiate the doubt that exists with regard to the use of the sharp-crested weir formulas for large discharges, calling obviously for considerable research with the weir at full scale under greater heads than have so far been investigated.

In Table 1 are given the results of the three other methods, with the percentage departure from the measuring-basin data. The mean velocity varied from 0.3 m. (0.985 ft.) per sec. to 1.2 m. (3.94 ft.) per sec. The two Ott "Texas" meters gave excellent results, each rating slightly under actual discharge. The Price meter average error of 1.845 per cent greater than actual discharge was at first attributed to the comparatively small cross-section of the canal, but a larger Ott meter showed an average error of only —0.378 per cent. It is of course pointless to base a comparison upon the action of a meter 27 years old, in however good a condition it may be. The negative errors of 0.3 per cent and 0.6 per cent are a proof of the accuracy of the Ott instruments, but it depends nevertheless upon the rating of the meter prior to usage, since only after careful and dependable rating may a meter be so reliable.

Table 2 gives the relation of error in the salt-velocity method to the location and distance apart of the electrodes used, the results improving as the distance from the point of injection was increased.

Nearly all of the values are lower than the actual discharge, and a great number of individual tests is necessary before the average reduces the error to a satisfactory point. As may be seen from Table 1, the error of this method (— 1.2 per cent) is the greatest of all three. A further drawback to its practical use is the impossibility of determining beforehand the most favorable location of the electrodes.

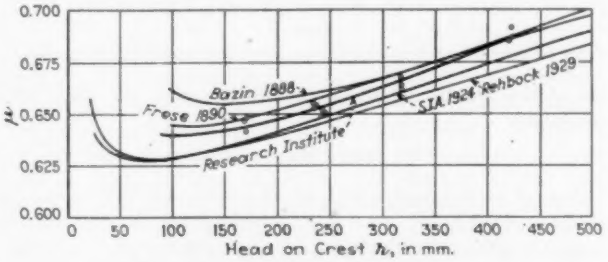

FIG. 35 GRAPH OF WEIR RESULTS
(Coefficient μ versus head on crest, plotted with curves from formulas by Bazin, Frese, S.I.A. 1924, and Rehbock 1929. Weir height, 523 mm., or 1.716 ft.)

Experience in penstock tests at the Walchensee Power Plant led to the same conclusion.

Most consistently accurate of all was the titration method, the departure being almost equally distributed above and below the measuring-basin data, and giving average errors of only + 0.03 per cent and + 0.06 per cent, respectively, for a mean of all points in the canal cross-section and a weighting of each sample to the existing velocity at that point. Since the current meter is suitable for only uniform flow conditions and the titration method depends upon turbulence for satisfactory mixing of the concentrated salt solution with the discharge, the two methods cover well the field of stream gaging.

ENGELS RIVER EXPERIMENTS

In the fall of 1930 work was started on a large, shallow flume of trapezoidal cross-section in which Geheimrat H. Engels, former director of the River Hydraulic Laboratory at the Technische Hochschule of Dresden, planned to conduct a series of river studies. These were to correlate his previous small-scale experiments on behavior of river sediment, performed indoors at the Dresden laboratory and based upon actual conditions of the Elbe River. (See "Hydraulic Laboratory Practice," pp. 95, 105.)

The flume was located some distance to the west of the upper end of the main canal (see Fig. 2), so that only a short intake canal was necessary from the western end of the supply basin. The flume was approximately 10 m. (33 ft.) wide and 100 m. (330 ft.) long and was lined with packed stone and coarse gravel from the Obernach bed. Discharge into the upper end of the flume was regulated by a vertical gate similar to that on the main canal, while at the lower end a short concrete canal section identical with the main concrete canal was constructed, with the same measuring weir that had been rated in the initial major experiments already described. The water discharged directly into the Obernach from the tumble bay below the weir.

Experimentation was started after the completion of the measuring apparatus early in the summer of 1931. Unfortunately it is impossible at this writing to describe in detail the exact methods and results of this research, as these have not yet been made public. A report will, however, appear in the near future in one of the American engineering papers.

The plans for procedure as proposed in July, 1931, are shown in Fig. 36. In all, five different channel and levee layouts were to be studied, each under the three discharges, giving, respectively:

(*a*) Low-water stage, with a water depth over channel sediment bed of 5 cm. (1.97 in.)

(*b*) Medium high-water stage, water depth 10 cm. (3.93 in.), just topping the channel banks (*c*) Maximum high-water stage, water depth 20 cm. (7.87 in.), in which the whole flume or river bed between main levees would be flooded.

These three separate stages were to be supplemented by rising and falling stages, for the purpose of studying the influence upon bar formation of varying discharge.

Preliminary experiments with different grades of sediment from the Obernach were first conducted in a straight temporary wooden flume of the same width as the model channel, to determine the most satisfactory slope and grain diameter. Sediment of a grain diameter varying from 0 to 5 mm. (0 to 0.2 in.) and a slope of 0.1 per cent or 0.05 per cent were finally chosen.

This sediment was leveled in the model at a depth of 10 cm. below the low-water banks before each run commenced; thereafter additional sediment was fed into the upper end of the channel in measured quantities, and collected at the lower end in a catch basin. Water depths were taken at intervals over the channel length by means of piezometer connections leading from the channel bed to gages of type A outside the flume. A trussed timber traveler had been built across the flume, moving longitudinally along tracks on each bank, to facilitate measuring the contours of the bars formed in the channel during the various flow stages.

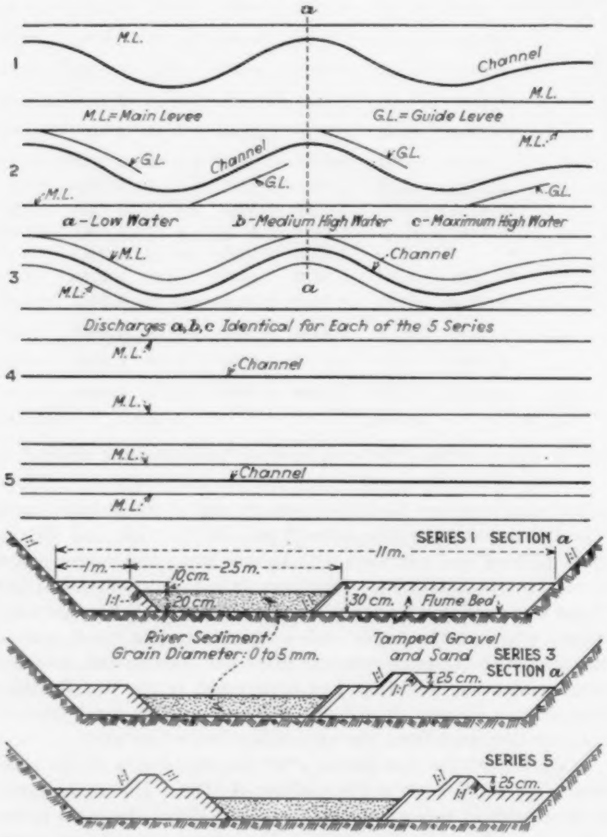

Fig. 36 Engels River Flume

Fig. 37 is the Engels river model at flood stage, without dykes. Though the water covers the bed of the flume, the serpentine outline of the submerged banks is clearly visible.

Fig. 38 is a view of the Engels river flume, looking downstream. The bed is dry, showing the construction of the continuous dykes. The tracks at right and left carry the observation and contour platform visible in the distance.

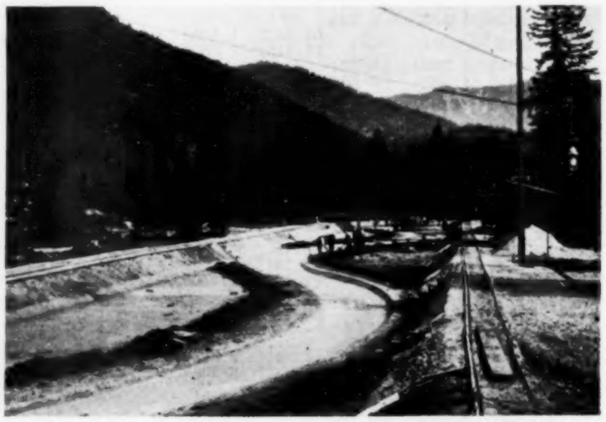

Fig. 38 Dry Model With Continuous Dykes

HYDRAULIC INVESTIGATIONS AFIELD

Soon after the founding of the research institute, but prior to the completion of the experiment station, its staff began a series of studies on canal flow, using actual channels in the vicinity to the south of Munich for their research—namely, the Isar diversion canal below Krünn and the Ampelsbach canal near the Achensee in Tyrol. Results of the experiments have not yet been published, since it is intended to carry on the investigations several years longer with further observations in other localities. At the same time, a study over a period of years is being conducted by the institute dealing with the deposition of sediment by the Isar River at its entrance into the small reservoir at Krünn just before its diversion.

The first model study completed by the institute staff was carried on in the laboratory of the Munich Hochschule, for the design of a spillway crest at one of the Mittleren Isar power plants northeast of Munich. Results were made known in the first publication of the institute in 1928; they may also be found in "Hydraulic Laboratory Practice" under the chapter about the Munich laboratory, in a brief discussion by Dr. Kirschmer.

Flow Measurements at the Walchensee Power Plant

For the purpose of comparing the leading European and American methods of measurement of penstock discharge for the determination of turbine efficiency, a series of tests was made at the Walchensee Power Plant by several English and German firms in collaboration with the research institute. The power plant permitted the use of one penstock and an 18,000-hp. Pelton turbine. Salt-velocity and pitometer measurements were conducted by the British Pitometer Company, Ltd., of London, commissioned by the Canadian and General Finance Company, London; current-meter tests were supervised by J. M. Voith, Heidenheim-am-Brenz; a Gibsonmeter was installed and operated by Dipl.-Ing. P. Volkhardt, Munich; electrical measurements of power output were in charge of the staff of the Walchensee Power Plant; and the research institute contributed a portion of the salt-velocity apparatus and supervised the measurement of the penstock for head, diameter, and location of apparatus, and published the description of the measurements and a tabulation of results in the *Z.V.D.I.*[11]

The six steel penstocks of the power plant lead from a concrete surge tank down an approximately 40-deg. slope to the plant 183 m. (600 ft.) below, giving an over-all head of 192 m. (See Fig. 39.) They vary in diameter from 2.250 m. (7.39 ft.) at the top to 1.850 m. (6.07 ft.) at the lower end, and are anchored at six points, two of these being on the slope between the surge tank and the plant; at the upper anchor on the slope, the penstocks make a small vertical bend. Penstock No. 5, selected for the tests, supplies two Pelton turbines, one being shut down entirely during the runs.

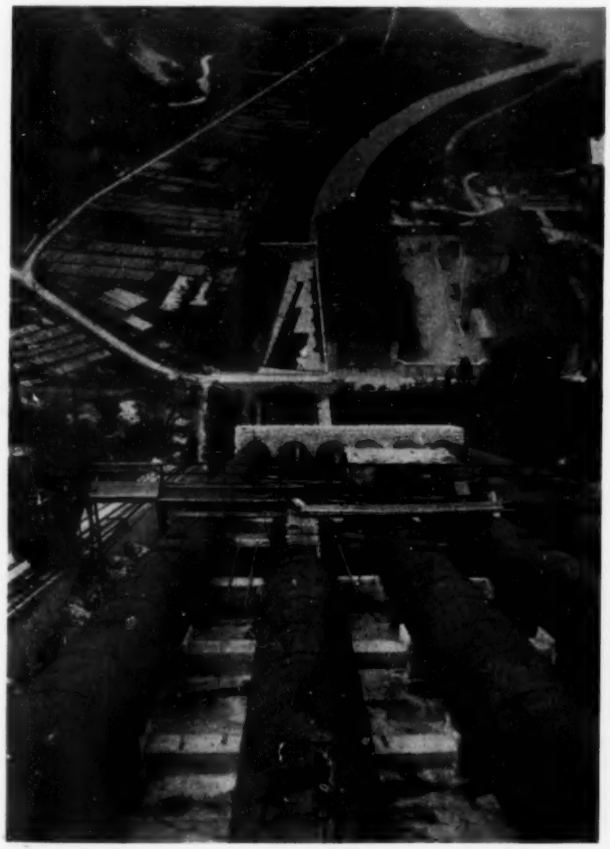

FIG. 39 VIEW FROM SURGE TANK DOWNWARD UPON PENSTOCKS AND PLANT OF THE WALCHENSEE KRAFTWERKE

(Platform for recording instruments is visible at site of current meter and pitot-tube measurements.)

Injection apparatus for the salt solution was located just below the surge tank, operating under a pressure of 7.8 atmospheres to overcome the head on the penstock at this point of 20 m. (65.60 ft.) and the excessively high friction loss in the valves and joints of the apparatus. A single injection valve, furnished by the British Pitometer Company, was set at the midpoint of the penstock cross-section, in such a way that it could be withdrawn for inspection without shutting down the flow. A single injection, 25 to 35 liters (quarts) of solution, lasted from 1 to 2 sec. Four electrodes were distributed over nearly the length of the penstock, in order to offset the difficulty of determining in advance the most advantageous location. They consisted of pairs of short copper strips held rigidly 3.2 mm. (0.126 in.) apart, each strip 52 by 19 by 1.6 mm. (2.05 by 0.75 by 0.063 in.) in size. They were of necessity set at the wall of the penstock, rather than extended over the entire diameter, to avoid complicated construction. It was believed that this would not influence the results materially, since they were four in number and set at various points around the circumference.

Some 18 diameters below the surge tank, the supporting rods for both the pitometer and the current meters were built into the penstock wall in the same cross-section at an angle of 90 deg. from each other, so that when the pitometer was in use, the other was drawn as far as possible out of the way against the penstock wall; the pitometer could be completely withdrawn. Two Ott form-V "Texas" electrically recording current meters were fastened upon their shaft at a distance of 1.038 m. (3.41 ft.) from each other, so that the shaft could be moved to cover the entire diameter in 28 points, coming to within 5.3 cm. (2.09 in.) of the walls; readings for each run were completed in less than half an hour. At the end of the experiments the meters were again rated on the same shaft.

The pitometer measurements were made simultaneously with two instruments, working from opposite ends of the penstock diameter. Due to the presence of the current shaft, the pitot tubes could be inserted only to within 25.5 cm. (10 in.) of the penstock axis. Readings were made from a wood scale behind a glass U-tube filled with carbon tetrachloride, the specific gravity being determined before each experiment. Measurements were made at 16 points on the diameter, the process lasting about twice as long as the current-meter readings.

NOTE: All loads and discharges converted to a head of 192 m.

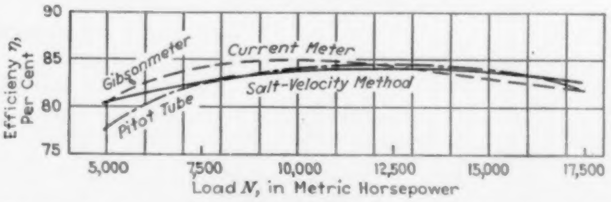

FIG. 40 GRAPH OF EFFICIENCY VERSUS LOAD AS MEASURED BY CURRENT METER, PITOT TUBE, GIBSONMETER, AND SALT-VELOCITY METHOD

Depending upon the intensity of back pressure on the shutting down of a turbine to give indirectly the previous velocity in the penstock, the Gibsonmeter was designed to record photographically the intensity record, in such a way that the internal friction in the instrument is reduced to almost nothing. Unfortunately, incorrect regulation of a spring in the mechanism was not discovered till the films were developed, so that only two experiments gave usable results. The fact that the turbine required a double valve action to close down gave further difficulty under high loads.

---

[11] Vergleichs-Wassermessungen am Walchenseewerk," by Dr.-Ing. O. Kirschmer, *Z.V.D.I.*, 1930, bd. 74, no. 17.

Results of the experiments (see Table 3 and Fig. 40) show clearly that, with the conditions under which the tests at the Walchensee plant were made, the current meters gave by far the most dependable results, judging by mean values and a comparison with ratings made at the plant four years previously. The pitometer readings required some four times as long a period, and the unstable level in the U-tube proved particularly bothersome under low discharges. The salt-velocity method showed excessive departure from its own average of readings except on the stretches from the injection point to the third and fourth electrodes, and as these were in use on only four out of twelve runs, the other values were discarded. The cause of the poor results is laid to the very short electrodes used and the difficulty in determining the center of gravity of the graphed areas. These computations were made independently by both the British Pitometer Company and Professor Allen. The two successful Gibsonmeter results are within 0.5 per cent of the current-meter readings.

Although these experiments were conducted by recognized authorities in the field of practice, they demonstrate only too well the great differences in the results of even the best measurement methods known today and the necessity of some absolute standard with which each method can be compared. Comparative tests among several such methods show, at best, simply comparative values, from which the true results can only be assumed. It is to this end—the actual volumetric checking during measurement—that the research institute is striving. When the performance of instruments under actual flow conditions is established, discharge measurement will be far more accurate.

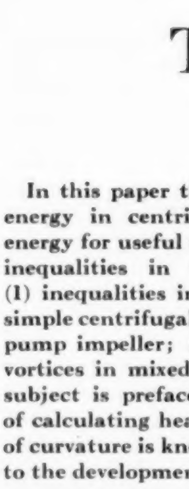
HYD-54-4

Turbulence in Centrifugal Pumps

By J. W. MACMEEKEN,[1] BERKELEY, CALIF.

In this paper the author discusses whirlpool or vortex energy in centrifugal pumps, the harnessing of this energy for useful work, and the effect of different kinds of inequalities in vortices. He deals respectively with (1) inequalities in the forced vortex of an impeller in a simple centrifugal pump; (2) waste energy in a centrifugal pump impeller; and (3) the synchronization of parallel vortices in mixed-flow impellers. The treatment of the subject is prefaced by a brief description of a method of calculating head losses in river bends when the radius of curvature is known, the results obtained with which led to the development of the pump study presented.



THE theory of centrifugal or turbine pumps has been elaborated in great detail during the last fifteen years as a result of the broad advance in the science of applied fluid dynamics. Since the modern centrifugal pump first came into use with Young's invention in 1851, its application in modern improved forms has placed it in the first rank among other important power machines in which efficiency of operation and economy of construction have reached a highly perfected stage of development. The development of the theory of kinematic and dynamic similarity has made possible the wide application of successive improvements obtained by research combined with analytical development of theory. During a period of years, a wide industrial field of application for centrifugal pumps has offered a stimulus for gradual improvement, which justifies very careful study as a means to ultimate economy of power and material.

The following discussion is not intended to introduce any new theory or contradiction of recognized theory of centrifugal-pump performance and design. It has for its object rather the introduction of some aspects of centrifugal-pump problems from the point of view of our knowledge of the observed characteristics of the vortex. A centrifugal pump is essentially a hydraulic machine which allows the generation of hydraulic pressure by means of a forced vortex created by a rotating impeller, combined with a free vortex at its outlet, so constructed as to make all the static and kinetic energy generated available as far as possible in the discharge pipe. This combination of forced spiral vortex and free spiral vortex is capable of certain variations and imperfections, some of which have an adverse effect, and some of which merely result in variations in pump characteristics without impairing the efficiency of the machine or the continuity of the characteristic curve.

The author had occasion several years ago to make a detailed study of hydraulic conditions in a section of the St. Lawrence River from the point of view of head available for hydroelectric power. It was noted that sections of the river and of large power canals, in which flow occurred in curved directions (partial free vortex), showed marked variations in surface levels and in loss of head, which could not be explained by the usual formulas for flow in rivers, such as Bazin's 1897 formula combined when necessary for change in cross-sections of channel with a modified Bernoulli equation. It was necessary to find a means of calculating the water-surface levels in curved channels by some method based on mathematical principles known to be correct to within a small margin of error, and to check these calculations against more than one actual surveyed condition of the river. After this had been done satisfactorily, a means was established for calculating the effect on water levels and available power head of construction work on the river to alter its flow in modified and partially artificial channels in order to gain increased available power head. Correction factors or coefficients of local distribution as a function of the channel curvature were found by both field observation and by calculation. These factors are remarkably similar in value to those used in the case of centrifugal pumps to correct mean velocities to the mean energy values, so that it appears that the flow of water in the curved river channels and in the curved path through a centrifugal pump may be treated both in the same way and calculations may be made based on geometrical considerations only. In short, the flow of rivers in curves may be calculated on the same basis as the flow in straight canals by using correction factors which are a function of the curvature and may be calculated, and similarly the flow of water in a centrifugal pump and its effect on generated head may be calculated by the use of the same correction factors as a function of channel curvature.

In addition to foregoing considerations, this discussion deals with a method of obtaining synchronization of effect of vortex action in mixed-flow impellers where the flow may be regarded as a series of parallel spiral forced vortices in the impeller, modified to some extent by included local free vortex action.

NOTATION

ω = angular velocity, or angular displacement
R = radial distance from center of rotation
g = acceleration due to gravity
U = peripheral velocity of impeller vane
W = absolute velocity
V = relative velocity
V' = value of V when used for mean total-energy calculations
H = head
H_t = theoretical head
C = peripheral component of W. C is also used as a coefficient in the formula $V = C\sqrt{(rs)}$ and is the value for uniform motion in a straight line
V_r = radial component of W or V
$\tan \beta_2$ = tangent of actual exit angle of impeller
$\tan \beta_2'$ = tangent of apparent exit angle
L = length of channel
r = the hydraulic mean radius

---

[1] Hydraulic Engineer, Byron Jackson Company. Mem. A.S.M.E. After graduating from the University of Edinburgh in Arts (1909) and Science (1911), the author served on the engineering staffs of the Dominion Bridge Company and the Montreal Light, Heat, and Power Company for the Cedars Rapids Hydro-Electric Development. During the World War he served abroad for three years with the Canadian Expeditionary Force. Since 1919 Mr. Macmeeken has specialized in the engineering and development of centrifugal pumps.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

$Z_{1,2}$ = fall in water surface in an open channel between two points

$(1 + \rho)$ = calculated from the curvature of the streamline boundaries of a channel and the position of the first and second centroids with reference to the local center of curvature

η_H = hydraulic efficiency

γ = Bazin's coefficient in the formula $C = 157.8/[1 + (\gamma/\sqrt{r})]$

V_R = radial velocity

METHOD OF CALCULATING HEAD LOSSES IN RIVER BENDS WHERE THE RADIUS OF CURVATURE IS KNOWN

When the loss of head in a large curved river channel as shown in Fig. 1 was computed by Bazin's 1897 formula where $C = 157.8/[1 + (\gamma/\sqrt{r})]$, in the equation, head lost by friction $= V^2L/C^2r$, it was found that the computed loss of head was very much less than the actual loss even when the channel had been accurately surveyed and carefully measured. When the value of γ was determined for a similar straight channel, it was found that the head lost in a carefully surveyed river bend could only be explained by the following equation: Head lost between two sections of channel a given distance apart =

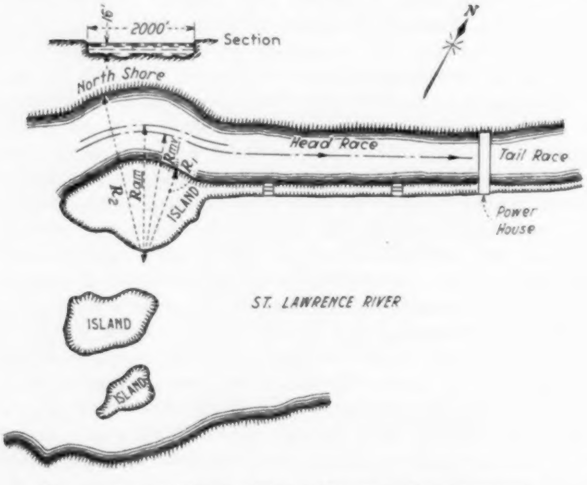


FIG. 1 LARGE CURVED RIVER CHANNEL INVESTIGATED
(Additional coefficient to use with Bazin's formula to correct for curved channels: $(1 + \rho) = {}^1/_2(R_1^2 + R_2^2)/[(R_1 + R_2)/2]^2$.)

$$Z_{1,2} = \frac{(1 + \rho_1)V_1^2 - (1 + \rho_2)V_2^2}{2g} + \int_{L=0}^{L=1-2} \frac{V^2(1 + \rho)dL}{C^2r}$$

$(1 + \rho)$ is a coefficient of local distribution, and its value was obtained in two ways: First, by gaging the stream at sections 1 and 2 a short distance apart, recording all the values of the velocity at a uniformly distributed number of points, and finding both the average velocity and ΣV^2/number of observations; then

$$(1 + \rho) = \text{ratio } \frac{\Sigma V^2/N}{(\text{average } V)^2}$$

The value of $(1 + \rho)$ was next computed by the formula

$$(1 + \rho) = \frac{\dfrac{R_1^2 + R_2^2}{2}}{\left(\dfrac{R_1 + R_2}{2}\right)^2}$$

and the same values resulted.

When values of $(1 + \rho)$ were inserted in the equation for head lost $Z_{1,2}$ between a consecutive series of points located in mid-channel about 300 ft. apart in a channel two miles long, the solving of the equation to explain the existing hydraulic gradient for known river discharge and known channel cross-sections resulted in approximately the same values of C and of Bazin's γ as were found for straight sections of the same kind of channel. The reason apparently is that all losses are proportional to V^2. This is not correct, but the error in assuming it to be so is very small. Therefore the mean value of V^2 should be used rather than the square of V as capacity/area of the channel section.

The fact that the results by both methods were the same showed that the variation was caused by curvature and could be calculated. Before calculating this coefficient, the direction of flow was traced by a series of floats whose bearings were referred to a base line on the shore, so that the curvature of the streamlines of flow as well as of both banks of the stream was known.

The consistent reliability of the results obtained by both methods gave the author great confidence in the reliability of the formula. The value of the coefficient $(1 + \rho)$ varied from 1.20 to 1.70 in curved channels down to 1.06 in straight channels adjoining bends in the stream.

The fact that these values were within the same range as similar coefficients obtained from the analysis of a large number of tests of centrifugal pumps, prompted a study of the significance of this effect, particularly as the variation in value of the coefficient with variation in the ratio of values of R_2/R_1 showed marked functional similarity in both pump and river channels. The purpose of this "coefficient of local distribution," which might be called a "coefficient of turbulence," is to convert "mean velocity" into its equivalent value for "mean-energy" calculations.

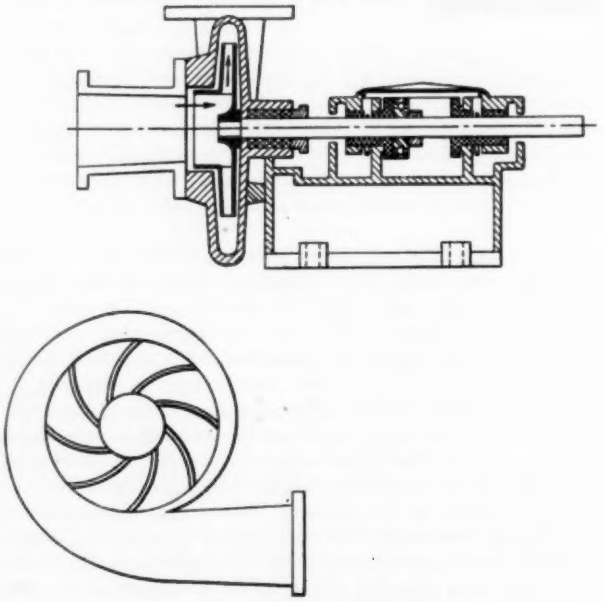

FIG. 2 SIMPLE CENTRIFUGAL PUMP

I—INEQUALITIES IN THE FORCED VORTEX OF AN IMPELLER IN A SIMPLE CENTRIFUGAL PUMP

A simple centrifugal pump is shown in Fig. 2. This consists of an impeller and an outlet chamber. Water flows through the impeller theoretically as a forced spiral vortex and through the outlet chamber into the pipe as a free vortex, or rather as a free spiral vortex. This simple centrifugal pump is narrow for its diameter, and the equations for centrifugal force and total energy, assuming a perfect forced vortex in which all particles have the same angular velocity, are generally given as follows:

$$\text{Total energy per pound at periphery} = \frac{\omega^2 R^2}{g} = \frac{U^2}{g} \quad \text{. . . . [1]}$$

when there is no flow

$$\text{Total energy when flow takes place} = \frac{W^2}{2g} + \frac{U^2 - V^2}{2g} \quad \text{. . [2]}$$

or more correctly, the difference between these values for the outlet and inlet radii of the impeller. The element $W^2/2g$ represents the kinetic energy discharged into the free vortex of the outlet where the value of W becomes greatly reduced under the law of constant moment of momentum, viz., $W_1R_1 = W_2R_2$, etc. per unit mass.

FIG. 4 TYPICAL IMPELLER WITH MODIFIED INVOLUTE VANES

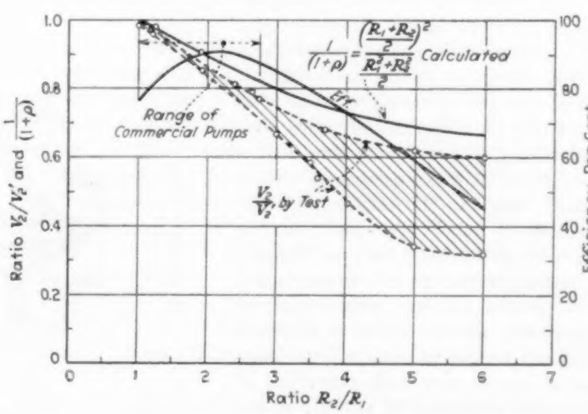

FIG. 5 CALCULATED CORRECTION FACTORS COMPARED WITH TEST RESULTS

The element $(U^2 - V^2)/2g$, which represents the static head developed in the impeller, being a function of V^2, V^2 should not be calculated as (average V)^2, but rather as the mean value of V^2, V not being constant across the channels of the impeller. The mean value of V^2 may be calculated from the test of a pump by measuring all purely mechanical losses and obtaining the hydraulic efficiency

$$\eta_h = \frac{\text{Water hp.}}{\text{B.hp-losses}}$$

and theoretical head

$$H_t = \frac{\text{Actual head}}{\text{Hydraulic efficiency}}$$

An equivalent form of Equation [2] for total energy is

$$H_t = \frac{U_2C_2 - U_1C_1}{g} = \frac{U_2C_2(1-e)}{g} \quad \text{. . . . . [3]}$$

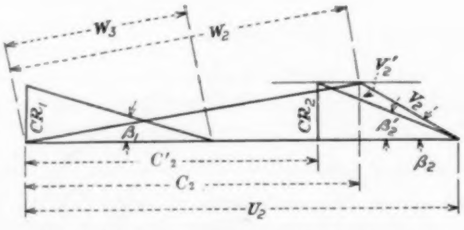

FIG. 3 DISCHARGE-VELOCITY DIAGRAM

$$H = \frac{U_2C_2 - U_1C_1}{g} = \frac{U_2^2}{2g} + \frac{W_2^2}{2g} - \frac{V_2^2}{2g}$$

By solving this equation for C_2, other values being known, the discharge-velocity diagram (see Fig. 3) may be constructed and a new or apparent value of V_2 may be found, which we may call V_2'. This value is always greater than the average value of V_2 measured as Q/A. The reason obviously is that this new value V_2' represents in the energy equation the square root of the mean value of V^2, because the static pressure in the impeller is a function of V^2, and the mean value of $V^2 = \Sigma V^2$/number of observations should be used rather than (average V)^2, because V is not uniform across the impeller channel. All impeller vanes in pumps of this simple type are either involute curves or approximations to such curves (see Fig. 4), and each water channel is bounded by two curves, one of which has a radius approximately equal to R_2, and the other a radius approximately equal to R_1, so that there is a secondary variation in velocity in each impeller channel bounded by two vanes in accordance with the laws of a free vortex, because water is not an elastic medium, and the influence of the vanes for creating a perfect forced vortex is only local. This variation of V between two vanes should be a function of the bounding radii R_1 and R_2 as in the flow in a curved river channel, and the

$$\frac{\text{Mean value of } V^2}{(\text{Average } V)^2} = \frac{\dfrac{R_1^2 + R_2^2}{2}}{\left(\dfrac{R_1 + R_2}{2}\right)^2} = (1 + \rho) \qquad [4]$$

which latter is a factor of local distribution in terms of curvature. This may be expressed for convenience in the form of a change in tan β_2. Correction factors calculated in this way are shown plotted in Fig. 5 compared with actual test values. In Fig. 5, the similarity of variation of V_2/V_2' according to test values, to the variation of the factor $1/(1 + \rho)$ is clear, $(1 + \rho)$ being a coefficient of local distribution and a function of channel curvature. The lower values of V_2/V_2' require to be multiplied by an additional coefficient $(1 + \alpha)$ having a value of from 1.04 to 1.06 in the range of commercial pumps. The coefficient $(1 + \alpha)$ is a coefficient of local distribution, expressing inequalities due to change of cross-section only, and when the impeller

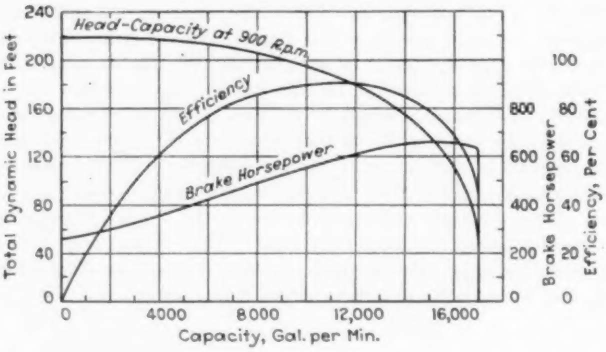

FIG. 6 CHARACTERISTIC CURVE OF AN 18-IN. DOUBLE-SUCTION CENTRIFUGAL PUMP AT CONSTANT SPEED

channels are so proportioned geometrically that there is little change in cross-section in the relative path through the impeller, its value approaches unity. This explains the variation in the values of V_2/V_2' due to effects other than curvature, which are incidental to the geometrical construction of the impeller. Thus the coefficient $(1 + \alpha)$, which is a coefficient of local distribution for a channel of varying cross-section, and $(1 + \rho)$, which is a coefficient to convert (mean velocity)^2 into mean energy on a basis of the mathematical mean value and is a function of channel curvature, afford a means of calculating the head generated by a centrifugal pump, supplementary to the fundamental Equation [2] or [3], which assumes a perfect forced vortex in the impeller. These coefficients make allowance for the effect of partial free vortex distribution of velocity in the space between vanes.

In general, it has been found by experience that the values of these coefficients are independent of the number of vanes, vary with curvature of vanes and with the unit velocity in the impeller, but most of all are dependent on the ratio $R_2:R_1$. This explanation of the apparent reduced value of tan β_2 as due to merely local free vortex action makes it clear why this effect causes no measurable falling off in hydraulic efficiency. Such suggested causes as "component of whirl at exit," "tractive effort of the vane," "impedance of the casing," etc., would be more likely to cause a reduction in efficiency. If the effect is caused merely by free vortex effect in the curved channels of the impeller mixed with the general forced vortex effect of the impeller, the underlying cause is the only condition under which water could flow through the impeller in accordance with the laws of fluid dynamics, and therefore no loss in efficiency should be expected.

It may be argued that free vortex effect on secondary distribution of velocity between the vanes would result in expected distribution of flow opposite to that which has been observed in experimental research. Consider, therefore, the effect of this secondary distribution on the composite action of acceleration commonly referred to as "Coriolian effect." As soon as this secondary circulation begins to appear in the initial stages of the impeller passage where composite acceleration is small, it creates local differences of pressure (rapidly increasing toward the end of the channel), which result in the generally accepted distribution of flow at the exit end of the impeller passage. This explains why impellers having considerable prerotation have a more equal distribution of velocity at the exit. However, once inequalities in the relative velocity have been produced, they are likely to persist, necessitating some cross-flow at the exit of the impeller. The viscosity of the fluid then resists the necessary

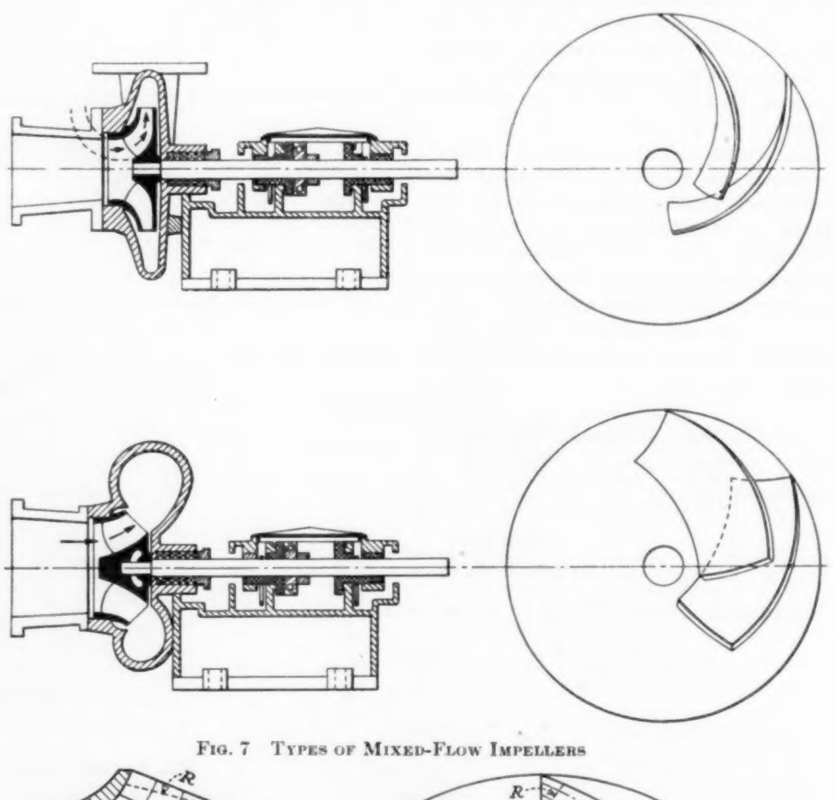

FIG. 7 TYPES OF MIXED-FLOW IMPELLERS

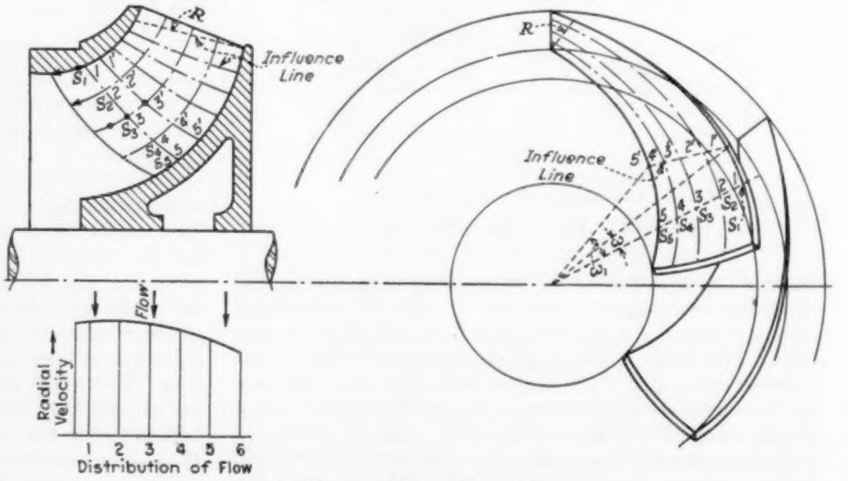

FIG. 8 TYPICAL MIXED-FLOW IMPELLER

interchange of particles at the exit of the impeller to some extent, and therefore the actual head generated is influenced slightly by the viscosity of the fluid pumped. It should be noted that variation in flow at the exit of the impeller due to the effect of composite acceleration is the direct result of initial variations due to free vortex effect between vanes, and therefore the free vortex effect due to curvature of channel is a measure of the exit variations. (See Fig. 4.)

Referring to Fig. 5, note that the calculated coefficient of distribution $(1 + \rho)$ is very closely in agreement with test results throughout the range of R_2/R_1 values for commercial impellers. The visualization of these effects is only of practical value as a guide in research work in obtaining the variations of vane angularity and channel proportions which are best for hydraulic efficiency and least conducive to fluid turbulence.

Fig. 6 shows a characteristic curve plotted from an official test of a modern centrifugal pump in operation in the water-supply system of a large city. The continuity of characteristics and the high overall efficiency are an example of the application of carefully studied design, embodying all recent improvements, in which the various considerations involving turbulence in vortex action have been reduced to a minimum.

II—WASTE ENERGY IN A CENTRIFUGAL-PUMP IMPELLER

A forced vortex is stable when all its particles revolve with the same angular velocity. It is also stable if the angular velocity of the inner particles is less than that of particles at a greater radius. However, there are faults in design which may result in higher angular velocity of the inner particles. Some of these are: too much prerotation, proportions involving poor continuity so that part of the impeller does not run full of fluid, local vapor pockets, either permanent or periodic in formation, and a profile outline of passage which, when combined with the space between the vanes, results in lack of continuity of area and direction. All these considerations may create an instability of vortex and result in local eddies and whirlpools, the inherent energy of which is supplied by the motive power driving the pump without creating useful head. These effects may be combined with flow of dissolved gases from the fluid and rapid deterioration of metal. An example of this is the case of a centrifugal pump accidentally run under reversed rotation when one month's operation with pure water caused deep holes to be cut in the casing, but no wear whatsoever in the impeller. The reason for this is that under these conditions the vortex in the impeller was stable but that in the case was unstable.

Other possibilities of waste energy arise in faulty impellers of the mixed-flow type where more head is generated in one part of the impeller than in an adjacent element, so that local back flow may occur at certain capacities. This effect is discussed in the following paragraphs.

III—SYNCHRONIZATION OF PARALLEL VORTICES

In the case of mixed-flow impellers such as are illustrated in pump types shown in Fig. 7, a typical impeller being shown in Fig. 8, conditions of flow become more complex. The drawing of this impeller shows that it is bounded by two walls which are of approximately parabolic cross-section. The impeller may be divided into any number of parts or units of equal volume as shown by lines 1, 2, 3, 4, 5. Each of these lines is the boundary of a unit of volume. A flow section represented by unit volume of the impeller is therefore an annulus bounded by two surfaces of revolution of approximately parabolic profile. The ring area of a unit volume may be constant from R_1 to R_2, or it may vary continuously in value. Each unit of volume is acted on by the impeller vane in such a way that it becomes a forced vortex with a steady gain in centrifugal force, the amount of which is controlled by the angularity of the vane. The vane may either be so proportioned that all units of volume are acted on in the same way or so that they are all acted on differently. That is, the pumping may be done uniformly or it may be done more on one side. The designer therefore has a wide choice in porportioning the degree to which power is applied to each unit of the total impeller volume. An impeller of this kind may function as a series of parallel vortices, the characteristics of which are determined by the action of the vane on each particle of the fluid, and each particle of the fluid is influenced in addition by the integral effect of all other particles. Obviously, an infinite number of designs are possible, each of which may generate the same capacity and head for a given speed, but each should have a different characteristic performance curve through a range of capacity, and a variation in efficiency would be expected for different designs.

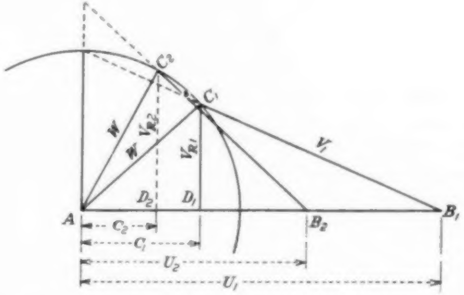

FIG. 9 VELOCITY DIAGRAM OF IMPELLER SHOWN IN FIG. 8

Two requirements must be met in this impeller for stability of characteristic and highest possible efficiency: (*a*) The head generated in each unit of volume should be the same for uniform capacity and the work done on each particle of fluid should be the same. (*b*) As flow occurs in three-dimensional space instead of in a single-plane, the forced vortex of each unit volume must have stability in a lateral as well as a radial direction, as mentioned in Section II. For simplicity, let us make certain assumptions of flow as a basis on which to determine the requirements necessary for condition (*a*). As a second step, these assumptions of flow may be so chosen as to either satisfy condition (*b*) also, or they may be transposed into dynamically equivalent conditions to meet the requirements of (*b*) in addition to those of (*a*).

Referring to the impeller shown in Fig. 8, let us assume that the fluid approaches the revolving vane with a uniform absolute velocity W_1 in all units of volume; also that it leaves the impeller with a uniform absolute velocity W_2 in all units of volume. These are justifiable assumptions because parallel units of volume in the discharge case should have the same velocity in order that the total energy there should be constant in successive layers measured axially parallel to the shaft. In other words, there is a reason both at the entrance and exit for the absolute velocity's being equal in all units of volume. A third assumption that should be made is that the same amount of centrifugal force should be imparted to each particle of the fluid after each unit of time throughout its course through the impeller, provided each particle takes the same total time to pass through the impeller.

Referring to the impeller shown in Fig. 8 and the velocity diagram in Fig. 9, let 1, 2, 3, 4, 5 be a series of points on the vane reached by fluid particles moving along the flow line after the same unit of time; these points are then all points of equal angular displacement from the edge of the vane, and the distances S_1, S_2, etc. represent the velocities in a radial direction to some particular scale. The centrifugal force imparted to a single particle independently at any radius R is equal to C^2/R for unit mass, where R is the radial distance of the particle considered as unit mass from the center of rotation. Hence, for constant centrifugal force applied to each particle along the line 1–5, $C_1^2/R_1 = C_2^2/R_2$, etc., and the radial velocities at each of these five points may be computed as follows:

$V_{r1}^2 = W^2 - C_1^2$; $V_{r2}^2 = W^2 - C_2^2$, etc. (W being constant) Hence

$$V_R = \sqrt{W^2 - KR} \qquad [5]$$

K and W^2 being constant.

The mean value of V_R is:

$$\bar{V}_R = \frac{\int_{R_5}^{R_1} V_R dR}{R_1 - R_5}$$

$$= \frac{\int_{R_5}^{R_1} (W^2 - KR)^{1/2} dR}{R_1 - R_5}$$

$$= \frac{\frac{2}{3k}\left[(W^2 - kR_1)^{3/2} - (W^2 - kR_5)^{3/2}\right]}{R_1 - R_5}$$

$$= \frac{\frac{2}{3k}\left[V_{R_1}^3 - V_{R_5}^3\right]}{R_1 - R_5} \qquad [6]$$

This equation for the mean value of V_R enables us to calculate also the mean radius for purposes of design.

Fig. 10 shows the relative variation of V_R plotted to a scale, and since the points 1–5 represent equal angular displacements, the spaces S_1, S_2, etc. are proportional to V_{R1}, V_{R2}, etc. and represent the relative pitch of the vane. In other words,

$S_1 = V_{R1} \times$ unit time (see Fig. 8)
$S_2 = V_{R2} \times$ unit time (to some scale)

and S_1, S_2, S_3, etc. are velocity-time products representing constantly applied centrifugal force; i.e., lines 1–5 and 1′–5′ are *lines of equal influence*. If the velocities thus obtained are not correct for the requirements of condition (*b*) we may reduce the velocity on any flow line, provided we increase the corresponding time element. This is the same thing as increasing the angular displacement of a point on any flow line, or again, as increasing the length of vane without changing the position of the influencing line. The sum of the spaces S_1–S_5 to S_1'–S_5', etc. measured along each flow line, determines the relative length of vane in radial profile. If the time taken for each particle to pass through the impeller is the same, each flow line will have the same constant angular displacement. However, since $S = V_R \times t = V_R \times \omega$, the radial velocity may be altered to suit condition (*b*), provided the angular displacement ω is altered in the inverse ratio.

Condition (*b*) requires that each point on a transverse section of the vane at the same angular displacement from the end of the vane, shall have a vane angle whose tangent is the ratio of the velocity at maximum capacity to the peripheral velocity of the point. The fact that the total-energy Equation [3] is a linear function at all capacities establishes the stability of the forced vortex at all capacities provided the variation of angle at all points of equal angular displacement is such that the tangent is proportional to $V_{\max}/R$, where $V_{\max}$ is constant and R variable. This is fully explained by Joseph Lichtenstein in Trans. A.S.M.E., paper HYD-50-3, 1928, pages 2 and 3.

The vane angles and the relative variation of V_R having been determined to meet condition (*b*), the relative angular displacement of points 1–5 on each influence line can be calculated, and the influence lines combined with the value of ω may be used as construction lines for the designing of the vane by a method of graphical integration. But now the influence lines are no longer meridional sections and the assumptions made have been modified to the dynamic equivalent by altering the values of time t or angular displacement ω inversely to the ratio: Value of V_R according to (*b*) to its value under the original assumptions.

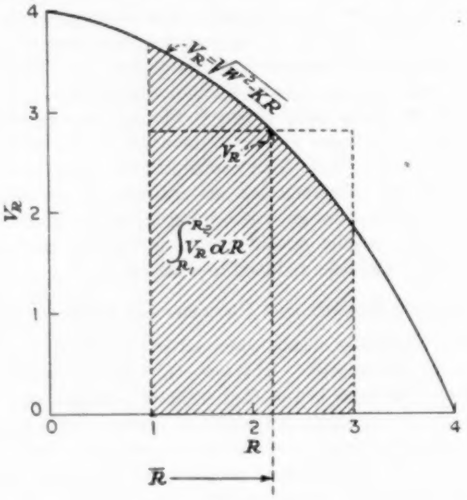

FIG. 10

The significance of Equation [5] can be realized best by manipulation of one or two particular designs. In plotting influence lines on the profile view of the impeller, the space between them will vary similarly to the ordinates in Fig. 10 between the range of values of R occurring on the influence line.

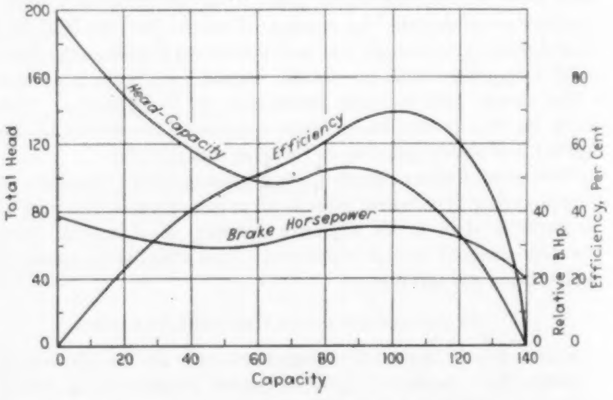

FIG. 11 CHARACTERISTIC SHOWING FAULTY DESIGN

Note that if for any point in an influence line the calculated value of KR becomes equal to W^2, V_R will become equal to 0, and there will be no flow. Also if KR is greater than W^2, V_R will be a function of $\sqrt{-1}$, which is an imaginary quantity. Manipulation of Equation [5] will show that imaginary values of V_R can be reached at one point in an influence line provided the average radial velocity is very low compared to the value of W and K, or provided the value of K is high for the ratio of values of R along the same influence line.

When zero or imaginary values of V_R are reached by calculation, the design should be changed to employ higher average values of V_R or lower values of C, at least in the early stages of the vane. Calculations with these new values will establish C_R as positive and real at some new average value of C_R and K. For this reason Equation [5] is valuable in the designing of new types because its manipulation provides a means of detecting such faulty design as too low radial velocity, too high acceleration, or too much variation in the range of R values along one influence line. The characteristic shown in Fig. 11 is an example of faulty design of this kind where zero and imaginary values of V_R follow from Equation [5]. Curves shown in Figs. 6 and 12 are examples of the absence of such faults.

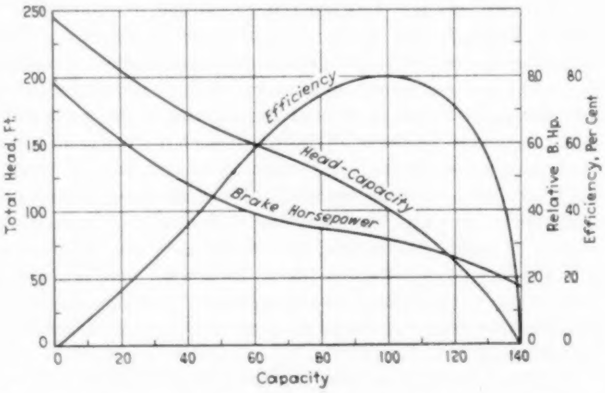

FIG. 12 CHARACTERISTIC SHOWING ABSENCE OF FAULTS FOUND IN FIG. 11

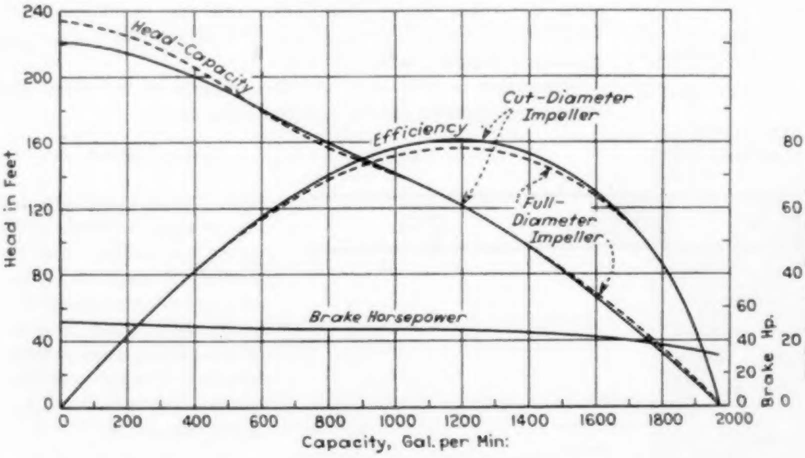

FIG. 13 SHOWING PRACTICAL USEFULNESS OF INFLUENCE LINES PLOTTED FROM EQUATION [5]

The curve shown in Fig. 13 provides an interesting example of the practical usefulness of influence lines plotted from Equation [5]. An impeller such as that as shown in Fig. 8 was tested with a certain discharge edge. Part of this discharge edge was then cut off, as shown at R, Fig. 8, so as to conform with the length of vane indicated by the influence lines. The new discharge edge, although resulting in a smaller average impeller diameter, gave exactly the same head capacity under test, but with a higher efficiency, thus pointing to the value of these influence lines in determining the relative lengths of vane for all flow lines so that all parallel units of impeller volume shall pump uniformly. For this purpose the correct values of ω for each point on an influence line must be determined in order to satisfy condition (*b*), as previously pointed out. The use of such a routine in pump design may appear rather laborious, but it is well worth while in the development of new types because the laws of dynamic similitude make each new type available for wide, general application. A designer can develop a fixed rule for tabulating values according to Equation [5] step by step with the graphical method required for constructing the vane layout. This involves little extra labor and tends toward more reliable design. It is worth recalling that impellers in which unit volumes are separated by internal metal partitions have been most inefficient. The proper balance of vane angularity and length of vane is the better method for efficiency and stability of characteristic. The influence of vane length is such that if ideal variation of angularity in the vane results in less head being developed by one unit of volume than in another, then increased length of vane will enable the fluid to be acted on for a greater length of time in accordance with the influence lines, calculated to fulfil condition (*a*) and values of ω calculated to fulfil condition (*b*).

CONCLUSION

The general discussion of stability and equalization of vortex in Section III includes no considerations which have not been applied repeatedly in actual practice. The careful application of these principles, when made part of the general routine of design according to an established system of procedure, has resulted in a certain reliability of attainment. The variations referred to in Section I are of course included also in the mixed-flow impellers discussed in Section III, where the object in view was regarded as the equalization of vortex effects in parallel units of volume for a uniform integral effect.

With reference to the distribution of flow in curved channels, the coefficient of distribution for mean energy value, viz.,

$$\frac{\dfrac{R_1^2 + R_2^2}{2}}{\left(\dfrac{R_1 + R_2}{2}\right)^2} = (1 + \rho)$$

is somewhat different from that which would result from Isaachen's formula for velocity distribution in elbows, but apparently it has the advantage of agreeing better with field observations of bends in large rivers. If, as Isaachen claims, $V \times R$ = a constant = C, then the mean value of V^2 is

$$\int_{R_1}^{R_2} \frac{V^2 dR}{R_2 - R_1} = \frac{\dfrac{C^2\,(R_2 - R_1)}{R_2 R_1}}{R_2 - R_1} = \frac{C^2}{R_2 R_1}$$

and the mean value of V is $= \int_{R_1}^{R_2} \frac{V dR}{R_2 - R_1}$

$$\frac{\int_{R_1}^{2} V dR}{R_2 - R_1} = \frac{\int_{R_1}^{R_2} C \times \frac{1}{R}\, dR}{R_2 - R_1} = \frac{C\,[\log R_2 - \log R_1]}{R_2 - R_1}$$

$$= \frac{C \log \dfrac{R_2}{R_1}}{R_2 - R_1}$$

Therefore the coefficient of distribution for mean energy value would be:

$$\frac{\dfrac{\left(C \log \dfrac{R_2}{R_1}\right)^2}{(R_2 - R_1)^2}}{\dfrac{C_2}{R_2 \times R_1}} = \frac{R_2R_1\left(C \log \dfrac{R_2}{R_1}\right)^2}{C^2\,(R_2 - R_1)^2}$$

This gives slightly lower computed values of the coefficient.

Discussion

B. M. Woods[2] and M. P. O'Brien.[3] The paper serves as a reminder of the fact that the elementary theory of centrifugal pumps and reaction turbines, developed by Euler for an infinite number of blades, leads to an absurdity when applied in the usual manner to a runner having a finite number of blades. The pressure is assumed to be uniform over areas concentric with the axis of rotation, and under this condition it is evidently impossible that a torque can be exerted on the fluid or that any energy can be transmitted to it. Even in the hypothetical case of frictionless flow, the elementary theory, as explained in most texts, is mechanically unsound and needs to be corrected in such a manner as to give a pressure difference between the two sides of the blades. The torque equation, $T = \left(\frac{Q\gamma}{g}\, r_2C_2 - r_1C_1\right)$ and the head equation, $H = \frac{1}{g}\,(U_2C_2 - U_1C_1)$, are applicable, provided that a means of predicting the actual mean value of C can be devised. In other words, the flow does not follow the blade angle at discharge, and the necessity for such a deviation can be shown from elementary considerations of torque and power, but this discrepancy in fundamental conceptions has not been given much consideration in the American literature on the subject. As the German hydraulic engineers have made some notable contributions to the solution of this problem, it may be of interest to present a brief outline of their method of attack.

The lift of an airfoil presents approximately the same difficulty as the torque of a centrifugal pump, in that the theoretical pressure distribution, obtained from Bernoulli's equation on the assumption of purely translatory motion, gives no resultant thrust in any direction and consequently no lift. As the lift was not to be denied, it was necessary that a theory be developed which would agree with observation, and Professor Prandtl, of Göttingen, brought forward the conception of a circulatory motion superimposed upon that of pure translation. This circulation is assumed to be in such a direction that the velocities due to the two component motions are additive above the airfoil and subtractive below it, thus giving a pressure difference sufficient to account for the lift. However, such a circulation could not arise in a frictionless liquid originally at rest, and the theory was expanded to include the effect of viscous forces, which are negligible everywhere in the fluid except in the immediate vicinity of solid boundaries. The elaboration and application of this theory by von Kármán, Betz, Joukowsky, and others has resulted in an agreement between theory and experiment in aerodynamics which is absent in most of the other branches of fluid mechanics.

In 1918 Kucharski[4] applied the circulation theory to the frictionless flow in a pump impeller having a finite number of radial blades extending to the axis of rotation, and his success in solving this idealized problem mathematically paved the way for a more elaborate treatment by Spannhake[5] and the development by Pfleiderer[6] of a simple method of predicting the effect of a finite number of runner blades.

Circulation is defined as the line integral of the tangential velocity component around a closed path, or

$$\Gamma = \int W \cos \alpha \, ds$$

where Γ is the circulation and α is the angle between the direction of motion and the element of path ds. Considering two-dimensional flow symmetrical about a point, and computing the circulation around a circular path concentric with this point of symmetry, we obtain

$$W \cos \alpha = C = \text{constant}$$

and

$$\int C ds = 2\pi r C = \Gamma$$

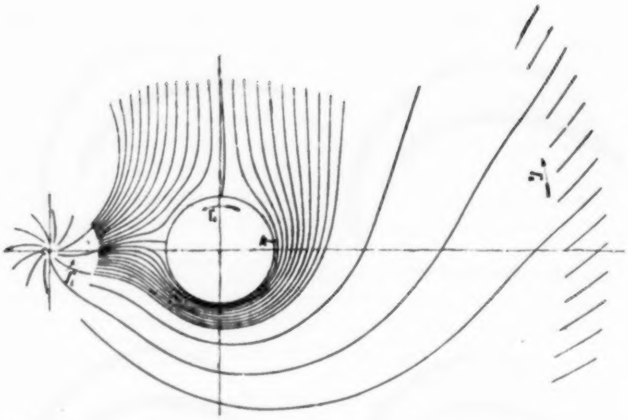

FIG. 15 RADIAL AND ROTATIONAL FLOW AROUND A CYLINDER (AFTER SPANNHAKE)

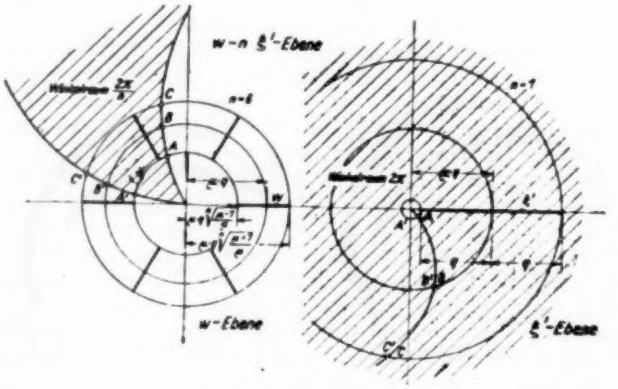

FIG. 16 TRANSFORMATION OF FLOW IN FIG. 15 INTO *n* SEGMENTS (SPANNHAKE)

(*Winkelraum* = angular area; *Ebene* = plane.)

Using this relation, the torque equation becomes

$$T = \frac{Q\gamma}{2\pi g}\,[\Gamma_i - \Gamma_a]$$

Referring to Fig. 14, these circulations are composed of a number of elements contributed by the circulation around the individual blades, and since the circulation is to be computed in the same sense for each blade, the components along the radial lines will cancel, giving

$$\eta\Gamma_s = \Gamma_i - \Gamma_a$$

where η is the number of blades and Γ_s is the circulation about each blade. The circulation around the blades is therefore related to the torque, head, and power. The theory really involves no new principles, since we have merely replaced $(r_2u_2 - r_1u_1)$ by the term $\frac{\eta\Gamma_s}{2\pi}$, but the changed conception is important, since it provides a connection with the aerodynamical theory. Fig. 15 shows a combination of radial and circulatory flow from a central source past a cylinder, about which the circulation is Γ_s. The circulation along any closed path surrounding the source alone is Γ_i, while that along a path including both source and cylinder is Γ_a, and the change Γ_s is a measure of the torque exerted by the cylinder on the fluid.

From the equations describing the flow in Fig. 15, Spannhake obtained the flow pattern around the radial blades in Fig. 16 by conformal transformation which made the sector $\therefore \frac{2\pi}{\eta}$ represent the entire plane of Fig. 15. By comparing the product (ηC) obtained by this method for η blades with the same quantity for an infinite number of blades, the correction for the elementary theory is obtained. In view of the high degree of turbulence in centrifugal pumps, this rather complicated treatment may appear unwarranted, but it should be remembered that a torque *is* developed and must be explained. The corrections obtained are in the right direction and of about the proper magnitude, so that the method appears to be worthy of consideration.

From a less rigorous analysis, but with practically the same assumptions, Pfleiderer has developed a method of correcting for the effect of a finite number of runner blades. His equation is

$$H_w = H\left(1 + \frac{\psi}{\eta}\,\frac{r_2^2}{S}\right)$$

where H_w is the head for the same quantity and speed computed by Equation [2] (Equation [3], page 3, original paper), H the actual head developed, r_2 the discharge radius, η the number of blades, S the statical moment of the center line of the runner passage about the axis of rotation, and ψ a coefficient depending on the blade angle at discharge. Pfleiderer gives the value of ψ as lying between 0.8 and 1.0 for pumps with diffuser vanes. Using this equation and correcting H for friction and impact loss, the head-capacity curve for a small modern centrifugal pump was constructed and the results were compared with data obtained in the laboratory at the University of California. The two curves intersected near the point of best efficiency, and the divergence was small through the entire operating range. Pfleiderer's method is an example of the practical results which often follow rigorous mathematical treatment.

A notable contribution to the experimental data on centrifugal-pump performance has been made recently by the Technische Hochschule at Munich, where the flow in a pump has been

Fig. 18 Dead-Water Spaces in Centrifugal-Pump Impellers (After K. Fischer)

observed under approximately operating conditions.[7] The impeller was fitted with a glass side and the seal was made at the outer periphery, so that the location of dead-water spaces could be discovered by injecting colored liquid. Direct observations were made with a rotoscope, while photographs were obtained with a camera revolving with the pump. Fig. 17 shows one of the photographs obtained, while Fig. 18 shows a series of diagrams of the dead-water spaces. What makes these experiments of considerable interest is that the impeller passages were never found to be completely filled with active fluid.

We are indebted to the author for the interesting questions raised concerning the circulation theory and for illuminating comments. It is somewhat to be regretted that his treatment is not more definite in certain particulars.

Boris A. Bakhmeteff.[8] The author touches on many subjects of great interest. This discussion deals with only one point, which appears to be the most important in the paper—namely, the taking into account of the unequal distribution of velocities when calculating the mean energy of flow, and of applying, "when converting mean velocity into its equivalent of mean energy," a special correcting coefficient which the author calls the "coefficient of local distribution."

The question is of basic character in hydraulics, and the profession should be thankful for bringing it forward, especially as it seems that considerable misunderstanding prevails regarding the very fundamentals of the case. It should be understood, therefore, that this discussion is offered solely with the purpose of elucidating the matter.

The case brought forward by the author, and which so often has been neglected, dates back to a celebrated "Memoire" by Coriolis of nearly a hundred years ago,[9] in which the great savant, of "acceleration" fame, first laid down the reasoning regarding energy in fluid motion, which since has been the cornerstone of hydraulics and has passed from textbook to textbook in establishing the so-called Bernoulli equation.

Among other features, Coriolis pointed out that the mean kinetic energy carried by a stream (Fig. 19), in which the individual velocities v differ, is greater than the kinetic energy corresponding to the mean velocity v_m obtained by dividing the discharge Q by the cross-sectional area a. Coriolis in this connection suggested introducing a certain correcting coefficient α_k into the relation:

$$\text{Mean kinetic energy head} = \alpha_k \frac{v_m^2}{2g} \dots\dots\dots [7]$$

which coefficient α_k fulfils a purpose analogous to that of the author's "coefficient of local distribution."

To determine the value of α_k, first assume that the whole liquid in Fig. 19 flows with the mean velocity v_m. In this case the total energy carried by the fluid passing through the cross-section a per unit of time, would be

$$\gamma Q \frac{v_m^2}{2g} = \frac{\gamma}{g} a \frac{v_m^3}{2} \dots\dots\dots\dots\dots\dots [8]$$

where γ is the weight of the liquid per unit volume, while g is the acceleration of gravity.

In actual flow one will have to calculate the kinetic energy carried by each separate filament, and then obtain the total energy carried by the stream, by summing up the energies of the individual streamlines. In figuring the kinetic energy carried by a filament passing through an element of the cross-section da (shaded area in Fig. 19), the element of flux across da will be $dq = da\, v$, where v is the particular velocity corresponding to the cross-section point, and the elementary kinetic energy is

$$\frac{\gamma}{g} dq \frac{v^2}{2} = \frac{\gamma}{g} da \frac{v^3}{2} \dots\dots\dots\dots\dots\dots [9]$$

The total kinetic energy carried by the stream per unit of time is obviously

$$\frac{\gamma}{g} \int_a \frac{v^3}{2} da \dots\dots\dots\dots\dots\dots\dots [10]$$

where the value of the integral is taken over the whole cross-sectional area.

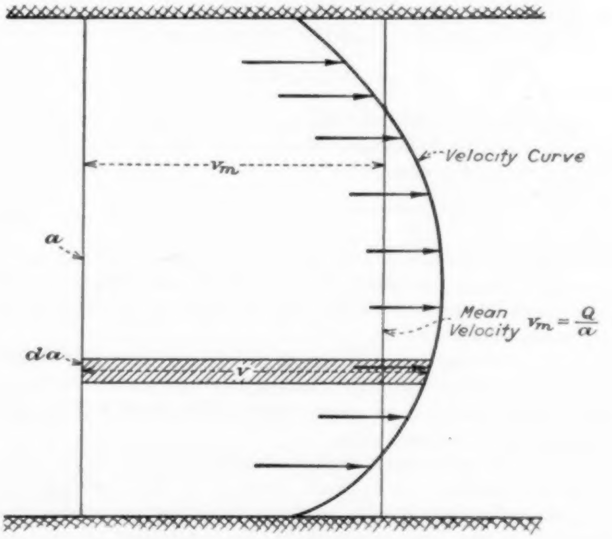

Fig. 19

To evaluate the correction coefficient, which is to express the total energy in terms of the energy head corresponding to the mean velocity v_m, we put

$$\alpha_k \frac{\gamma}{g} a \frac{v_m^3}{2} = \frac{\gamma}{g} \int_a \frac{v^3}{2} da \dots\dots\dots\dots\dots [11]$$

from which

$$\alpha_k = \frac{\int_a v^3 da}{v_m^3 a} \dots\dots\dots\dots\dots\dots\dots [12]$$

In other words, the correction coefficient α_k is the ratio of the mean value of the *cube* of the individual velocities to the *cube* of the average velocity, and in the author's notations should be expressed as

$$\frac{\Sigma(v^3/N)}{(\text{average } v)^3}$$

instead of being the ratio of the mean *square*, as is suggested in the paper. The coefficient α_k depends on the mean *cube* and not on the mean *square*, for the reason that kinetic energy is the product of one-half of the velocity square by the mass flux, and mass flux in its turn is proportional to the velocity. It should, however, be mentioned in this connection that the misapprehension indicated above and which figures in the paper, is quite widespread and is to be found at times in textbooks of recognized standing.

[7] K. Fischer, "Untersuchung der Strömung in einer Zentrifugal-Pumpe," Mitteilungen des Hyd. Inst. der Technische Hochschule, Munich, 1931.

[8] Professor, Columbia University, New York, N. Y. Mem. A.S.M.E.

[9] *Annales des Ponts et Chaussées*, 1836.

As shown by Coriolis, the coefficient

$$\alpha_m = \frac{\int_a v^2 da}{v_m{}^2 a}$$

obtained from calculating the mean square of the velocities, and which is the coefficient used by the author,

$$(1 + \rho) = \frac{\Sigma(v^2/N)}{(\text{average } v)^2} \dots\dots\dots\dots [13]$$

is a correction coefficient to be used when evaluating the actual momentum of flow

$$\alpha_m \frac{\gamma}{g} Qv_m = \alpha_m \frac{\gamma}{g} av_m{}^2 \dots\dots\dots\dots [14]$$

in terms of the momentum corresponding to the mean velocity.

Both α_m and α_k are > 1, so that one may put

$$\alpha_k = 1 + \delta, \text{ and } \alpha_m = 1 + \rho \dots\dots\dots [15]$$

Coriolis further showed that, in many practical cases, and in general when the individual velocities v do not deviate substantially from v_m, the relation between δ and ρ in [15] is close to

$$\delta = 3\rho \dots\dots\dots\dots\dots\dots [16]$$

meaning that the size of δ in the real correction coefficient $\alpha_k = 1 + \delta$, which is to be used in figuring out the mean kinetic energy head, is about three times the value of ρ in $(1 + \rho)$, obtained by the mean-square formula.

The author on many occasions points out that the results obtained from the use of the mean-square formula are far below the values derived from observations. The above will explain the source of the discrepancy.

As a matter of record it might be interesting to recall that the Coriolis treatment, as outlined, is more or less customary in French hydraulic manuals, particularly of the more advanced class.[10] In fact, one often finds the line expressing the average energy head in the so-called Bernoulli equation presented in the form

$$z + \frac{p}{\gamma} + \alpha_k \frac{v_m{}^2}{2g}$$

The value of α_k naturally depends on the circumstances of the case. As an average characteristic for uniform flow in open channels one often encounters the figure $\alpha_k = 1.1$, which was obtained on the basis of Bazin's experiments on the flow of water in canals.

Another point, to which the writer wishes to draw attention, is a matter of terminology. The term "coefficient of local distribution," suggested by the author, is most appropriate. On the other hand, equally unfortunate is the term "coefficient of turbulence." In fact, the word "turbulence," since the days of Osborne Reynolds, has been used to differentiate the so-called *laminar* or steady streamline motion, from the sinuous and eddying molecular movement which characterizes the unsteady flow of viscous fluid above the so-called critical velocity. Within the last decade or so the phenomenon of turbulence has been the object of repeated and preferred studies, and the meaning of the word in the Reynolds sense has been universally and internationally adopted. It would seem, therefore, that to apply the term in any other sense would be misleading.

The problem of expressing mean kinetic energy in terms of mean velocity by proper correction coefficients is of substantial importance. So the writer would like to further clarify the matter by some concrete examples.

1 We shall consider first the hypothetical case of linear distribution of velocities (Fig. 20), the velocity curve in a cross-section of the width d being a straight line ac. For simplicity, we shall further assume the movement to be two-dimensional, with a depth of flow in the direction perpendicular to the plane of the drawing equal to unity. We shall designate the relation of the minimum velocity v_c to the maximum v_a by

$$v_c/v_a = \beta \dots\dots\dots\dots\dots\dots [17]$$

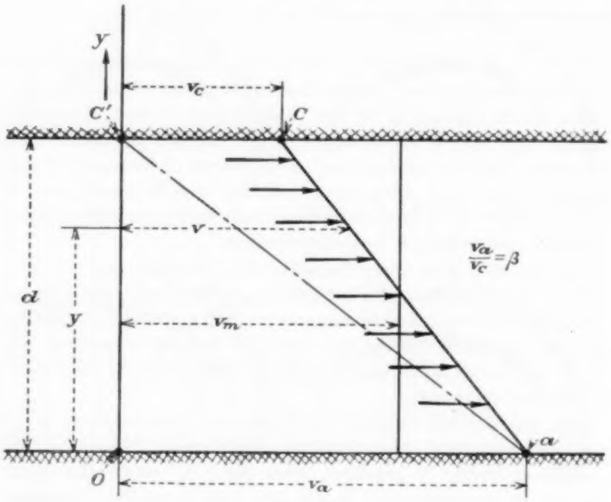

FIG. 20

With this the average velocity is

$$v_m = \frac{v_a + v_c}{2} = \frac{v_a}{2}(1 + \beta)$$

The velocity v at the distance y from o

$$v = v_a\left(1 - \frac{y}{d}(1 - \beta)\right)$$

and the correction coefficient

$$\alpha_k = \frac{\int_0^d v_a{}^3\left[1 - \frac{y}{d}(1 - \beta)\right]^3 dy}{v_m{}^3 d}$$

Carrying out the elementary integration, we obtain

$$\alpha_k = 2\frac{(1 + \beta + \beta^2 + \beta^3)}{(1 + \beta)^3} \dots\dots\dots\dots [18]$$

and in a similar manner

$$\alpha_m = \frac{\int_0^d v^2 dy}{v_m{}^2 d} = \frac{4}{3} \cdot \frac{1 + \beta + \beta^2}{(1 + \beta)^2} \dots\dots\dots [19]$$

The following table shows the values of α_k and α_m depending on β:

β	$\alpha_k = 1 + \delta$	$\alpha_m = 1 + \rho$
0	2.00	1.333
0.5	1.10	1.035
1.0	1.00	1.000

---

[10] Bresse, Boussinesq, Flamant, etc. See also Forchheimer's "Hydraulik."

The practical value of this rather hypothetical case is in the following. Consider flow with a velocity curve, as given in Fig. 21, with v_a and v_c the maximum and the minimum velocities in the center and at the borders. Obviously, no matter what is the form of curve, the triangle *cac′* will give a higher value of the correction coefficients α_k and α_m than the actual curve passing through the same points. Therefore, for any velocity curve lying outside the triangle, the values of α_k and α_m derived from [18] and [19] will be in excess of the actual value. Under such circumstances relations [18] and [19] can be used advantageously for control.

This is particularly important when one notices from the foregoing table that, even for rather extreme conditions, characterized by $\beta = 0.5$, the correction coefficient is relatively small. In other words, the difference between the mean cube and the cube of the mean velocity is oftentimes not very substantial, and the mistake incurred in ignoring the correction to be made may not be very great. The greatest value of α_k corresponding to $\beta = 0$, and featured in Fig. 20 by the broken line *ac′* is $\alpha_k = 2$.

2 The other practical case will be that of flow in concentric circular paths (Fig. 22), under the assumption that the distribution of velocities follows the law

$$vR = \text{const.} \qquad [20]$$

The author refers to it as the Isaachen formula for velocity distribution in elbows. As a matter of fact, relation [20] is one of the most general laws of fluid mechanics, featuring the so-called potential or irrotational movement of ideal fluid in concentric paths.

One often meets with the tendency on the part of the engineer to discard any notions suggested by hydrodynamics of ideal fluids. And it is very true that in so many cases the movement of frictionless liquids has little in common with the flow of actual viscous fluids. On the other hand, as amply demonstrated by the recent developments of aerodynamics and those of the more advanced analysis of hydraulic machinery, there are many cases where the teachings of so-called classical hydrodynamics may be of considerable assistance; particularly when, as in the present case, one bears in mind the concrete physical premises which underlie the term of irrotational or potential flow. Most important for the engineer is the fact that the fundamental physical premise of potential or irrotational flow is movement with an equal distribution of energy throughout the moving fluid as a whole.

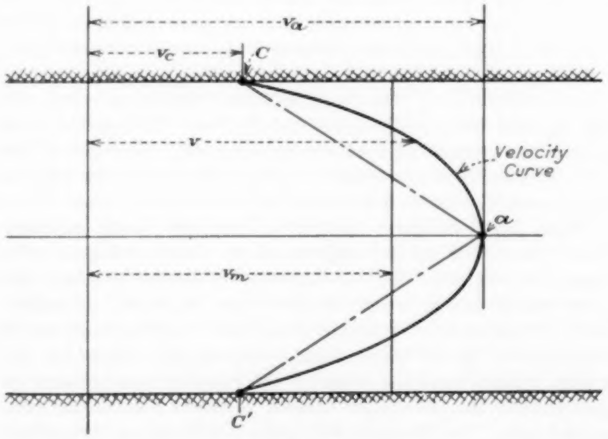

FIG. 21

To illustrate, assume (Fig. 22) that fluid is flowing out of a large container *A*, where it was previously at rest. Now each particle in the container obviously is possessed by the same quantity of energy. Since $v = 0$, this energy, measured per unit weight, is the potential energy head $z + \frac{P}{\gamma} = H$. By disregarding the insignificant losses which occur over the short stretch between the container and the elbow, it is correct to assume that in the movement through the elbow the individual particles will continue to carry approximately the same amount of energy.

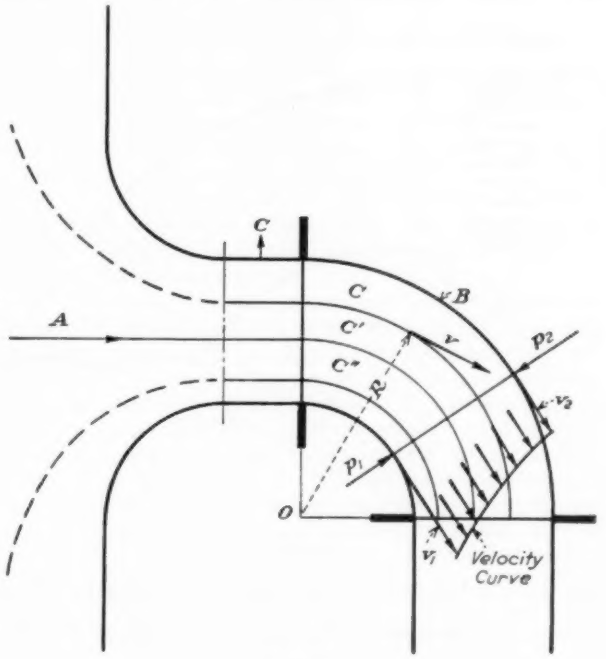

FIG. 22

In other words, the line of the Bernoulli equation

$$z + \frac{P}{\gamma} + \frac{v^2}{2g} = \text{const.}$$

will apply to each and every particle, so that for any particle *c*, *c′*, or *c″*, the relation between velocity and pressure will be

$$z + \frac{P}{\gamma} + \frac{v^2}{2g} = H \qquad [21]$$

As shown in hydrodynamics, equal distribution of energy (Equation [21]) in concentric flow translates itself into the kinematic condition $vR = \text{const.}$

Obviously [20] may be used in conjunction with [21] to establish a complete picture of the distribution of velocities and pressures over a cross-section. To make things still more concrete, may it also be recalled that the reduction of velocity toward the outer points in accordance with Equation [20] and the corresponding increase of pressure from P_1 to P_2 counterbalance the effect of the centrifugal forces acting normally to the concentric paths.

To find now the values of α_k and α_m, assume once more, as in the preceding, the flow to be two-dimensional. A discharge q flows through the rectilinear part *C* (Fig. 23) with a uniform velocity $v_m = \frac{Q}{d}$.

The curvilinear part has the outer and inner radii R_2 and R_1 and the width $d = R_2 - R_1$.

The geometric configuration is fully characterized by the mean radius $R_0 = \dfrac{R_1 + R_2}{2}$ and the relative width of the channel

$$\frac{d}{R_0} = 2\,\frac{R_2 - R_1}{R_2 + R_1} = \beta \ldots\ldots\ldots\ldots\ldots [22]$$

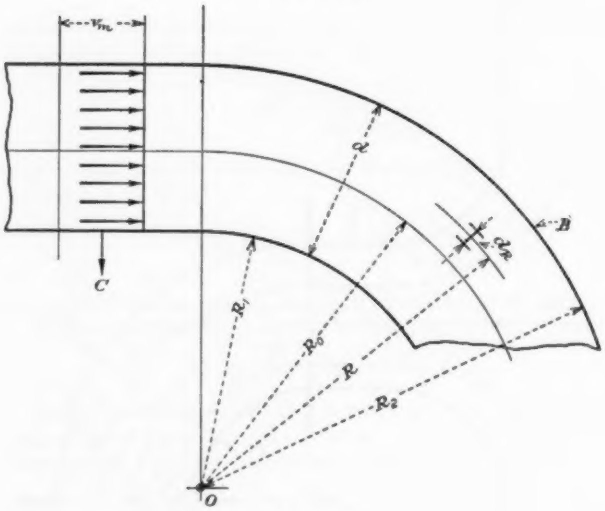

FIG. 23

Designating in Equation [20] the value of the constant by C, so that $v = \dfrac{C}{R}$, the elementary discharge across an element dR, with a radius R, is

$$dq = v\,dR = C\,\frac{dR}{R}$$

Hence the total discharge

$$Q = v_m(R_2 - R_1) = \int_{R_1}^{R_2} v dR = C\int_{R_1}^{R_2}\frac{dR}{R} = C\log_e\left(\frac{R_2}{R_1}\right)$$

and the value of the constant C in terms of the other elements of flow

$$C = \frac{v_m(R_2 - R_1)}{\log_e(R_2/R_1)} = \frac{Q}{\log_e(R_2/R_1)} \ldots\ldots\ldots\ldots [23]$$

To find α_k we have

$$\alpha_k = \frac{\int_{R_1}^{R_2} v^3 dR}{v_m{}^3(R_2 - R_1)} = \frac{C^3\int_{R_1}^{R_2}\frac{dR}{R^3}}{\left[\frac{C^3(\log_e(R_2/R_1))^3}{(R_2 - R_1)^3}\right]}$$
$$= \frac{(R_2 - R_1)^3(R_2 + R_1)}{2(R_1\,R_2)^2(\log_e(R_2/R_1))^3}$$

And by similar procedure

$$\alpha_m = \frac{\int_{R_1}^{R_2} v^3 dR}{v_m{}^2(R_2 - R_1)} = \frac{(R_2 - R_1)^2}{R_1R_2\left(\log_e\left(\frac{R_2}{R_1}\right)\right)^2}$$

Introducing

$$\beta = d/R_0 \text{ and } R_0 = \frac{R_1 + R_2}{2}$$

we obtain finally

$$\left.\begin{aligned} \alpha_k &= \frac{\beta^3}{\left(1 - \frac{\beta^2}{4}\right)^2\left(\log_e\left(\frac{2+\beta}{2-\beta}\right)\right)^3} \\ \alpha_m &= \frac{\beta^2}{\left(1 - \frac{\beta^2}{4}\right)\left(\log_e\left(\frac{2+\beta}{2-\beta}\right)\right)^2} \end{aligned}\right\} \ldots\ldots\ldots [24]$$

As is seen, the correction coefficients depend solely on the value of the relative width $\beta = d/R$.

The following table gives some figures permitting a concrete appreciation of the effect of curvature on the values of the correction coefficients:

β		α_k	α_m	$\left(1 + \frac{\beta^2}{4}\right)$
1.00	....	1.34	1.105	1.250
0.50	....	1.06	1.020	1.060
0.10	....	1.005	.....	1.002

Again it is clear that the correction coefficient assumes substantial values only when the curvature is extreme. The figures in the last column correspond to the author's coefficient

$$(1 + \rho) = \frac{\left(\frac{R_1{}^2 + R_2{}^2}{2}\right)}{\left(\frac{R_1 + R_2}{2}\right)^2} \ldots\ldots\ldots\ldots\ldots [25]$$

which, as he suggests, is derived from empirical observations. It is easily seen that the value of his coefficient is

$$\frac{1}{2}\,\frac{R_1{}^2 + R_2{}^2}{\left(\frac{R_1 + R_2}{2}\right)^2} = \frac{1}{2}\,\frac{R_0{}^2(1 + \beta/2)^2 + R_0{}^2(1 - \beta/2)^2}{R_0{}^2} = \left(1 + \frac{\beta^2}{4}\right)$$

It is seen further that the actual correction coefficients α_k resulting from figuring the mean cube are somewhat in excess of [25], although for medium values of β they practically coincide.

F. G. SWITZER.[11] The paper is full of interesting points. It has already been pointed out by Professor Bakhmeteff that kinetic energy must be obtained by integrating the cubes of the velocity instead of the squares. This point should be emphasized again, because it is a mistake quite frequently made.

While pump designers have for a long time made empirical corrections to the velocity diagram for exit from the impeller of a pump, we find here a method suggested for determining how this correction should be made. At best, this can be only an indication. It assumes, as we always have, that all of the water leaves the impeller at the same angle. Experiments made by the writer indicate that the angle of the relative velocity may be greater than the vane angle, instead of less as has usually been agreed upon. Furthermore, this angle is different at the shrouds and at the center of the impeller.

In Fig. 4 of this paper are shown radii of the vane and radii of the impeller using the same symbols. Does this mean that the vane radii and runner radii are the same? This hardly agrees with usual practice.

Non-uniform flow between runner blades has been noted in pumps of much lower specific speed than the mixed-flow runner of Fig. 8. In fact, there may be such differences as to cause water to flow out of the eye of the impeller, even in a pump of better than average efficiency. In such a case, changes in the suction passages may prove beneficial. It is not always the impeller that is to blame for this. In some pumps it has been found that the flow through any one passage between vanes may vary as the impeller rotates, being greater than average during part of one revolution and less during another part of the revolution. At first glance this may appear to be due to unequal pressures in the volute. However, tests show that radical changes in the volute which cause radical changes in pressure distribution do not show corresponding changes in this pulsation of flow. More can be done to improve this difficulty by changes in the suction passages. While measurements have not been made, it seems probable that variations in pressure around the eye of the impeller are of more significance than variations of pressure around the volute.

[11] Professor of Hydraulic Engineering at Cornell University, Ithaca, N. Y., and Consulting Engineer for Goulds Pumps, Inc.

O. G. Tietjens.[12] Generally speaking, one may say that the theoretical treatment of centrifugal pumps and blowers is based on the assumption that the medium (it may be water or air) is sufficiently guided by the impeller blades, since these blades usually are closely spaced. The well-known formulas [2] and [3] of the paper are based on this assumption also. The general idea is that the direction of the flowing water between the single blades is entirely determined by the shape of the blades, and it is assumed that the flow lines within the blades of a certain impeller would be the same if the number of blades were indefinitely increased with decreasing thickness of the blades. The pump with an infinitely large number of blades of zero thickness is the conception on which the simple flow-line theory of centrifugal pumps is based. The viscosity of the water, of course, is neglected in this theory, as it is also done in Equations [2] and [3] of the paper.

Fortunately, this comparatively simple method can be used as a good approximation even for pumps of a rather small number of blades, say eight blades. Although in this case the flow lines within the impeller are by no means similar to each other, the performance of the pump in general is fairly well described by the flow-line theory.

However, if we want detail information—if we want to know, for instance, in what manner the performance of a pump depends on the number of the blades or on the ratio of the inlet and outlet radii of the impeller, or if we want to know the actual shape of the flow lines within the impeller, etc.—then the simple flow-line theory proves to be insufficient. In this case another theory can be used which, however, is considerably more complicated. This theory was developed first in connection with the design of airplane propellers and later applied to Kaplan pumps, and recently[13] it has been applied also to centrifugal pumps.

The author does not follow the simple flow-line method in those parts of his paper where he leaves the ground of well-known data, and he also does not follow the more modern hydrodynamic theory mentioned. This is by no means a fault. However, the author introduces such a large number of new conceptions without defining them that it is very often impossible to follow him. For example, these ambiguities raised the following questions in the writer's mind: What is the difference between a forced vortex and a free vortex? What is meant by a stable vortex, and what is meant by an unstable vortex? What are the laws of a free vortex mentioned at the top of the third page? What is meant on the same page by saying that the influence of the vanes for creating a perfect vortex is only local? What is the significance of the following sentence at the top of the fifth page: "An impeller of this kind may function as a series of parallel vortices, the characteristics of which are determined by the action of the vane on each particle of the fluid, and each particle of the fluid is influenced in addition by the integral effect of all other particles." What, specifically, are the characteristics of parallel vortices? The well-known treatises on "Vortex Motion" by W. Thomson or by Helmholtz, for instance, do not help one to understand the behavior and the laws of the vortices dealt with in the paper. In developing a new theory, it is absolutely necessary to have a clear picture of the physical meaning of newly introduced conceptions, and it is also necessary to define these conceptions and so make it possible for the reader to comprehend their significance.

The writer is sorry that this lack of clearness makes it impossible for him to discuss the paper in detail. The pumps may be well built, though the theory given in the paper does not lead to increased confidence in their design.

It may be of interest to draw attention to one point mentioned on the fifth page, under II. The author deals here with the waste energy in a centrifugal-pump impeller, and he points out that this may be caused by the flow of dissolved gases from the water. His statement, however, that deep holes were cut in the casing of a pump which accidentally ran under reversed rotation makes it evident that this erosion was caused by cavitation and not merely by dissolved gases. It is well known that under certain conditions in centrifugal pumps and also in propeller-type pumps the pressure may decrease at certain points below the water tension due to local extremely high velocities, and that the water then vaporizes. If these vapor bubbles move on their way into parts of higher pressure, they collapse, causing high local forces by which the erosion effect is produced. During recent years several investigations have been made, mostly by using high-speed moving pictures, in order to explain the mechanism of this mysterious cavitation. This work has been quite successful, and now we know under what conditions and in what manner cavitation occurs. However, considerable work must still be done to find out what the shape of the runner and of the housing must be in order to avoid local high velocities which may give rise to cavitation.

A. J. German.[14] Messrs. Stepanoff and Macmeeken are certainly to be congratulated in having gone into such extensive details on the subject of centrifugal pumps, for they have brought out in their papers the vast amount of research work carried on, resulting in a great improvement in higher efficiency in operation and economy of construction.

The discussion, so far, has been in the nature of tests, designs, and formulas. The writer is not in a position to elaborate on these questions, but would like to comment instead on personal observations made of a great number of centrifugal pumps where used to supply the circulating water for surface condensers, both in the marine and stationary field, having particular reference to where the cooling agent is sea water, brackish or badly contaminated, causing the condenser tubes to deteriorate rapidly.

Investigations reveal that the circulating pump is one of the contributory causes of short tube life, and in some cases the principal one.

Centrifugal pumps, some years ago, were of larger dimensions than they are now, and were engine driven; hence of slow speed, unquestionably causing very much less turbulence than the modern high-speed centrifugal pump. It is now generally agreed that the greater the turbulence, the more rapid the tube deterioration. Undoubtedly, the centrifugal-pump manufacturers were forced into this much higher pump speed so that the same work could be performed with a lower-priced pump; hence the statement by one of the papers, "greater economy of construction."

[14] Chief Engineer, Scovill Mfg. Co., Waterbury, Conn. Mem. A.S.M.E.

While this greater economy of construction is unquestionably a fact when limited to the pump, it seems with the overall efficiency, including tube life, this economy of first cost of pump disappears.

Nearly duplicate installations in some plants have come to attention where the quantity of steam to be condensed was identical, turbine and condenser the same size, but one of the condensers received its cooling water from a large, slow-speed centrifugal pump, whereas the other condenser, of a later installation, was supplied with cooling water from a smaller but higher-speed pump. It was found that the tubes of the second installation began to deteriorate before any tube replacements were necessary on the first installation, undoubtedly caused by the fact that the water of the second condenser entered the tubes in a considerably more turbulent condition than that of the other. It seems that a better overall efficiency would be had by sacrificing, if found necessary, somewhat on first cost of pump and pump efficiency if this would bring about considerably less turbulent circulating water.

Occasionally we are told that some years ago condenser tubes were of superior quality than they are today, for they used to last for years, and that in some modern installations they give shorter life. One of the causes is that circulating water is now passing through the tubes in increased quantity and turbulence. While condenser-tube material has not reached a point of perfection, there is no doubt that, like other advancements, the art of making condenser tubes has greatly improved.

Author's Closure

The discussion of Professors B. M. Woods and M. P. O'Brien is of value to engineers in industry, because we are indebted to the universities for bringing the latest hydrodynamic theories closer to applicability to commercial work. We have found that certain velocity distributions give excellent results in practical application.

After a general picture with the circulation theory is made possible with simplified assumptions, modifications should be introduced leading to the same velocity distribution that has been proved by actual results, and it is to be hoped that this evolution of the theory will take place at an early date.

The equations involving the modern concept of Prandtl, called "circulation," were realized as important by pump designers several years ago, because the form of the function suggests that some components of velocity should be kept constant as far as possible in the course through the impeller. The use of coefficient of distribution is also of assistance in attaining practical corrections to this end. Previously published articles in the German press showing the calculated effect of the number of vanes on a basis of calculation resulting from the "circulation" theory, are of little value in practical pump design, because the margin of error is substantial and because the best shape of vane is different for each total number of vanes. However, the conception of "circulation" is important for realizing the minimum conversion of energy for head generation.

The method of Pfleiderer, in the experience of the author, may be used reliably for calculating the performance of the impeller, provided the value of the coefficients is assumed, but the assumption of change of direction in the flow of the fluid at the impeller exit by his theory does not agree with the conditions required for minimum shock in the discharge guide vanes. This is the reason for the author's stating his method of calculation by means of two coefficients of distribution, $(1 + \rho)$ for curvature and $(1 + \alpha)$ for change of cross-section. This method explains the condition of best efficiency in the guide vanes as well as the performance of the impeller. This is more apparent still when the same impeller is used in guide-vane casings of different angularity and characteristics. The significance of this is more clearly shown in the mathematical analysis of these effects given by Professor Bakhmeteff in his discussion when he points out that these coefficients of distribution should have different values for kinetic-energy effects compared with their values for momentum effects.

The author notes the reference by Professors Woods and O'Brien to the photographic study of eddies, disturbances, and distribution of flow, and undoubtedly much could be gained by these methods. At the present time the introduction of a new feature into a design must be made so as not to interfere with established features, and the effect noted in test results. Certain new features based on theory have in this way shown marked advantage under test. Photographic study of these would show their effect on flow-line distribution and on eddy formation. The efficiency of a pump is largely a matter of energy distribution in various components, for the best results, and this is best studied by mathematical analysis and may or may not be visible by photographic means. A thorough study of pump design by photography would require the development of a new technique, but may have great possibilities for the future. However, the hydraulic efficiencies already obtained in a wide range of the most prevalent types are so incredibly high that any further improvement possible may be too small to be really appreciable. The use of the camera might make the causes of the superiority of one design more intelligible to the student, particularly in the development of types free from cavitation. Photographic study might extend the range of types for which a similar statement would be true. Photographic study has great possibilities for improving our actual knowledge of conditions for partial and over capacities.

The discussion by Professor Bakhmeteff is of very great interest and importance as a further development of the use of coefficients of distribution in the application of elementary principles of dynamics to pump design. The author notes the important step taken by Professor Bakhmeteff in his Equations [8] and [10], in which he uses the total energy per unit of time as a function of v^3, whereas the energy per unit of mass is a function of v^2. This is an important step usually lost sight of in textbooks and is of importance also in calculating the axial thrust of a propeller.

Commenting on the difference in value between Professor Bakhmeteff's coefficient compared with the corresponding value derived from the author's Equation [4], the author found it necessary to use a coefficient $(1 + \alpha)$ additional to $(1 + \rho)$ due to curvature.

It is necessary to use this additional coefficient of distribution $(1 + \alpha)$ when the area of cross-section of the channel is changing. Professor Bakhmeteff's coefficient would require a smaller value of $(1 + \alpha)$, but it is noted that for the usual range of $R_2:R_1$ the author's coefficient [4] gives very nearly the same calculated value.

The author expects to find Professor Bakhmeteff's discussion, in all its fullness, of the greatest value in the future for pump design. It furnishes an exact means of calculating what would otherwise be empirical constants. Its use by the designer will result in a more accurate evaluation of primary quantities such as coefficients of distribution both for kinetic energy and for changes of momentum, and a resulting accuracy in secondary effects, the values of which are derived from these primary considerations. His clear distinction between the equations for use with kinetic energy and those for change in momentum effects should give a better understanding of the design of volute cases and guide vanes.

Referring to Professor Bakhmeteff's criticism of the use of the work "turbulence," and the accepted application of this term since the time of Osborne Reynolds, the author has used the word (perhaps wrongly) in the sense of its derivative meaning, a "spinning top" or "whirlpool" condition, which is the essential condition of vortex flow for head generation in a pump, there being variations and inequalities in that vortex; that is, all particles do not follow coincident paths. The subject is not a common one, and the author may be excused for using his own terminology in some aspects of the discussion.

Professor Switzer's interesting comments *re* the angle at which the water leaves the impeller, are worth noting because different shapes of impellers and casings show striking dissimilarity in effects as measured by the pitot tube, in both direction and magnitude. Velocities may be made much more uniform by profile and vane shapes of a nature to tend toward uniformity of flow resulting from uniformity of dynamic effect and absence of interfering surfaces. The direction of flow of the water varies, of course, depending on whether the capacity is the peak-efficiency condition of the pump or otherwise. The effect of shrouds is in some designs very local and influences a small percentage of the total volume of fluid.

His question concerning the radii of the vane and the radii of the impeller suggests that if the vane is of involute shape the scribing radii are generally proportional to the impeller radii, so that the ratio is the same. At any rate, the performance of any impeller has been found to be not appreciably changed by a vane construction resulting from two radii r_1 and r_2, which are equal to the inlet and exit radii of the impeller, as long as continuity in all components of velocity is carefully preserved.

In full agreement with Professor Switzer, the author realizes the importance of suction design, but has found that in the case of faulty characteristic curves such as Fig. 11 (original paper), changes in the suction may magnify or minimize the defect more or less, but only changes in the impeller and discharge guide can completely remedy the defect, as tests indicate. The design of the suction approach is, of course, very important and is now well known, but the author assumed that successful suction types would always be used. The author has found that the effect of forward or backward vanes in the suction approach is generally applied to the whole characteristic curve and does not correct local disturbances, as shown in his curve, Fig. 11. It is also his experience that one suction design is better than others, and the best design should always be used.

Mr. Tietjens raises some questions about the definition of terms. Owing to the nature of the subject, dealing with considerations and viewpoints that are not common in engineering textbooks, the author has used his own notation, such terms as are not defined in pages (1) and (2) being taken in their usual denotation. The terms "forced vortex" and "free vortex" are found in the older textbooks, and may have been used loosely. In a forced vortex we have flow with a rotary component with the addition of work. In a free vortex we have flow with a rotating component without interference from solid surfaces. The term "parallel vortices" is used to denote a series of vortices side by side and discharging in parallel rather than in series. Parallel vortices may be either separated by partitions, or, if in perfect equilibrium, imaginary partitions are assumed for purpose of analysis.

Regarding Mr. Tietjens' remarks on cavitation, an interesting fact is that in pumps handling a saturated saline fluid, destruction of metal occasionally takes place only in local areas where there is no flow. At other times it takes place where velocities are highest. Some chemists and metallurgists ascribe this to differences of polarity in the fluid.

Mr. German's instructive discussion about deterioration of condenser tubes resulting from circulating pumps suggests the following thoughts. A circulating pump of the propeller type, when operating submerged in a tank, has been observed to discharge water with a large number of entrained vapor bubbles, at a total pumping head of, say, 10 ft. When this same pump was operated at a higher speed and delivering against 25 ft. head, the quantity of air bubbles was greatly reduced but still appreciable. Low- and moderate-specific-speed types of pumps under similar conditions show no such delivery of air bubbles. This air is, of course, rich in oxygen and hydrogen and is the probable cause of tube deterioration. It would be desirable to limit the specific speed of circulating pumps, particularly when sea water is used for circulating water. The reason for this is that in the higher specific speeds, even of the most efficient design, local low pressure areas (especially at partial capacities) subject to vapor formation are likely to occur.

Leakage Loss and Axial Thrust in Centrifugal Pumps

By ALEXEY J. STEPANOFF,[1] BERKELEY, CALIF.

The paper reports on experiments performed by the author at the Hydraulic Laboratory of the University of California with the equipment furnished by the Byron Jackson Company, Berkeley, Calif. Factors governing leakage loss and means to reduce leakage loss were studied. With a special pump, leakage was measured under actual operating conditions, using wearing rings of various types, width, and clearances. Tests were performed at four speeds and different heads. The results are presented in the form of curves, the coefficient of discharge through the clearances being plotted as ordinates against pressures at the wearing ring as abscissas. To facilitate the calculation of the pressure at the wearing ring the pressure distribution in the pump case was studied and an approximate formula was developed. The axial thrust in single- and multi-stage pumps was measured with a specially designed thrust bearing which indicated the thrust directly in pounds under actual operating conditions. New sources of thrust were established—those caused by unequal pressures on the impeller shrouds from the inside due to various causes, the most important of which are an uneven radial velocity distribution and cavitation. In multi-stage pumps, with impellers mounted back to back, generally considered balanced on account of symmetry, it was discovered that there is considerable axial thrust produced by unequal pressures in adjacent stages acting upon the shaft shoulders and impeller hubs extending through the walls of the adjacent stages. Means to eliminate this thrust were found.

INTRODUCTION

IN THE design of centrifugal pumps a few years ago, very little attention was paid to leakage loss, as efficiencies then were comparatively low and this loss constituted only a small portion of the total loss. With modern efficiencies well over 90 per cent, leakage loss takes on an important aspect. To measure leakage loss under actual operating conditions, a commercial centrifugal pump was modified slightly in design. This pump permitted the use of various types and sizes of wearing rings, including those of the labyrinth, stepped, spiral-grooved, circular-grooved, and plain types, as well as plain rings of various widths. The various types were tested with constant clearances, the plain ring being tested with variable clearances. The effect of width on leakage also was observed by testing a plain ring with a constant clearance, but varying the width in steps of $^{3}/_{16}$ in. All tests were performed at speeds of 1400, 1700, 2000, and 2500 r.p.m., with pressures varying from 10 to 160 ft. The results are presented in the form of curves, with the coefficient of discharge calculated from the leakage flow through the clearances plotted as ordinates and the pressure as abscissas.

In order to determine the leakage loss in a new design, it would be necessary to calculate the difference in pressure across the wearing ring. The pressure distribution in the pump case was studied by inserting pipe taps at various points and actually measuring the variation in pressure, including a point adjacent to the wearing ring. This revealed that the pressure at the discharge nozzle is greater than in the volute case for capacities less than the capacity at maximum efficiency. For capacities greater than the capacity at maximum efficiency the pressure at the discharge nozzle is less than in the volute case. At the point of maximum efficiency, the pressure distribution in the volute case was found to be uniform. When operating at capacities other than that of maximum efficiency, the variable pressure distribution throughout the pump case produces a side thrust upon the rotating element. An approximate formula was developed for calculating the pressure at the wearing ring which agreed very closely with the observed values.

In centrifugal-pump design, multi-stage pumps with impellers arranged in groups, mounted back to back, were considered balanced hydraulically due to their symmetry. Investigation has disclosed that this is not the case and that a considerable axial thrust results. This axial thrust is produced by unequal pressures in adjacent stages acting upon shaft shoulders and impeller hubs extending through the walls of the pump casing, the magnitude of the thrust depending upon the operating head, dimensions of the shoulders and hubs, and the arrangement of the stages. By proper arrangement of the stages and by providing special collars on the runner hubs of one group of runners, this thrust was reduced to a very small value or entirely eliminated. The analytical conclusions were confirmed by actual measurement. Due to large oil companies abandoning transportation of oil by mobile tanks and resorting to pipe lines with high-speed booster centrifugal pumps, the elimination of axial thrust is of extreme importance, since ball thrust bearings have their thrust capacity greatly reduced at the higher speeds. These high-speed oil-line pumps operate at 3600 and 3000 r.p.m., at 60 and 50 cycles, respectively.

For measurement of axial thrust, a special thrust bearing was designed which enabled the reading of thrust directly in pounds. A special L-shaped arm hinged at the apex converted the horizontal thrust into a vertical thrust, permitting the use of a platform scale. The thrust was measured at speeds of 1400, 1700,

[1] Design Engineer, Byron Jackson Company. Assoc-Mem. A.S.M.E. Dr. Stepanoff was born in 1895 in Russia. He was graduated in mechanical engineering in 1918 in Russia; 1920–1923, was superintendent of the city pumping station, City of Harbin, China; 1923–1925, with American Brake Shoe and Foundry Co., San Francisco, Calif. He received B.S. degree in 1926 and M.S. degree in 1927 from the University of California. Since May, 1927, he has been designing engineer for Byron Jackson Company, Berkeley, Calif. He received Ph.D. degree in mechanical engineering in 1930 from the University of California.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers. All papers are subject to revision.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

2000, 2500, and 3000 r.p.m. for two different diameter impellers, viz., $8^1/_2$ in. and $10^1/_8$ in. Various balancing devices in the form of radial ribs and low-pressure chambers on the back side of a single suction impeller were tested at the various speeds and the two different diameter impellers. From these results it was impossible to explain the shape of the thrust-capacity curves by the pressure distribution in the case. A new source of thrust was established—that due to unequal pressures on the impeller shrouds from inside, owing to various causes, the most important of which is an uneven radial velocity distribution and cavitation.

NOTATION

Q_t = quantity of liquid discharged by the runner
Q = quantity of liquid discharged by the pump, or measured pump capacity
Q_L = amount of leakage
H_t = theoretical total head
H = actual or useful total head
H_L = pressure difference on two sides of wearing rings
WHP = pump water horsepower, pump output
BHP = motor brake horsepower, pump input
e_v = volumetric efficiency
e_m = mechanical efficiency
e_h = hydraulic efficiency
e = pump efficiency
A = area of the clearance between wearing rings
C = coefficient of discharge
g = gravitational constant
s = radial clearance between the runner and case wearing rings
D = mean diameter of clearance
u_2 = runner peripheral velocity at discharge
u_1 = runner peripheral velocity at entrance
c_{2m} = radial velocity of flow through the runner
c_{2u} = tangential component of the absolute velocity at runner discharge
V_e = velocity through the runner eye
β_2 = vane angle at discharge
α_2 = angle between the absolute velocity of discharge from runner and u_2.

PART I LEAKAGE LOSS

1 Leakage Loss—Definitions and Descriptions

LEAKAGE LOSS in centrifugal pumps is understood to be the loss of high-pressure liquid through the clearances between the rotating element and the stationary pump case. A portion of the liquid pumped is "short circuited," or returned back to the suction. Sometimes this loss is referred to as "short circuit loss" or "clearance loss." The pump capacity measured is less than the amount of liquid passing through the runner by the amount of leakage. The ratio of the quantity of liquid discharged by the pump to that passed through the runner is the volumetric efficiency of the pump.

$$\frac{Q}{Q_t} = \frac{Q}{Q + Q_L} = e_v \qquad [1]$$

The volumetric efficiency is related to the pump efficiency in the following way:

$$e = e_m\, e_h\, e_v = \frac{\text{Pump output}}{\text{Pump input}} = \frac{WHP}{BHP} \qquad [2]$$

Water horsepower (WHP) is equal to $\frac{Q\gamma H}{550}$, where Q is measured in cubic feet per second, γ in pounds per cubic foot, and H in feet.

$$e_m = \frac{BHP - \text{Mechanical losses}}{BHP} \qquad [3]$$

The mechanical losses include power lost in bearings, stuffing-box friction, and the disk friction of the runner.

e_h is hydraulic efficiency, equal to the ratio of the head measured at pump discharge, or total useful head, to the theoretical head, or

$$e_h = \frac{H_t - \text{Hydraulic losses}}{H_t} \qquad [4]$$

The hydraulic losses are the following: Shock loss at the entrance to the runner, friction loss in the runner, shock loss at the discharge from the runner into the pump case, friction loss in the volute case, and all losses due to turbulence, whatever its causes may be.

H_t is the theoretical head, or head attainable with a viscousless fluid and a runner with an infinite number of vanes. It can be calculated using formulas developed by the theory.[2]

From the foregoing it is seen that the mechanical losses are losses of power, the hydraulic losses are losses of head, and the leakage loss is a loss of capacity. This should be kept in mind when investigating the performance of a pump. Thus, if the pump efficiency is better or worse than anticipated, each of the three sources of losses should be studied independently.

The clearance between the rotating element and the pump case may be axial or radial. Figs. 1 and 2 show examples of the axial clearances used in the early pumps. This type of clearance presents two major disadvantages: First, the exact machining and assembly required does not allow any end play; and, second, a high-velocity jet is projected across the flow in the runner eye. This jet becomes considerable where clearances are worn, and impairs the pump efficiency. The axial clearances are used in modern pumps only in connection with the balancing devices shown in Figs. 71 and 72 and described in Section 14.

Close radial clearances in centrifugal pumps prevent the return of high-pressure water from the pump case to the runner suction. In the early pumps close clearances were provided at the entrance to the runner eye as well as at the discharge, as

---

[2] Dr. C. Pfleiderer, in his book "Die Kreiselpumpen," Julius Springer, Berlin, p. 48, Equation [7], and p. 69, gives the following expressions for the pump efficiency:

$$e = \frac{QH}{(Q + Q_L)\, H_t + \text{Mechanical losses}}$$

$$= \frac{1}{\left(1 + \frac{Q_L}{Q}\right)\frac{H_t}{H} + \frac{\text{Mechanical losses}}{QH}}$$

It will be shown that these are the same as Equation [2] of this paper. Substituting for Mechanical losses, Input × $(1 - e_m)$, we get:

$$e = \frac{1}{\left(\frac{Q + Q_L}{Q}\right)\frac{H_t}{H} + \frac{\text{Input}\ (1 - e_m)}{QH}}$$

$$= e = \frac{1}{\frac{1}{e_v}\cdot\frac{1}{e_h} + \frac{1 - e_m}{e}} = \frac{e_v e_h e}{e + (1 - e_m)\, e_v e_h}$$

or

$$1 = \frac{e_v e_h}{e + (1 - e_m)\, e_v e_h}$$

$$e + e_v e_h - e_m e_v e_h = e_v e_h$$

$$e = e_m e_v e_h$$

shown in Figs. 1, 2, and 3. In modern pumps close clearances are made at the runner eye only, as shown in Figs. 30 and 75. Close clearances at the runner discharge were brought into pump practice from hydraulic turbines, where the flow is in the opposite direction, the intake being at the outer runner diameter.

Clearances at the outer runner diameter have been discontinued in centrifugal pumps for these reasons: (*a*) The clearance area at the outer diameter is much greater than that at the runner eye with the same radial clearance. It is easier to make close running fit at a smaller diameter. (*b*) It is difficult to make a double fit equally accurate. (*c*) Usually one pump is designed to cover a certain range of heads and capacities, which is accomplished by cutting the runner diameter. A close clearance at the outer diameter would mean cutting the runner vanes only, leaving the runner shrouds of full diameter and resulting in some unnecessary disk friction and a lower efficiency. (*d*) With close clearances in modern pumps it is always possible, due to inaccuracy in machining or wear of bearings, that the runner may rub against the case wearing rings. If rubbing takes place at this large diameter, the torque required to overcome friction will be much greater. (*e*) The cost of machining of a close clearance at the runner outside diameter is greater, with no gain in efficiency; therefore this method of sealing has no advantage.

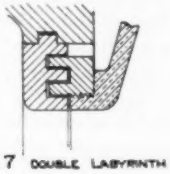

Fig. 7 Double Labyrinth

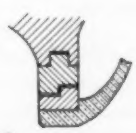

Fig 8 Stepped Wearing Rings

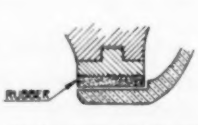

Fig 9 Case Wearing Ring Lined with Rubber.

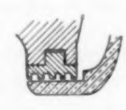

Fig 10 Case Wearing Ring with Circular Grooves

Figs. 4 to 10 show several designs of wearing rings. The pump case and runner in Fig. 4 have no wearing rings. This construction is used for small, cheap pumps. Figs. 5, 9, and 10 show case wearing rings and no runner rings. The rest of the designs provide case and runner wearing rings which can be replaced when clearances become too large. Thus the original clearances are reestablished. In Figs. 6 and 7, respectively, are shown single- and double-labyrinth type of wearing rings. Fig. 9 shows a rubber-lined wearing ring. It is maintained that this type of ring lasts longer with cold, gritty water and that smaller clearances may be used. The disadvantage of this type of wearing ring is that the pump cannot run dry (started without priming or lose priming), even for a short time, without "freezing."

It is evident that in double-suction pumps the leakage loss occurs on both sides of the runner (Fig. 11), while in single-suction pumps leakage takes place only on one side. But for the sake of hydraulic balance single-suction pumps are often provided with a chamber on the back side of the runner of the same diameter as the runner wearing ring and separated from the high-pressure case by wearing rings similar to those used at the runner eye, and connected in some way to the pump suction. Fig. 30 shows one of these pumps, a detailed description of which is given in Section 8. It is seen that, for the sake of hydraulic balance, some portion of the pump capacity is sacrificed in this way.

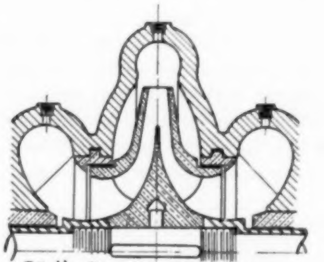

Fig 11 Double Suction Pump

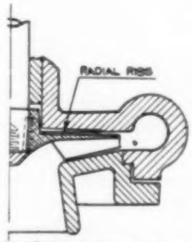

Fig. 12 Open Runner Pump

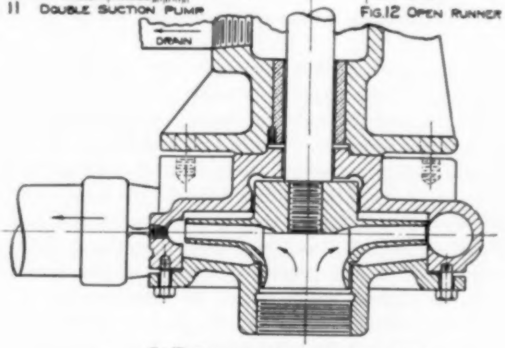

Fig 13 Close Clearance Bushing Used Instead of a Stuffing Box

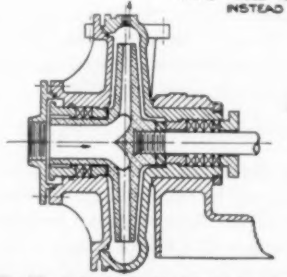

Fig 14 A Stuffing Box Used Instead of a Close Clearance Wearing Ring

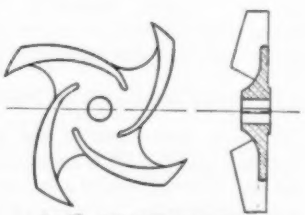

Fig 15 A Runner without Shrouds

In multi-stage pumps, in addition to the loss of the high-pressure water at the runner eye, there is a loss of capacity due to leakage from stage to stage through the clearances between the shaft and the case wall separating the adjacent stages. Depending on the arrangement used, the pressure between two adjacent stages may be that of one stage or more (Fig. 81). If there is one stage pressure across the clearances between the case and shaft, the per cent of liquid lost in this way is that of one stage only, as the same liquid may be regarded as short-circuited from stage to stage.

There is another example where a portion of the pump capacity is sacrificed and additional leakage is introduced for the sake of simplicity of construction. Fig. 13 shows a section of a vertical pump with a close-fitted bushing instead of the stuffing box.

Any leakage through the clearance is drained to the pump intake. With a close clearance this bushing works as a water-lubricated bearing. Special bronzes with a large percentage of lead are especially suited for this purpose.[3]

There are two types of "open runner" pumps. In one type the runner vanes are shrouded on one side only, while in the other the runner vanes are not shrouded, but are cast, with suitable reenforcement, integral with the hub (Figs. 12 and 15). In these pumps running clearance is provided between the runner vanes and the pump cover. The determination of the leakage loss for these pumps is difficult because the clearance is uncertain and it is impossible to separate the short-circuited water from the main flow. These pumps are used for special services, such as pumping milk, pulp, etc., where easy access to the runner vanes is required for cleaning.

Propeller or screw pumps belong to the open-runner type. Due to the very low pressure and large capacity of these pumps, the amount of leakage is a small percentage of the total pump capacity.

In addition to the leakage through the clearances between the pump case and the rotating element, a very small part of the pump capacity may be used for sealing the stuffing boxes or cooling the pump bearings. In the first case, if the stuffing box is under the suction pressure, there is always danger that air may be drawn through the stuffing box and the pump lose priming. To prevent this a cage ring is provided in the middle of the stuffing box (Fig. 30), and high-pressure water is fed in from the pump case. In high-pressure pumps a similar cage ring is inserted in the stuffing box to relieve the pressure on it, and the leakage through the first section of the packing is drained to the pump suction. This leakage is also a net loss. The amount of water used for sealing the stuffing boxes and for cooling the bearings is usually negligible. The amount of leakage from a high-pressure stuffing box may be considerable, depending upon the pressure and the method of packing the stuffing box.

2 LEAKAGE LOSS AND DESIGN OF CENTRIFUGAL PUMPS

A study of the leakage loss is important from several points of view. First of all, a knowledge of the amount of the leakage and the factors governing it and of its effect on pump performance may indicate the ways to reduce this loss and thus to improve the pump efficiency. There is no information about the amount of leakage in the literature on centrifugal pumps. R. L. Daugherty[4] estimates the leakage loss as 1.5 per cent in one case and 13.3 per cent in another case. C. Pfleiderer[5] states that the leakage loss may be from 3 to 10 per cent. L. C. Loewenstein[6] assumes the loss to be 6 per cent. F. Neumann[7] estimates this loss as from 4 to 6 per cent. Many treatises do not mention the leakage loss at all.

While the theory of the leakage loss is considered in a later section, it is convenient, for the purpose of the study of factors governing the leakage loss, to represent the amount of leakage by the following formula:

$$Q_L = AC\sqrt{(2gH_L)}$$

where Q_L is the quantity of water short-circuited through the clearance between the runner and case wearing rings; H_L is the pressure difference across the clearance; A is the net area of the clearance equal to $D\pi s$, where D is the mean diameter of the clearance space and s is the radial clearance. Owing to the small value of s compared with D, the diameter of the wearing ring can be used instead of the mean diameter of the clearance without appreciable error. C is a coefficient of discharge, including the coefficient of contraction and the velocity coefficient, and accounting also for the resistance of the ring due to friction or change in direction or section of the flow. Then

$$Q_L = \pi DsC\sqrt{(2gH_L)}$$

It is evident that the smaller the factors on the right-hand side of this equation are, the smaller will be the leakage.

Each factor is to be considered separately, as follows:

(*a*) The pressure on the clearance H_L varies with the pressure developed by the pump, being smaller for a low-pressure pump and higher for a high-pressure pump. For the same pump this pressure increases as the pump pressure increases and is a maximum at shut-off or no discharge. The ratio of the pressure at the wearing ring to the pressure in the volute case, or the pump total head, depends upon the ratio of the wearing-ring diameter to the mean diameter of the volute case. It decreases as this ratio decreases. This is due to the centrifugal effect produced by the water set in rotation in the space between the runner and the case walls.[8] This effect is greater for smaller clearances between the runner and the pump case. Still greater reduction in pressure at the wearing rings is effected by providing radial ribs on the runner back.

(*b*) It is evident that the smaller the radial clearance between the runner and the case wearing rings, the smaller will be the leakage. But a very small clearance requires exact machining of all parts of the pump, because there is always danger of rubbing in of the wearing rings due to inaccurate bearing centering or too liberal running clearances in the bearings. In this case the saving in the leakage is more than counterbalanced by the power lost in overcoming friction in the wearing rings, which takes place at a comparatively large diameter. Again, it should be kept in mind that pump shafts are not perfectly rigid, but have a certain deflection due to the runners and their own weight. For the wearing-ring clearances the following values represent good practice: For rings of 6 in. diameter and smaller, the clearance is made 0.010 in. on the diameter[9] with 0.001 in. additional for every inch of the wearing-ring diameter over 6 in., or:

$$s = 0.010 + (D - 6) \times 0.001 \text{ in.}$$

where s and D are in inches. This gives for rings of

6 in. diameter, 0.010 in. clearance
12 in. diameter, 0.016 in. clearance
18 in. diameter, 0.022 in. clearance
24 in. diameter, 0.028 in. clearance
36 in. diameter, 0.040 in. clearance.

The wearing ring should be made sufficiently strong to permit chucking for machining without distortion. The final cut of the runner wearing ring should be taken after it is pressed on the runner. The pump shafts should be handled with care as they are easily bent or sprung during machining. Usually the shafts, made of steel, which requires heat treatment, are distorted after that operation and should be trued in the lathe very carefully.

There have been attempts to use a stuffing box instead of a close clearance between the wearing rings to eliminate the leakage loss, as shown in Fig. 14.[10] They were not successful, because the friction in the stuffing box more than counterbalanced the saving in the leakage. Also, a long revolving tube in front of the runner vanes is detrimental to the runner performance.

---

[3] A bronze much used for similar services has a composition of copper, 70 per cent; lead, 26 per cent; and tin, 4 per cent.

[5] C. Pfleiderer, "Die Kreiselpumpen," p. 57, Julius Springer.

[6] L. C. Loewenstein and C. P. Crissey, "Centrifugal Pumps," p. 140, Van Nostrand Company.

[7] Fritz Neumann, "Die Zentrifugalpumpen," p. 31, Julius Springer.

[8] It has been found by the author in tests described later that for the same pump case the ratio of the pressure at the wearing ring to the pump total head depends very little upon the runner diameter, the ratio being fixed by the case size and the ring diameter.

[9] For small wearing rings on a pump with very exact machining and ball bearings, the minimum clearance may be reduced to 0.008 in.

The decrease of pump efficiency with time is mainly due to an increase of leakage resulting from the wear of the wearing rings. This wear is caused by the presence of abrasive matter in the water, which passes through the clearance at high velocity. Also, due to bearing wear, the rotating element drops, and the runner wearing rings start to rub against the case wearing rings. It is good practice, therefore, to provide both the pump case and the runner with wearing rings and to make each ring of a different material. If both are of bronze, bronzes of different hardnesses should be used. The following compositions may be recommended: For the runners or runner wearing rings, Cu, 88 per cent; Sn, 10 per cent; Zn, 2 per cent. For the case wearing rings, Cu, 85 per cent; Sn, 5 per cent; Pb, 5 per cent; and Zn, 5 per cent.

(*c*) The leakage decreases also with a decrease in the clearance diameter. A reduction of the diameter of the clearance for a given runner-eye area may be obtained by a reduction of the runner hub and shaft diameters. Fig. 75 shows an example of the hub entirely eliminated from the suction side of the runner and the shaft diameter reduced in the runner eye and shaped to conform to the direction of the flow. Here, again, is a danger of weakening the shaft so that the static deflection will grow above the permissible maximum. The strength of the pump shaft for a maximum deflection is not always a determining factor for the size of the pump shaft; it also should be strong enough to transmit the required torque and it should be checked for critical speeds.

The small runner-eye diameter is advantageous also from a hydraulic point of view, because (1) with a small runner-eye diameter the inevitable shock losses at entrance take place at a smaller diameter and absorb less power; (2) for the same runner diameter, the head produced is higher for a smaller runner-eye diameter, or for the same head a runner of smaller diameter may be used. The disk friction will be reduced in this way and the pump efficiency be improved. (3) For the same radial velocity a higher vane entrance angle and a lower relative velocity may be used.

(*d*) The decrease of the coefficient of discharge in the formula $Q_L = AC\sqrt{(2gH_L)}$ may be effected by an increase of the resistance to the flow through the clearance by a change in direction of the flow, by a sudden change of the section, by using labyrinth rings, etc., as illustrated in Figs. 6, 7, 8, and 10. To find the coefficients of discharge for different rings, and also to investigate the relative advantages of various rings, is a part of this work.

The consideration of the leakage affects the design of the pump case, as will be seen from the following. Since water is discharged from the runner with a high velocity, the leakage water does not separate from the main flow at that point, but from a space farther in the volute where the outward radial component is destroyed and the flow is reversed, as shown in Fig. 16. If the pump case is designed with small clearance between the case wall and the runner, the leakage flow will interfere with the main flow, thus impairing the efficiency. Fig. 17 shows an example of a tight case design. Another disadvantage of a case of this shape is that if the runner is displaced from its central position because of inaccurate assembly, poor casting, or excessive bearing end play, the stream from the runner may strike the corners of the volute. In multi-stage pumps with long cases the conditions are even worse. Due to an improper allowance for shrinkage, the center lines of the volutes may differ from those of the runners on the shaft, and rubbing of the runners against the case will result. If a pump with the volute shaped as in Fig. 17 is run with a runner cut in diameter, the stream will hit the corners of the volute and produce disturbance, since the flow from the runner is divergent. The modern pumps are designed with ample clearance between the runner and case wall, as shown in Figs. 75 and 30. These clearances are made approximately $^1/_2$ in. per ft. of the runner diameter, and never less than $^3/_8$ in., the exact value being determined by the runner profile.

Another disadvantage of the tight pump case is that, due to slight non-central runner location in the case, it is possible even with a double-suction runner, inherently balanced, to have an axial thrust which may be variable, thus producing shaft vibration, as explained in Section 17.

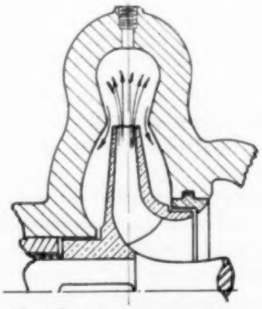

FIG. 16 VOLUTE CASE WITH AMPLE CLEARANCE BETWEEN THE RUNNER SHROUDS AND PUMP CASE WALL

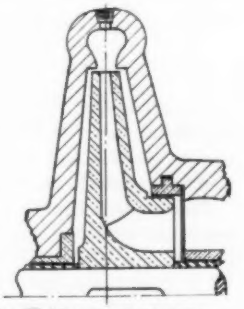

FIG. 17 VOLUTE CASE WITH SMALL CLEARANCE BETWEEN THE RUNNER AND CASE.

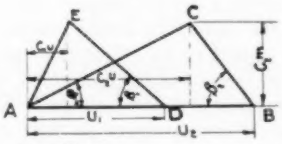

FIG. 18

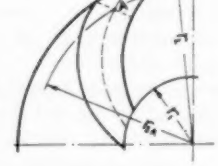

FIG. 19

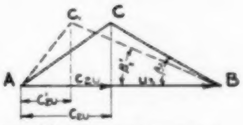

FIG. 20 DISCHARGE TRIANGLE

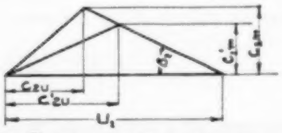

FIG. 21 DISCHARGE TRIANGLES FOR TWO RADIAL VELOCITIES C_{2m} AND C'_{2m}

From a hydraulic point of view the volute case with an ample clearance between the runner and pump case shows a decided advantage over the tight case, the difference in efficiency being from 3 to 10 per cent at high capacities. In a tight case the high jets discharged by the runner come in contact with the stationary walls. The shock and friction losses are higher than when the runner discharges into a body of revolving water.

It should be noted that one of the main reasons for the low efficiency of small pumps is an excessive leakage loss. This is due to the fact that the clearances cannot be reduced below a certain minimum. The wearing-ring diameter is comparatively large, the overlap of the wearing rings is small, and due to small dimensions no labyrinth or stepped rings can be used. Again, since the small pumps are usually of a low-specific-speed type or of small capacity and high head, for the same head the amount of short-circuited liquid constitutes a higher percentage for a small pump. The other reasons for the low efficiency of small pumps are: (1) The low-specific-speed type of pump is inherently less efficient than the medium-specific-speed type of pump. The high percentage of leakage loss is only one reason for this. There is no demand for small pumps of the high-specific-speed type, as pumps of small capacity and low head have little application (the deep-well turbine pump being an exception, as the total head in this pump is split between several stages). (2) Lower mechanical efficiency is inherent in all small machines and mechanisms. (3) Simplicity of design and manufacture must be maintained on small pumps, as the price is the main selling factor, the efficiency being of secondary importance.

---

[10] *Engineering*, Jan. 28, 1921.

3 Leakage Loss and Theory of Centrifugal Pumps

In the elementary theory of centrifugal pumps it is shown that the theoretical head produced by a pump is equal to

$$H_t = \frac{u_2c_{2u} - u_1c_{1u}}{g} \qquad [5]$$

where H_t is the theoretical head produced, u_2 and u_1 are the peripheral speed of the runner at the outlet and inlet, respectively, and c_{2u} and c_{1u} are the tangential components of the absolute velocity, as shown in Fig. 18.

Though this equation has been generally accepted for many years, the actual values of head produced never have approached this theoretical head even under the most favorable conditions. Very often the value of the hydraulic efficiency H/H_t, where H is the actual head, is found to be lower than the over-all efficiency of the pump, which is absurd. The general conclusion is that the theoretical head, as given by the foregoing formula, is too high. One of the reasons for this discrepancy is to be seen in the fact that this theory admits an infinite number of vanes or that all particles of liquid move in a similar manner and leave the blade with an angle β_2 of the vane. In actual practice the number of vanes is limited to from 2 to 16. This conclusion is made logical by the fact that by increasing the number of vanes the head produced may be increased a certain amount. Naturally, attempts have been directed toward improving this formula by introducing some corrective factors, but up to the present time the problem has not been solved. The difficulty lies in the very simplicity of the formula,

$$H_t = \frac{u_2c_{2u}}{g} \qquad [6]$$

the term u_1c_{1u} being equal to zero for the radial inlet.

It was proposed to substitute for u_2, not the peripheral velocity corresponding to r_2 radius of the runner, but a value of peripheral velocity of the point A, Fig. 19, in the middle of the line drawn from the tip of the vane normal to the stream lines. It was supposed that from this point the vane ceased to act upon the water streams in the runner. It is evident that the value of u_{2A} for the point A will be smaller for a smaller number of vanes. But this is true only if the angle β_2 is far from 90 deg. With the increase of β_2, the difference between the u_2 and u_{2A} becomes smaller and disappears when β_2 equals 90 deg.

The second method of correction of the fundamental formula consists in correction of c_{2u} so as to take into account the number of vanes of the runner. But as in the triangle at the outlet u_2 and c_{2m} are determined from the actual test or are assumed, the only way to make c_{2u} smaller is to conclude that water leaves the runner with an angle β_2' smaller than the actual vane angle β_2.

Dr. Pfleiderer[11] developed a corrective factor for c_{2u} and gave also an expression for the angle of the deviation of the stream as compared with the actual vane angle. Thus a discharge triangle ABC' is substituted instead of the ABC given by the elementary theory (Fig. 20). It seems, however, that all attempts to correct the elementary formula by introducing some terms to account for various factors affecting the head produced will be futile until it is known just what the theoretical head should be. The only information available about the theoretical head is that the ratio of the actual to the theoretical head or hydraulic efficiency should be less than unity and greater than the pump efficiency $e < e_h < 1$, and every designer or investigator has to use his judgment as to what "reasonable" value for the hydraulic efficiency should be used for different types of pumps.

But if the leakage loss is known, the hydraulic efficiency and theoretical head can be determined with great accuracy from the pump efficiency:

$$e = e_m\, e_v\, e_h,$$

$$e_h = e/e_m\, e_v \qquad [7]$$

where e_v is the volumetric efficiency obtained from

$$e_v = Q/(Q + Q_L) \qquad [8]$$

Q_L being the amount of leakage.

e_m is the mechanical efficiency.

$$e_m = \frac{\text{Power input} - \text{Mechanical losses}}{\text{Power input}}$$

The mechanical losses include friction in bearings and disk friction of the runner. The first can be easily measured by driving the shaft, without the runner, in the pump case filled with water under pressure. A considerable amount of the experimental data on disk friction are available, which enables the designer to calculate this loss with great accuracy. The description and the results of these tests are found in the following articles and treatises: Hesse, Bulletin No. 2, University of California, 1887; J. N. LeConte, *Journal of Electricity, Power,*

and Gas, Sec. 3, 1910; J. N. LeConte, *Hydraulics;* A. H. Gibson, "Hydraulics and Its Applications;" F. Zur Nedden, Trans. A.S.M.E., 1915.

From the hydraulic efficiency e_h obtained from Equation [7], the theoretical head H_t is found:

$$H_t = \frac{H}{e_h}$$

where H should be obtained by test.

4 THEORETICAL HEAD WITH NON-UNIFORM RADIAL VELOCITY

Equations [5] and [6], Section 3, for the head developed by the runner, assume that all water particles are moving along similar paths with uniform velocities, although experience shows that the flow with uniform velocities does not exist, being approached in the most favorable conditions only. Since in every runner particles of water are deflected 90 deg. before they are acted upon by the vanes, the velocity is no longer uniform. It is usually supposed that for this case the formula for the head developed still holds if the mean values of velocities are used. It will be shown that for this case the theoretical head for an infinite number of vanes, with no losses, is smaller, the difference being greater the more pronounced is the difference between the maximum and minimum radial velocities.

With an ideal fluid and the flow along a curved path, the velocities change according to the law vr = constant, where r is the radius of curvature of the path. This gives low velocities at the outer side and high at the inner side of the curved path. With actual liquids and high mean velocities this velocity distribution holds only for a portion of the curved path; then the inertia forces (centrifugal) come into play, and the liquid leaves the inner wall and the velocity distribution is reversed—i.e., the high velocities are at the outer side and the low at the inner side. The latest and very extensive tests by H. Nippert[12] and R. Bambach[13] show that such distribution of velocities is found in 90-deg. elbows. With small mean velocities of flow and large values of the ratio r_m/d (where r_m is the radius of curvature of the mean stream lines and d is the diameter of the elbow), the theoretical velocity distribution vr = const. was confirmed by these tests except for layers of water near the walls which were affected by friction. The pressures are higher at the outer wall of the turn. With high mean velocities of flow and small values of the ratio r_m/d, or sharp turns after a short portion of the turn, the higher velocities are shifted from the inner wall to the outer. Water leaves the inner side due to inertia, and forms a "dead water" space filled with eddies at the inner wall. Figs. 24 and 25, taken from the Nippert and Bambach papers, illustrate this very clearly. This velocity distribution is maintained for a long distance in the straight portion of pipe and is brought to the normal distribution very slowly by wall and internal friction. The maximum pressures are near the outer wall in this case also. The values of the velocities producing the first or the second form of the velocity distribution, and the relation of the critical velocity to the r_m/d, were not established by these tests.

Assuming that the radial velocity varies uniformly from v_1 at the front shroud to v_2 at the back shroud and at some point located at a distance x from the front shroud, Fig. 26(*a*), the radial velocity is $v_r = v_1 + ax$, where $a = \frac{v_2 - v_1}{b}$, b being the runner width at the discharge. The head produced at this point is:

$$H_t = \frac{u_2 c_{2u}}{g} = \frac{u_2}{g}\left(u_2 - \frac{v_r}{\tan \beta_2}\right) = \frac{u_2^2}{g} - \frac{u_2 v_r}{g \tan \beta_2} \ldots . [9]$$

The volume of water discharged by an element of the runner dx wide is equal to

$$dQ = v_r \pi D_2 dx \ldots\ldots\ldots\ldots\ldots\ldots [10]$$

The power output of this element is:

$$dP = \gamma H_t dQ = \gamma H_t v_r \pi D_2 dx \ldots\ldots\ldots\ldots [11]$$

Substituting for H_t its value from [9], we get:

$$dP = \left(\frac{u_2^2}{g} - \frac{u_2 v_r}{g \tan \beta_2}\right) \gamma \pi D_2 v_r dx$$

For brevity denote:

$$\frac{u_2^2}{g} = A; \quad \frac{u_2}{g \tan \beta_2} = B; \quad \gamma \pi D_2 = C$$

The formula then takes the form:

$$dP = (A - Bv_r)\, Cv_r dx = C(Av_r - Bv_r^2)dx$$

Substituting for v_r its value $v_r = v_1 + ax$,

$$dP = C[A(v_1 + ax) - B(v_1 + ax)^2]dx$$

Integrating between the limits 0 and b, we obtain the power output of the runner:

$$P = \int_0^b CA(v_1 + ax)dx - \int_0^b CB\,(v_1 + ax)^2 dx$$

$$= CA\left[\frac{(v_1 + ax)^2}{2a}\right]_0^b - BC\left[\frac{(v_1 + ax)^3}{3a}\right]_0^b$$

$$= CA\left[\frac{(v_1 + ab)^2}{2a} - \frac{v_1^2}{2a}\right] - BC\left[\frac{(v_1 + ab)^3}{3a} - \frac{v_1^3}{3a}\right]$$

But $v_1 + ab = v_2$; then

$$P = CA\,\frac{(v_2^2 - v_1^2)}{2a} - CB\,\frac{(v_2^3 - v_1^3)}{3a}$$

Substituting for a its value $a = \frac{v_2 - v_1}{b}$ and denoting $\frac{v_2 + v_1}{2}$ the mean radial velocity by v_m, the expression for the power output takes the form:

$$P = CA\,\frac{(v_2 - v_1)}{a}\,\frac{(v_2 + v_1)}{2} - CB\,\frac{(v_2 - v_1)}{a}\,\frac{(v_2^2 + v_2 v_1 + v_1^2)}{3}$$

$$= CAbv_m - CBb\,\frac{(v_2^2 + v_2 v_1 + v_1^2)}{3}$$

The average head produced by the runner is obtained by dividing the runner power output by the weight of water discharged W.

$$W = \gamma \int_0^b dQ = \gamma \int_0^b v_r \pi D_2 dx$$

$$= \gamma \int_0^b \pi D_2 (v_1 + ax) dx = \gamma \pi D_2 \left(v_1 b + \frac{ab^2}{2} \right)$$

$$= \gamma \pi\, D_2 \left[v_1 b + \frac{(v_2 - v_1)\, b^2)}{2b} \right] = \gamma \pi D_2 b \, \frac{v_2 + v_1}{2}$$

$$W = \gamma \pi D_2 b v_m = C b v_m \ldots\ldots\ldots\ldots\ldots [12]$$

which could be written at once, since the velocity involved is a linear function of x.

$$H_t = \frac{P}{W} = A - \frac{B}{v_m} \left(\frac{(v_2^2 + v_2 v_1 + v_1^2)}{3} \right)$$

$$= A - \frac{B}{v_m} \left[\frac{(v_2 + v_1)^2 - v_2 v_1}{3} \right]$$

$$= A - \frac{B}{v_m} \left[\frac{3\,(v_2 + v_1)^2 + (v_2 + v_1)^2 - 4 v_2 v_1}{12} \right] \ldots\ldots [13]$$

$$= A - \frac{B}{v_m} \left[\left(\frac{v_2 + v_1}{2} \right)^2 + \frac{(v_2 - v_1)^2}{12} \right]$$

$$= A - \frac{B}{v_m} \left[v_m^2 + \frac{(v_2 - v_1)^2}{12} \right]$$

$$= A - B v_m \left[1 + \frac{(v_2 - v_1)^2}{12\, v_m^2} \right]$$

$$H_t = \frac{u_2^2}{g} - \frac{u_2 v_m}{g \tan \beta_2} \left[1 + \frac{(v_2 - v_1)^2}{12\, v_m^2} \right] \ldots\ldots\ldots [14]$$

Comparing this formula with [9], it is seen that the average theoretical head produced by a runner with radial velocity varying from v_1 to v_2 is smaller than that for the mean radial velocity v_m. The difference in the head is greater for the greater difference between v_2 and v_1, this difference disappearing when v_2 is equal to v_1. The effect of the variable radial velocity on the head produced will more clearly be understood if it is kept in mind that the elementary formula [9] gives the head per pound of liquid pumped and that more pounds per second of the low-pressure water is discharged by the runner where the radial velocity is greater, since the head developed is smaller for a higher radial velocity.

From the formula [14] it is seen that for the same ratio of v_2 to v_1 the correction factor is more effective for the runners, for which the second term $u_2 v_r / g \tan \beta_2$ is greater in comparison with the first u_2^2/g. In the normal designs the second term is greater for runners of high specific speed; hence the correction affects more the theoretical head for these runners. In addition, the factor $\left(1 + \frac{(v_2 - v_1)^2}{12\, v_m^2} \right)$ is greater for wide runners, since the velocity distortion is greater and the length of the water path is smaller for runners of high specific speed. This explains the reason for a greater discrepancy between the theoretical and the actual heads for runners of higher specific speed.

It is evident that the formula [14] holds for the velocity distributions shown in Figs. 26(*b*) and 26(*c*), with a linear relation between the maximum and minimum velocity. For any other relation between the minimum and maximum radial velocities the form of the expression for the correction factor will change, but the significance of the expression will remain the same.

5 Other Theoretical Considerations Involving Leakage Loss

Sometimes in the analysis of the pump performance the power at shut-off or no discharge is taken as that used to overcome the mechanical losses and to pump the leakage.[14] This may lead to very erroneous conclusions, as these losses are only a portion of the power at shut-off, the rest being dissipated in hydraulic friction and in turbulence caused by the circulation of water inside the runner. These latter losses are comparatively small in the low-specific-speed runners—i.e., narrow runners with many long vanes—but they increase for medium-specific-speed runners. The horsepower curve for this type of pump is a horizontal line, while for the high-specific-speed runners of the propeller type the horsepower is a maximum at shut-off and decreases as the pump output increases. It is evident that deductions made on the assumption that the power at shut-off is used to overcome the mechanical losses and to pump leakage are absurd for pumps with this shape of the horsepower curve.

Knowledge of the leakage loss is of importance from another point of view. The present design of centrifugal pumps is based on the application of the laws of similarity of flow for homogeneous pumps, which laws when applied to pumps state that runners of the same type or geometrically similar give heads proportional to the squares of their diameters and capacities proportional to the cubes of their diameters. These, combined with the so-called "affinity laws,"[15] form the foundation of the pump design. But both of these laws hold for the quantities discharged by the runner, which is different from the measured pump capacity by the amount of leakage. This is one of the reasons why these laws are not accurate for large multiplications, as the leakage loss is not proportional to the pump size. The other reasons for the discrepancy are that for large multiplications the shaft sizes and runner hubs cannot always be made strictly to factor and that the roughness of castings is not proportional to the pump size.

The excessive leakage, being a loss by itself, impairs the pump efficiency by destroying the favorable velocity ratios through the runner. Thus the drop in efficiency with time is mainly due both to loss of capacity by leakage through the worn wearing ring and to decrease of hydraulic efficiency on account of upset velocity ratios. The same takes place in multi-stage pumps if there is a great difference in pressure between the adjacent stages.

The leakage loss affects the shape of the pump head-capacity curve in distinction from that of the runner, since the runner capacity is equal to that of the pump plus the leakage through the clearances. Thus the zero discharge for the pump does not mean that for the runner. In addition to that, there is a difference in the pressures in the volute and the discharge nozzle not accounted for by the usual form of friction or shock losses, which may be termed as a loss due to "cross-flows."[16] It is important to note that the theory, elementary and improved, applies only to the runner and does not consider the pump case at all.

The question of leakage is again encountered when viscous fluids like heavy oils are to be pumped. It was found by many experimenters that, as a general rule, when pumping viscous oils, both the head and the capacity decrease as the viscosity increases. From the study of a large number of tests the author has found that for viscosities not over 5000 S.s.u., the decrease of the head and capacity is such that the specific speed N_s =

---

[14] A. F. Sherzer, "Centrifugal-Pump Economics," Trans. A.S.M.E., 1929, paper FSP-51-15.

[15] Affinity laws are the following relations between pump head, capacity, and speed: If a pump is run at different speeds, the head varies directly with the square of the speed and the capacity varies directly with the speed.

[16] Detailed discussion of this is found in Section 9.

$NQ^{1/2}/H^{3/4}$ remains constant. The exceptions to this rule were two small pumps (one $1^1/_2$ in. and one 2 in.), in which the capacity increased with an increase in viscosity, while the head decreased quite normally with the viscosity. The probable explanation of this is that in small pumps pumping water the leakage loss is excessive, while with increased viscosity the leakage is reduced so that the measured pump capacity is increased.

6 PREVIOUS RESEARCH ON LEAKAGE

In the early stage of centrifugal-pump design very little attention was paid to the leakage loss because the efficiencies were so low that the leakage loss was a small part of the total loss. The attention of the designers was directed toward the perfection of hydraulic design and mechanical construction. But as time went on pump efficiencies were improved, so that today pumps are built with efficiencies over 90 per cent. Now, the leakage loss, which has been estimated to be from 3 to 5 per cent, has become an important item and deserves more consideration than formerly.

While the theoretical calculation of the leakage loss was a comparatively simple matter, the experimental determination of the necessary coefficients offered certain difficulties. Of these the most important are (1) the impossibility of separation of leakage water from the main flow and (2) the great variety of sealing appliances in use. The latter is greatly simplified at the present time, as a small number of wearing-ring types have been worked out and adopted generally by all manufacturers.

One of the earliest investigators in this field was Dr. Becker,[17] who in 1907 published the results of his tests with the apparatus shown in Fig. 29. This apparatus consisted of a hollow cylinder with a concentric piston having small radial clearance. The dimensions shown in the figure are in millimeters. Water under pressure was applied to one end, and the leakage was measured at the opposite end. The primary aim of this test was to check Poiseuille's law for viscous flow through an annular clearance and to find Reynolds' number for the critical speed. To eliminate the effect of the entrance and discharge losses the edges of the piston were rounded off. Dr. Becker developed a formula for the calculation of the flow:

$$V = \frac{D_m \pi s^2 (P_1 - P_2)}{12\, l \eta}$$

where D_m is average diameter of the clearance space, s is radial clearance, l is length, $(P_1 - P_2)$ is a differential pressure, and η is viscosity of liquid; V is volume of discharge per second. The clearances tested were 0.062 in. and 0.042 in. The critical velocity was found to be at Reynolds' numbers 1346 and 1348.[18]

While these tests were of great interest, they did not furnish any information for calculation of the leakage loss in pumps because the arrangement used was far from that found in pumps. There we have the flow through a radial clearance formed by two concentric cylindrical surfaces, one stationary and one rotating. The axial length of the channel formed in this way is very short, and the resistance to the flow is mainly at the entrance and the discharge. Besides that, all means are used to increase the resistance to the flow by sudden change of direction of flow (as is found in labyrinth or stepped rings), or by sudden change of the cross-section of the clearance by means of grooves, etc.

In Fig. 28 is shown another apparatus tested by Dr. Becker. This consisted of a drum with four steps revolving in a container shaped to suit the drum, forming four close clearances and four changes in direction of the flow. This arrangement was a step forward in reproducing the actual conditions existing in pumps. But the sealing rings of this form are not used at the present time.

Professor Susuki of the Tokio University ran a test to determine the leakage loss through both the axial and the radial clearances.[19] His apparatus for measuring leakage through the radial clearances consisted of a cylinder (Fig. 27) with three nozzles. Water under pressure was admitted through the middle nozzle and passed through the small annular clearance between the cylinder walls and two pistons, and was discharged through the nozzles on both ends of the cylinder. This arrangement did not give any axial thrust. The clearances tested were 0.010 in., 0.018 in., 0.025 in., and 0.050 in. The pistons were driven at 800, 1000, 1600, and 2000 r.p.m. Pressures varied from 0 to 185 ft. for the smallest clearance and from 0 to 36 ft. for the largest. The results were presented in the form of velocity versus pressure curves. From the study of these results the following conclusions can be drawn: (1) For the same clearance and the same pressure, velocities of flow decreased slightly with the speed of rotation of the piston. Expressing the amount of leakage by a formula:

$$Q = AC\sqrt{(2gH_L)} \qquad [15]$$

where A is the area of the clearance, C is a coefficient of discharge, H_L is the head across the clearance, and Q is the amount of leakage. Comparing the coefficients of discharge for the same

---

[17] Becker, "Strömungsvorgänge in ringsformigen Spalten," *Z.D.V.I.*, 1907, s. 1133.

[18] Dr. Becker used the expression $R = 2Sv\gamma/\eta$ for the Reynolds number, which corresponds to that for the pipe flow $R = Dv\gamma/\eta$, the mean hydraulic radius in the first case being $s/2$ and in the latter case $D/4$.

[19] Journal of the Faculty of Engineering, Tokio Imperial University, vol. 18, no. 2, 1929 (in English).

clearance and speed, it is seen from these results that C is increasing with the increase of pressure and C is increasing for larger clearances and the same pressure and speed.

The latest tests on the leakage through small annular clearances are those of Dr. Masanao Yendo published in June, 1930.[20] He experimented with an apparatus shown in Fig. 80. Two disks were tested, 10 and 20 mm. wide (0.394 and 0.788 in.), with the clearances 0.25 and 0.50 mm. (0.010 and 0.020 in.) on the radius. The maximum pressure used was 5.0 m. (16.4 ft.). The following tabulation gives the values of the coefficient of discharge obtained, using formula [15]:

7 CALCULATION OF LEAKAGE LOSS

Dr. Neumann in his book on centrifugal pumps[21] develops the following formula for calculation of the amount of leakage through the clearance between the runner and case wearing rings:

$$Q = fC\sqrt{(2g\eta H_n - w_2^2 - \varphi^2u_2^2)} \qquad \text{..........[16]}$$

where (Neumann's notation)

Q = amount of leakage per second
f = area of clearance space = $D\pi i$
D = diameter of wearing rings
i = radial clearance
H_n = actual head produced by pump
$1/\eta$ = hydraulic efficiency
w_2 = absolute velocity of water leaving the runner
u_2 = peripheral velocity of the runner at discharge
φu_2 = peripheral velocity of water in space between the pump case and runner shrouds
C = coefficient of discharge through the clearance between the wearing rings.

The expression under the radical is the difference of pressure on both sides of the clearance space. The term $\varphi^2u_2^2$ represents the decrease in pressure in the space between the pump case and the runner shrouds on account of rotation of water caused by skin friction of the runner shrouds. This formula includes three coefficients C, η, and φ which are not known and for which no method of estimating has been offered. It has been pointed out that the value of hydraulic efficiency $1/\eta$ obtained by calculation from actual tests is considerably lower than the pump overall efficiency. This is absurd.[22]

Dr. Pfleiderer[23] gives the following formula for calculating the amount of leakage:

$$V_{sp} = M_iD_i\pi b_i\sqrt{(2gH_{pi})} \text{ (Pfleiderer's notation)} \qquad \text{....[17]}$$

where $D_i\pi b_i$ represents the area of the clearance space and M_i a coefficient of discharge. For this Pfleiderer gives a formula:

$$M_i = \frac{1}{\sqrt{(0.04L_i/b_i - 1.5)}} \qquad \text{..............[18]}$$

where L_i is the width of the wearing ring or length of the water path and b_i is the radial clearance. The first term in the denominator takes into account the friction loss, while the second accounts for the velocity head, increased 1.5 times to provide for the contraction at the entrance. The same formula may be presented in the form:

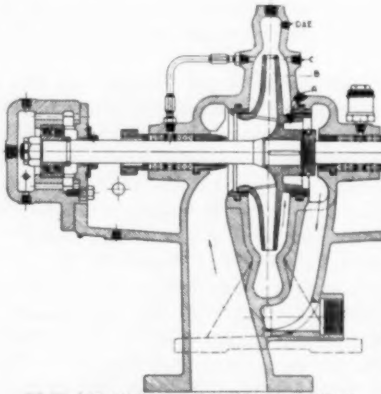

FIG. 30 3-INCH SINGLE SUCTION PUMP WITH ARRANGEMENT FOR MEASURING LEAKAGE THROUGH WEARING RINGS

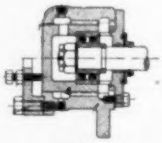

FIG. 30-a

$$H_{pi} = 1.5v^2/2g + \lambda L\frac{U}{4F}v^2/2g \qquad \text{...........[19]}$$

where U/F is the mean hydraulic radius equal to $D\pi b_i/2D = b_i/2$ and λ is a friction coefficient. For this Pfleiderer takes the mean value obtained by Becker[24] with stationary clearance walls equal to 0.08.

The pressure across the clearance H_{pi} is calculated from:

$$H_{pi} = H_p - \frac{(u_2/2)^2 - (u_1/2)^2}{2g} = H_p - \frac{1}{4}\frac{u_2^2 - u_1^2}{2g} \qquad \text{..[20]}$$

where H_p is the pressure in the pump case and u_2 and u_1 are the peripheral velocities of the runner at the outside diameter and the wearing ring, respectively.

The subtractive term in the last formula provides for reduction of pressure near the wearing ring due to rotation of water between the pump case and runner shrouds. The assumption is made that water rotates with half the angular velocity of the runner. This formula applies only to the simplest case of the plain wearing ring; even in this case the result is not accurate enough, because the coefficient of friction varies with pressure and clearance, and the value of the volute pressure has to be calculated

from the theoretical head, which is subject to a considerable error. Dr. Pfleiderer himself in his illustrative design (p. 98) did not use these formulas. He roughly estimated the leakage loss as 5 per cent of the pump capacity.

8 Description of the Apparatus Used for Measuring Leakage

The author's original intention was to measure the leakage through clearances between the case and the runner wearing rings by using a double-suction pump with the runner discharge sealed by a band and driving the shaft at various speeds while applying water under pressure from an outside source to the pump case through the discharge nozzle, and to measure the leakage through the clearance between the rings on the suction nozzle. So far as leakage is concerned, this method might have been quite satisfactory, but it would have left the question as to the pressure distribution in the pump case in doubt, as this might be affected by the discharge from the runner. Again, in every pump under actual operating conditions, there are observed very small vibrations of the shaft which may affect the flow through the small clearances, while if running with no discharge, these vibrations may be absent or considerably reduced. Therefore this idea was discarded, and a new scheme was devised in which the leakage was measured under actual operating conditions, pressures being produced by the same pump. However, to compare the two methods a sealing band for the runner was provided, and the leakage was measured with pressure from an outside source.

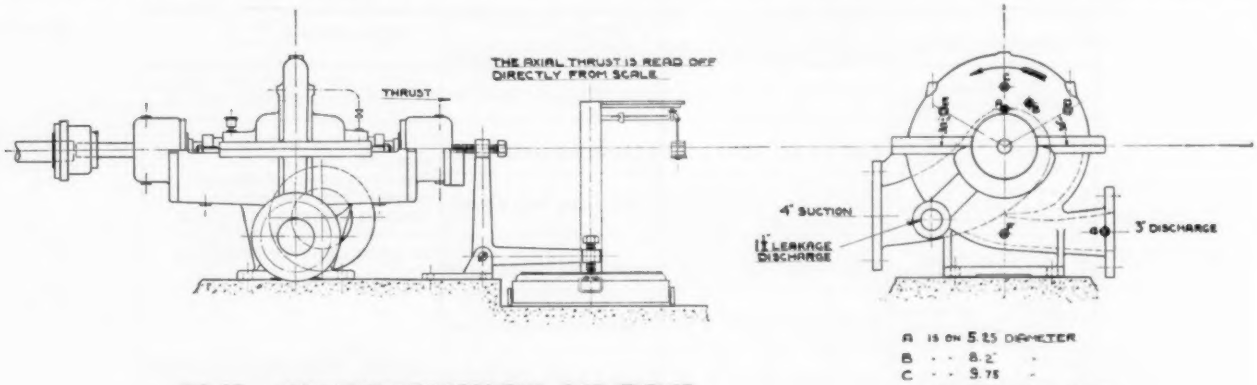

FIG. 32 ARRANGEMENT FOR MEASURING AXIAL THRUST

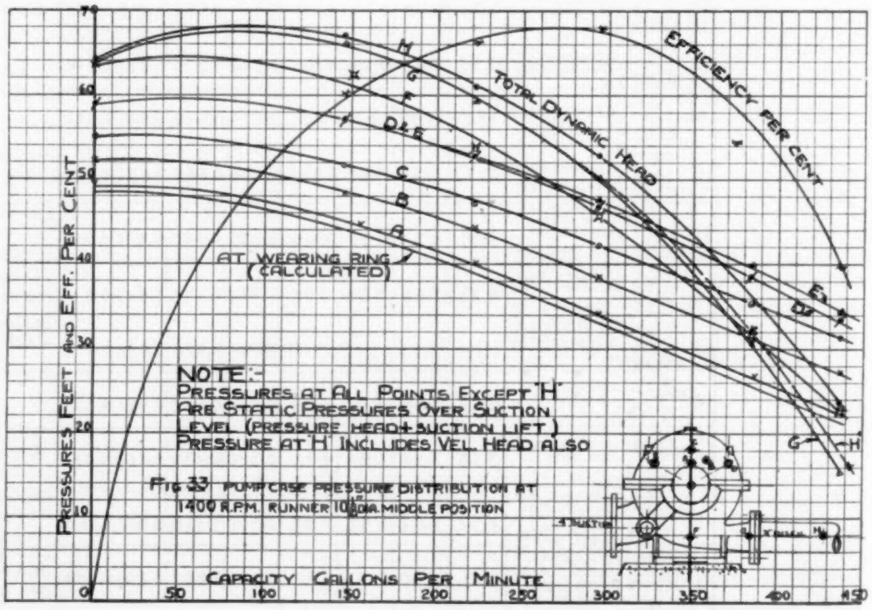

FIG 33 PUMP CASE PRESSURE DISTRIBUTION AT 1400 R.P.M. RUNNER 10 3/16" DIA. MIDDLE POSITION

To measure leakage through the wearing-ring clearances, a 3-in. single-suction pump was used, as shown in Fig. 30. To separate the leakage water from the main flow, a chamber was provided on the back side of the runner. This was separated from the pump case under discharge pressure by a close clearance. The diameter of the runner wearing ring on this side was the same as that on the suction side ($4^1/_8$ in. nominal). Leakage through the clearance between the wearing rings on the runner back was discharged through a $1^1/_2$-in. nozzle and weighed. It should be noted that the pressure difference across the wearing rings on the suction side of the runner is greater than that on the back of the runner because the pressure in the runner eye is smaller than that of atmosphere by the amount of the suction lift and velocity head. However, the results were plotted against pressure. For any suction lift and capacity the true leakage could be obtained from these curves, as explained later.

The different wearing rings tested, with the percentage of leakage, are tabulated in Fig. 31. To compare the effects of a labyrinth and the width of the wearing ring on leakage through the same clearance, different sizes were obtained by cutting the same ring by $^3/_{16}$-in. steps. To find the leakage through different clearances, five rings were made of the same width and with clearances from 0.010 to 0.040 in. nominal (the actual dimensions are given in Fig. 31, wearing rings Nos. 6 to 10). To study the effect of circular grooves on the coefficient of discharge, the grooves were cut on the rings previously tested, in order to assure the same radial clearance. The effect that the spiral grooves on the runner wearing rings had on the resistance to the flow was tested by using two rings, one with single thread and another with triple thread (higher pitch). Both were tested with two radial clearances. The direction of the spiral grooves was such that, when revolving, they produced a pumping effect from the leakage chamber into the pump case.

To study the pressure distribution in the pump case, eight taps, *A* to *H* inclusive, were made in the pump-case walls, as shown in Figs. 30 and 32. Tap *A* was drilled as close as possible to the runner wearing ring. Taps *B* and *C* were drilled on 8.2 in. and 9.75 in. diameters. Taps *D, E,* and *F* were drilled on the volute case 120 deg. apart and opposite the widest part in the volute section, which is approximately on the same diameter as the center of gravity of the section. Tap *F* was drilled near

the beginning of the nozzle, or volute throat. Tap *G* was located at the discharge flange. Tap *H* was drilled on the discharge pipe 18 in. from the discharge flange.

The primary purpose of the study of the pressure distribution was to obtain, from the pressure in the volute case or total pump head, some means of estimating the pressure near the wearing rings and to check the theoretical formulas given for this purpose. However, the results were rather unexpected and proved to be of importance in other respects, as discussed in Section 9.

The pressures were measured with mercury manometers and calibrated pressure gages. All eight taps for measuring pressures at different points in the pump case were connected into one manifold with necessary cocks allowing the pressures at all points to be measured with the same pressure gage. The capacity was measured with a 90-deg. V-notch weir calibrated against a measuring tank. A General Electric-Sprague dynamometer was used for driving the pump and for measuring the pump power input. All tests were made at four speeds, 1400, 1700, 2000, and 2500 r.p.m., with the runner $10^1/_8$ in in diameter, and at 1700, 2000, 2500, and 3000 r.p.m., with the runner cut to $8^1/_2$ in. in diameter.

9 Discussion of Results—Pressure Distribution in the Pump Case

The results of pressure measurements in the pump case with the $10^1/_8$ in. runner diameter and at 1400, 1700, 2000, and 2500 r.p.m. speeds are shown in Figs. 33 to 36. The pressures at points *A* to *G*, inclusive, are static pressures above the pump-suction level or pressures in the case plus the suction lift. The curves for *H* include the velocity head and are the total or kinetic head of the pump. The nearest point to the wearing ring where the pressure could be measured was point *A* on the 5.25 in. diameter, the diameter of the wearing ring being 4.125 in. To find the pressure at the ring, the pressures at the points *A*, *B*, and *C* were plotted on the diameters as abscissas, and by extrapolation the pressure on the 4.125 in. diameter was obtained. Such curves for pressures at normal pump capacity are shown in Fig. 37. It will be noted that the pressure curves become quite flat for small diameters below 5 in., showing that pressure is almost uniform in that portion of the case. The pressures obtained in this way for the 4.125 in. diameter are shown also in Figs. 33 to 36, and are marked "calculated."

From the study of these curves several points should be noted, as follows:

(*a*) For capacities below the normal the pressures are increasing from *A* to *H*, the maximum pressure being on the discharge pipe. But for capacities over the normal the curves rearrange themselves, so that pressures at *G* and *H* are less than at any other point in the volute case. Pressures at *H* are slightly higher than at *G* (static pressures at *H* are shown by the dotted line H^1). Pressure curves for *A*, *B*, *C*, *D*, and *E* have the same relative position as at partial capacities. This result was rather unexpected, as it is a general belief that the maximum pressure is always at the discharge flange. This picture shows that pressures generated by the runner are considerably higher than those obtained at the discharge nozzle for capacities over the normal. These pressures, however, are not available at the discharge flange. The reasons for this are found in the case design. Assuming, for the sake of simplicity, that water enters the runner radially, then the theoretical head produced by the runner is equal to

$$H_t = u_2c_{2u}/g \qquad [21]$$

where u_2 is the peripheral velocity of the runner at the outlet and c_{2u} is the tangential component of the absolute water velocity at discharge from the runner, as shown in the velocity triangle at the discharge (Fig. 38). β_2 is the vane angle, w_2 the relative velocity of water, and α_2 is the angle between absolute and peripheral velocities. The volute case is designed so that the volute angle conforms to the absolute velocity angle α_2 at the normal capacity. At capacities over the normal the angle α_2 increases with the capacity, and the velocity triangle takes the form *ABC'*, the angle α_2 being changed to α_2'. While at the normal capacity the discharge from the runner immediately in front of the lip is approximately in the direction of the main flow in the volute (Fig. 39), at capacities over the normal the angle α_2 is increased so that the discharge from that portion of the runner is directed across the flow in the volute (Fig. 40). The effect of this is that (1) the nozzle is cut off from the pump case by the high-velocity stream and the pressure from the pump case cannot be transmitted through it, and (2) a dead space filled with turbulent water is formed behind the lip in the pump nozzle extending a considerable distance into the discharge pipe. This makes the actual velocities higher than those corresponding to the areas, and consequently makes the pressures lower. This explains why the pressure at the pump discharge flange is lower than that in the discharge pipe 18 in. from the flange at capacities over the normal. The turbulence and shock at this place in the pump case incur a great loss of pressure. The pressures at *G* and *H* are lower than those at *E*, *D*, and *F*, but since the velocities at *E*, *D*, and *F* are higher than at *G* and *H*, the reverse should be the case, as some pressure recovery should take place in the nozzle. Thus it is seen that not only is no pressure recovered in the nozzle against the pressures *E*, *D*, and *F*, but also that some pressure present at *F* is lost in the nozzle. This makes the shape of the head-capacity curve drop rapidly after the maximum efficiency point.

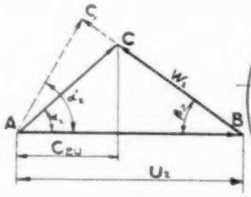

Fig. 38 Increase of Discharge Angle with Capacity.

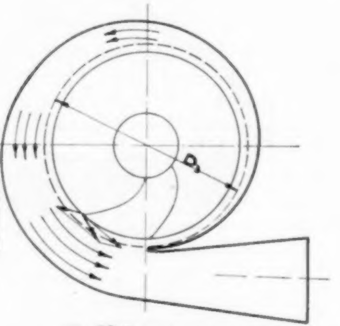

Fig. 39 Flow at Nozzle Throat at Normal Capacity.

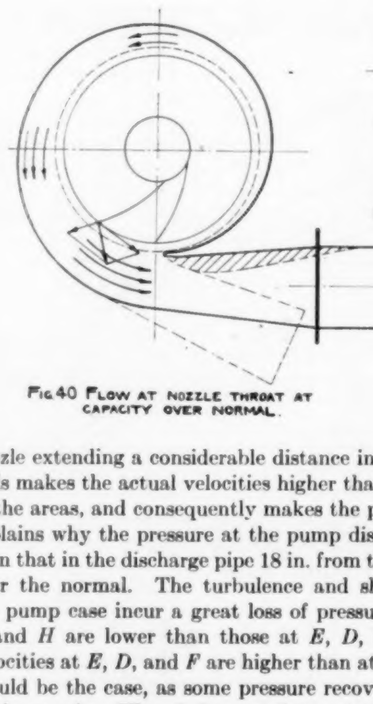

Fig. 40 Flow at Nozzle Throat at Capacity over Normal.

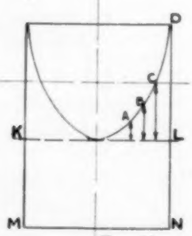

Fig. 41 Decrease in Pressure Due to Rotation.

It seems that conditions can be improved if the nozzle is turned through an angle as shown by the dotted line of Fig. 40. Higher heads can be obtained at the discharge flange, and efficiencies can be improved for capacities over the normal. Another way to make the head generated by the runner available at the discharge flange is to bring the main flow in the volute further out from the runner—i.e., to put the volute sections on a larger base circle. In this connection it should be noted that with a circular case the head capacity curve is considerably flatter than with a volute case.[25] The efficiency curve is also flatter.

(*b*) Refer to the pressures at D, E, and F, which are 120 deg. apart. F is near the nozzle throat (Fig. 32). The taps at these points are approximately opposite the center of gravity of the volute sections. It will be noticed that pressures at D and E are the same for capacities smaller than the normal, and that the pressure at E is greater than that at D for capacities larger than the normal. This difference may be explained by the fact that E is on a larger diameter than D, which makes the average peripheral velocity of water particles and the head produced higher for E than for D. At partial capacities not all the water in the volute case is discharged through the nozzle; part of it is circulated in the pump case, which equalizes the difference in pressure at different points in the volute. The pressure at F is higher than at D and E at partial capacities and lower at capacities over the normal. The pressure at F is lower than that at G and H at partial capacities and higher at capacities considerably greater than the normal. This means that at partial capacities there is a pressure recovery in the nozzle, but at capacities over the normal no pressure recovery takes place in the nozzle. There is, rather, a loss of pressure available at F.

(*c*) The important point to note, now, is that the pressure lines D, E, and F intersect practically at one point and that this point is the point of maximum efficiency. This indicates that at this point there is a constant pressure in the volute case and that the runner is discharging against the same pressure at all points. Hence, there is no unbalanced reaction from the volute case (side pressure) on the runner. The aim of a good design is to proportion the volute sections so as to get a uniform velocity and a constant pressure in the volute case. However, for capacities under and over the normal this balance is destroyed; the pressure varies along the volute case. The velocities vary, also, and there is a side thrust from the volute case on the runner. If the shaft is not strong enough, the deflection may become more than the running clearance between the wearing rings, and the runner will rub against the case wearing rings. Again, the difference in the volute pressure affects the runner performance so that the runner discharge varies as it passes the points of different pressure in the volute, causing pulsating flow and a lowering of efficiency.

(*d*) By inspecting the pressure curves for points A, B, C, D, and E, it will be noticed that they differ from each other by an amount approximately constant for the whole head-capacity range, so that the pressures at A, B, and C can be expressed in terms of the pressure in the pump case by a formula

$$H_a = H_v - \varphi^2 \frac{u_2^2 - u_a^2}{2g} \quad \ldots\ldots\ldots\ldots\ldots [22]$$

where H_v is the volute pressure, H_a is the pressure at A, u_2 is the peripheral velocity of the runner at discharge, u_a is the peripheral velocity corresponding to a diameter at A, and φ is a coefficient to account for the difference in angular velocity of the runner and of the water in the space between the runner and the pump case. This equation is obtained in the following manner: If water in an open cylindrical vessel is set in rotation with an angular velocity constant for all points, we have a forced vortex. The water surface will take the form of a paraboloid of revolution (Fig. 41). Water at point D will be higher than at point O by a distance $u_d^2/2g$, where u_d is the peripheral velocity of water at D, equal to ωr_d, ω being the angular velocity of rotation and r_d the radius at D. Similarly, point C on the surface is $u_c^2/2g$ over point O. If water is rotated with the same angular velocity in a closed cylindrical vessel (*KLMN*, Fig. 41), no paraboloid of revolution can be formed, but pressures will be produced equal to $u_d^2/2g$, $u_c^2/2g$, etc., at the points with radii r_d, r_c, etc. The pressure difference between points D and C will be $(u_d^2 - u_c^2)/2g$. In a pump, assuming that the pressure at the runner discharge is the same as in the volute H_v, the pressure difference between the point D in the volute (or at the runner periphery) and the point C will be $(u_2^2 - u_c^2)/2g$. Since the pressure at the runner discharge is H_v, that at C is equal to $H_v - (u_2^2 - u_c^2)/2g = H_c$. Since the angular velocity of water in the space between the runner and the case walls is lower than that of the runner, a coefficient φ is introduced, so that if ω is the runner angular velocity, that of water outside the runner will be $\varphi\omega$, and the formula for the pressure at the point A becomes

$$H_a = H_v - \varphi^2(u_2^2 - u_a^2)/2g$$

Calculating φ for the point A at 1400, 1700, 2000, and 2500 r.p.m., the following values, respectively, were obtained:

$$\varphi_a = 0.548,\ 0.559,\ 0.552, \text{ and } 0.557$$

The same for the point B are:

$$\varphi_b = 0.648,\ 0.681,\ 0.665, \text{ and } 0.667$$

Those for the point C are:

$$\varphi_c = 1.09,\ 1.205,\ 1.18, \text{ and } 1.17$$

It is seen that the value of φ is practically the same for each point at different speeds, but varies considerably from point to point, and for the point C it is greater than unity, which is impossible. The cause of this lies in the inaccuracy of the formula, which presupposes that the pressure in the volute case is the same as that at the runner discharge (substituting for u_a the value of u_2, the pressure H_a becomes equal to H_v). The latter is really lower, because the velocity in the volute case is considerably lower than the absolute velocity of discharge from the runner, and a recovery of pressure takes place after water leaves the runner. Again, the head produced by a runner depends to a certain extent on the dimensions of the volute case (mean radius). It is higher if the same volute sections are put on a larger base circle, since a forced vortex is formed of a larger diameter and the head produced is higher.

The values of φ can be brought to a closer agreement if instead of using u_2^2, which corresponds to the runner diameter, a value is substituted which corresponds to the diameter of a circle tangent to the volute-case lip (D_3, Fig. 39). For the pump tested, this diameter is equal to $11^3/_4$ in. On substituting for u_2 the value of the peripheral velocity u_3 (corresponding to D_3), the values of φ vary from 0.456 to 0.488 for all speeds and all points, the average value being 0.467.

The pressure distribution in the pump case with the runner cut to $8^1/_2$ in. is of the same character as that for full diameter, as is seen from Fig. 42, which is for 2500 r.p.m. Similar results were obtained for 1700, 2000, and 3000 r.p.m. The values of φ obtained from these tests with $8^1/_2$ in. diameter runner are as follows: For point A, 0.418; for B, 0.394; for C, 0.372. These values of φ are constant for all speeds.

Figs. 43, 44, and 45 show the pressure distribution in the pump case for a $10^1/_8$-in. runner with six radial ribs on the runner back $^3/_{16}$ in. high and 8 in. from tip to tip. The general arrangement of the pressure curves with respect to each other is similar to those discussed. The pressure drop between the points *A*, *B*, *C*, and *D* is greater than in the previous tests. This is to be expected, as the angular velocity of rotation of water between the runner and the case walls is greater. The average value of the coefficient φ for the point *A* is 0.632, for *B* it is 0.568, and for *C* it is 0.512. These values of φ are constant for all speeds. The variation of the coefficient φ shows that water is revolving with different angular velocities at different radii, which is probably due to the fact that the radial ribs do not extend to the runner outside diameter.

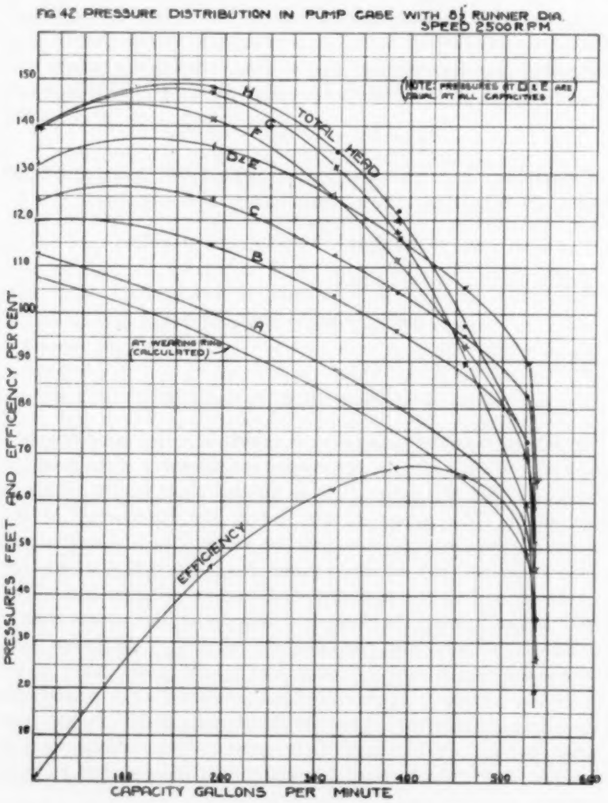
10 PRESSURE AT THE WEARING RING

The purpose of the study of the pressure distribution in these tests is to find the means of calculating or estimating the pressure near the wearing ring from the pump total head or volute pressure, knowing that it will be possible to calculate the leakage through the clearance between the wearing rings if the coefficients of discharge for various types of wearing rings are available. It is hardly possible to find a relation between the pressure in the volute case, or pump total head, and the pressure at the wearing ring for the whole head-capacity curve, as these vary for different capacities in different ways. Fortunately for the normal capacity, the pressures at different points in the volute become equal. This point is of most interest to the designer as it is the point of maximum efficiency.

FIG 42 PRESSURE DISTRIBUTION IN PUMP CASE WITH 8½" RUNNER DIA.
SPEED 2500 R P M



(*a*) *Pressure at the Wearing Ring in Terms of Total Head.* From these experiments it was found that the pressure at the wearing rings at normal capacity bears a certain relation to the total head which is constant for all speeds and is not affected by the runner cuts. This ratio for the pump tested is 0.63. Knowledge of such a factor, which will be denoted by K_r, provides the simplest way of determining the pressure at the rings. It probably will vary slightly with the diameter of the volute base circle, and to a smaller degree with the diameter of the wearing rings.

(*b*) *Pressure at the Wearing Ring in Terms of Volute Pressure.* The volute pressure can be expressed in terms of the theoretical head and the hydraulic efficiency:

$$H_v = H_t e_h - \frac{(c_2^2 - c_1^2)}{2g} \qquad [23]$$

where H_t is the theoretical head, e_h is the hydraulic efficiency, and c_2 and c_1 are, respectively, the absolute velocity of discharge from and entrance to the runner. The disadvantage of this method is that it involves the hydraulic efficiency, which is not known. The only information available about it is that it should be less than unity and greater than the overall pump efficiency. Also, the true value of c_2 is not known. The value of c_2 as given by the theoretical triangle of velocities at discharge is considerably higher than the actual value, as has been shown by many investigators.

It seems that a more convenient and more accurate way to determine the volute pressure is from the actual pump total head which is known, by assuming the nozzle efficiency. This will enable us to find the pressure at the nozzle throat, which is equal to the volute pressure at normal capacity. The pressure at the nozzle throat is calculated from

$$H_d - H_v = K_n \times (V_n^2 - V_d^2)/2g \qquad [24]$$

where H_d is the pressure at the discharge flange, H_v is the pressure at the nozzle throat and volute, V_d is velocity at the discharge flange, V_v is the velocity at the nozzle throat, and K_n is the nozzle efficiency. The average value of the nozzle efficiency calculated from these tests is 0.60 for a nozzle length of $8^1/_2$ in. and a ratio of areas of 2.15. The advantage of this method is that it contains only one constant, which can be easily found, or very closely estimated, for any pump.

Using this expression for the volute pressure, the formula for the pressure at the wearing rings becomes:

$$H_L = H_d - K_n(V_v^2 - V_d^2)/2g - \varphi^2(u_2^2 - u_r^2)/2g \qquad [25]$$

where H_L is the pressure at the wearing ring and u_r is the peripheral velocity of the runner wearing ring.

For calculation of the leakage through the clearance between the wearing rings into the runner suction, the pressure H_L should be corrected for the velocity head in the runner eye, since the pressure in the runner eye is lower than the suction lift by the velocity head.

(*c*) *H_L as Function of Peripheral Velocities u_2 and u_1.* For calculation of the pressure at the wearing ring for normal capacity a simple approximate relation can be deduced which gives results with sufficient accuracy for all practical purposes. The fundamental formula for the head developed by the runner:

$$H = \frac{u_2 c_{u2} - u_1 c_{u1}}{g} \qquad [26]$$

can be transformed by using the trigonometric relations between the component velocities from the discharge and entrance triangles into

$$H_t = \frac{u_2^2 - u_1^2}{2g} + \frac{w_1^2 - w_2^2}{2g} + \frac{c_2^2 - c_1^2}{2g} \qquad [27]$$

where the factors designated by *u* are the peripheral velocities, *w* the relative velocities and *c* the absolute velocities; the subscript ($_1$) refers to the entrance and subscript ($_2$) to the discharge.

In this formula the first two terms represent the pressure head

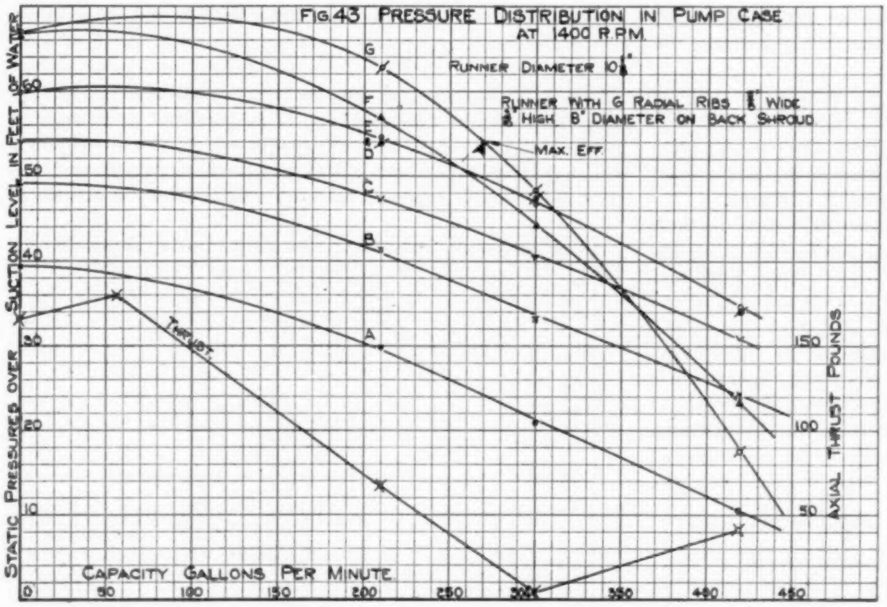


FIG. 43 PRESSURE DISTRIBUTION IN PUMP CASE AT 1400 R.P.M.

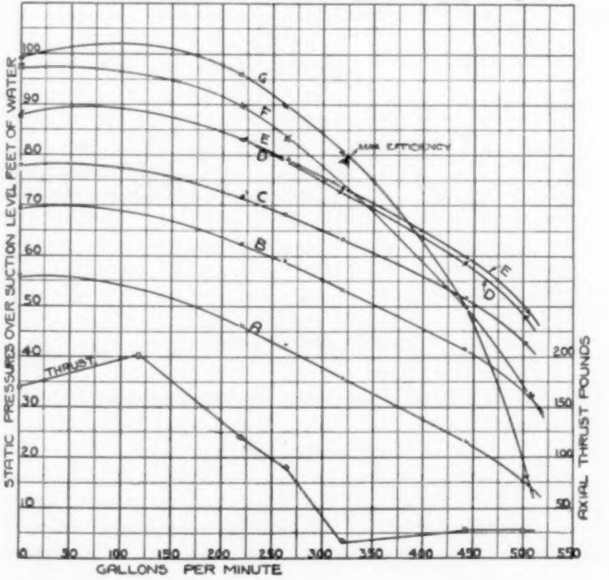
FIG. 44 PRESSURE DISTRIBUTION IN PUMP CASE AND AXIAL THRUST AT 1700 R.P.M. RUNNER WITH 6 RADIAL RIBS ⅝" WIDE 3/16 HIGH 8" DIAMETER ON THE BACK SHROUD. RUNNER DIA 10⅛"



and the last term the velocity head. Since the pressure at the wearing ring depends upon the pressure at the runner discharge, the first two terms need be considered only. Due to rotation of the water particles in space between the runner and case walls this pressure is reduced by an amount

$$\frac{\varphi^2(u_2^2 - u_r^2)}{2g} \ldots\ldots\ldots\ldots\ldots\ldots [28]$$

where u_r is the peripheral velocity of the runner wearing ring.[26] Then for the pressure at the ring we get:

$$H_L = \frac{u_2^2 - u_1^2}{2g} + \frac{w_1^2 - w_2^2}{2g} - \frac{\varphi^2(u_2^2 - u_r^2)}{2g}$$

This expression can be simplified, as in a modern pump of good efficiency w_1 is equal or slightly greater than w_2, and the term $(w_1^2 - w_2^2)/2g$ is always positive and small enough to be omitted. The dropping of this term will partly account for the hydraulic losses in the runner passages. An assumed value of 0.50 for φ is very close to the value observed in these tests. Another approximation will be made by taking u_r, the peripheral velocity of the runner wearing ring, equal to u_1, the peripheral velocity of the runner eye. The formula takes a very simple form:

$$H_L = \frac{u_2^2 - u_1^2}{2g} - \frac{1}{4}\,\frac{(u_2^2 - u_1^2)}{2g}$$

$$= \frac{3}{4}\,\frac{(u_2^2 - u_1^2)}{2g} \ldots [29]$$

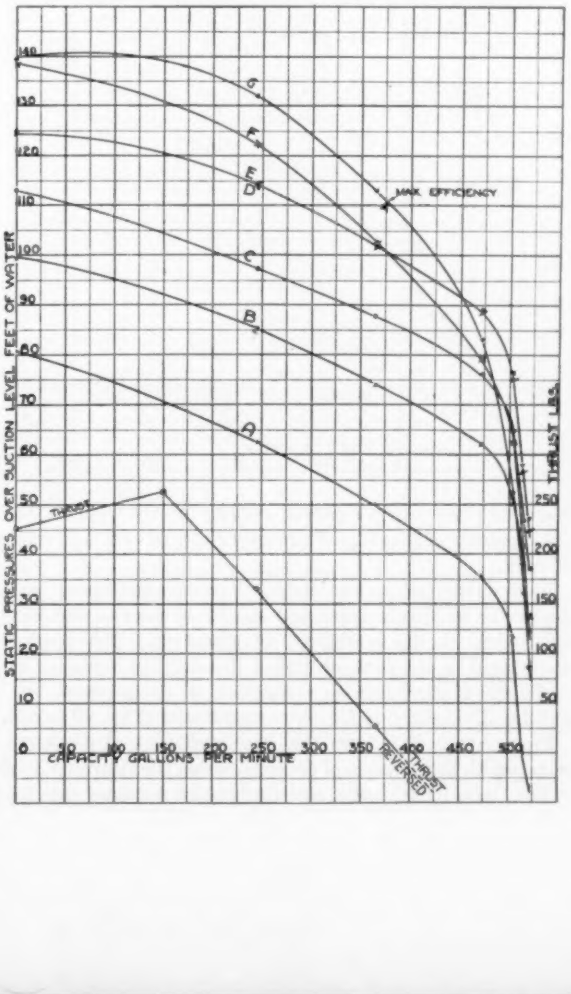
The values of H_L as calculated by this formula and actually measured are given in the following table:

Runner diameter	$10\frac{1}{8}$ in.				$8\frac{1}{2}$ in.	
Speed, r.p.m.	1400	1700	2000	2500	2000	2500
H_L, calculated feet	36.8	54.7	75.8	119.0	49.0	76.2
H_L, measured feet	36.0	55.0	76.0	120.0	49.0	73.0

11 Leakage Loss

For the sake of comparison of the relative advantages of

FIG. 45 PRESSURE DISTRIBUTION IN PUMP CASE AT 2000 RPM RUNNER 10⅛ D WITH 6 RADIAL RIBS ⅝" WIDE 3/16" HIGH AND 8" DIA ON BACK SHROUD



---

[26] Because the substitution of u_3 for u_2 has only small effect on the value of φ at small diameters, u_2^2 is used here for convenience.

different rings and the use of results of the test for calculation of the leakage for any wearing ring diameter and clearances, the following formula has been adopted:

$$Q_L = CD_r s\pi \sqrt{(2gH_L)}$$

where Q_L is the amount of leakage per second, D_r is the diameter of the wearing ring, s is the radial clearance, H_L is the head across the clearance, and C is the coefficient of discharge.

From a measured leakage and pressure difference on both sides of the wearing rings, for each ring the coefficient of discharge C was calculated for four speeds, 1400, 1700, 2000, and 2500 r.p.m., which correspond to peripheral velocities u_r of the runner wearing ring equal to 25.2, 30.6, 36.0, and 45.0 ft. per sec., respectively. With a very small value of the radial clearance, in comparison to the wearing ring diameter, the curvature of the ring should have very little, if any, effect on the coefficient of discharge. Thus the results of these tests can be extended for any ring diameter or speed, the choice of the coefficient of discharge depending only upon the type of the ring, the clearance, and the peripheral velocity of the runner ring u_r. The diameter of the ring affects only the area and the peripheral velocity.

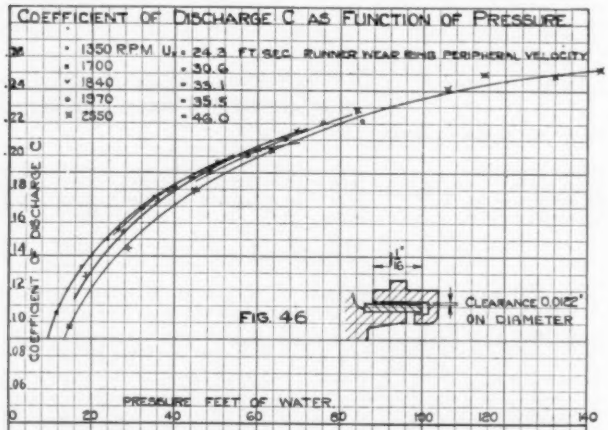


FIG. 46

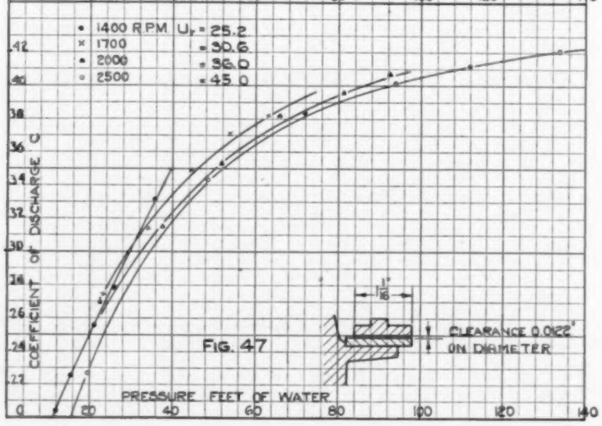

FIG. 47

In the rings where two radial clearances are found (such as stepped or labyrinth rings), the smaller of the two was used for calculation of the coefficient of discharge. The results are represented in the form of curves showing the variation of the coefficient of discharge as a function of the pressure for four peripheral velocities u_r for every ring tested (Figs. 46 to 65).

From curves it is seen that the coefficient of discharge increases with the increase of pressure across the clearance, rapidly at first, then more slowly, and almost at a constant rate for the higher pressures. The reason for this is the fact that the formula:

$$Q_L = CA \sqrt{(2gH_L)}$$

where $A = \pi D_r s$, assumes that the resistance to the flow, or drop of pressure across the clearance, is proportional to the square of the velocity; while, as in the case of the pipe flow, the power is less than 2, approximating 2 as a limit for very rough surfaces. The difference in exponent is compensated for by a change in the coefficient C, as is seen from the following modification of the formula:

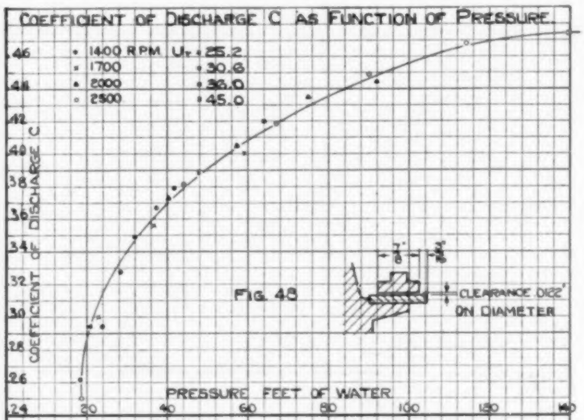

FIG. 48

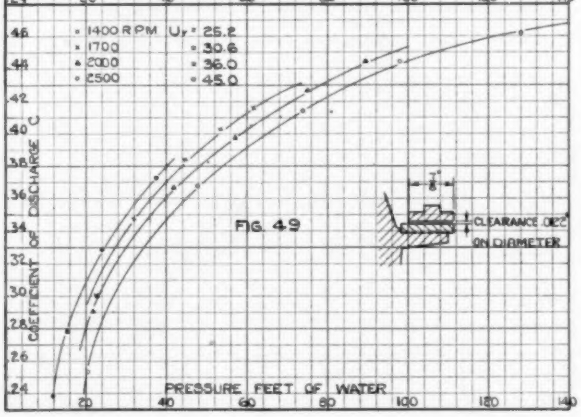

FIG. 49

$$Q_L = CA\sqrt{(2gH_L)}$$

or, dividing by A:

$$V = C \sqrt{(2gH_L)}$$

where V is the mean axial component of the velocity through the clearance space.

Then:

$$V^2/2g = C^2 H_L$$

or

$$H_L = 1/C^2 \; V^2/2g$$

The true fractional exponent of the velocity is not convenient for practical use, since it depends on surface conditions. It is customary to use the second power and a variable coefficient. Thus, it is seen that, as the pump pressure increases, the leakage increases faster than the square root of the pressure across the clearance.

The increase of the coefficient of discharge with pressure may seem contradictory to the general results obtained with sharp-edged orifices, where the coefficient of discharge always decreases with an increase in pressure.[27] The discrepancy is, however, apparent only, and can be explained by the difference in conditions in both cases. In the case of a sharp-edged orifice the coefficient of discharge is composed of the two parts $C = C_cC_v$. One, C_c, is a coefficient of contraction (the contraction occurs on all sides in this case), and C_v is a velocity coefficient which accounts for the resistance to the flow presented by the orifice. The coefficient of contraction decreases with an increase in pressure. The velocity coefficient increases with an increase in pressure from 0.96 to 0.994 according to Weisbach, but not enough to counterbalance the decrease in the coefficient of contraction; hence the coefficient of discharge decreases with an increase in pressure. The increase of the coefficient of velocity in the case of a sharp-edged orifice is due to the fact that the formula assumes that the pressure drop is proportional to the second power of the velocity, whereas the true exponent is slightly less than 2. Thus the decrease of the coefficient of discharge is due to a predominance of the coefficient of the contraction over the velocity coefficient. In the case of the flow through clearances between the wearing rings, the reverse is true. The coefficient of contraction is of less importance, since the contraction is incomplete. Due to projection of the runner wearing ring beyond the case wearing ring at entrance, the contraction is on one side only. At the same time the resistance to the flow is considerably greater than in the case of a sharp-edged orifice; hence the coefficient of discharge for the flow through the clearance between the wearing rings increases with higher pressures.

[27] A. H. Gibson, "Hydraulics," 1925.

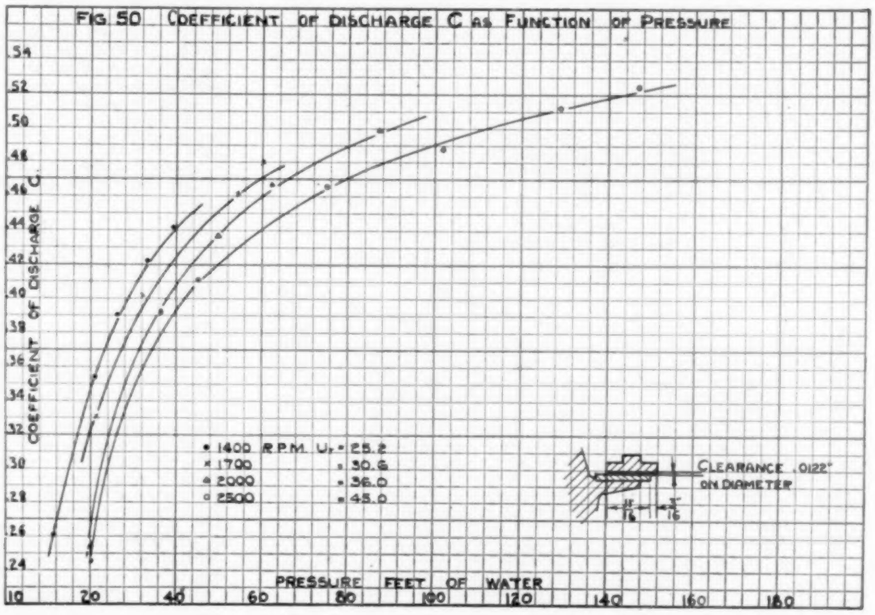

FIG. 50 COEFFICIENT OF DISCHARGE C AS FUNCTION OF PRESSURE

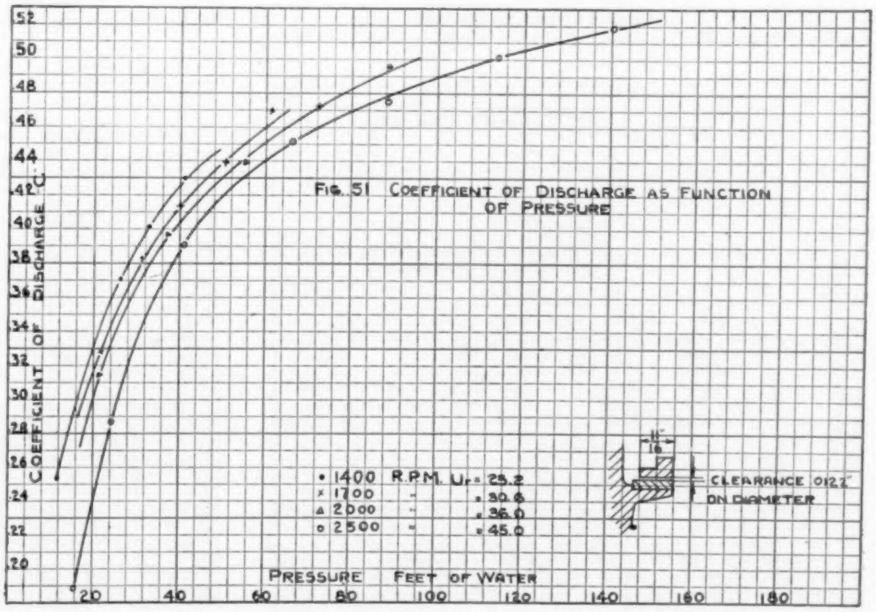

FIG. 51 COEFFICIENT OF DISCHARGE AS FUNCTION OF PRESSURE

Since the pressure in the chamber on the back side of the runner (where the leakage was measured) was equal to that of the atmosphere, and the pressure in the runner eye was below atmospheric pressure by the amount of the suction lift and velocity head in the runner eye, the leakage measured was smaller than the leakage on the suction side of the runner. From measurements of suction lift and pressure at the wearing rings for each capacity, which have been plotted above the suction pressure of the pump in Figs. 46 to 65, the leakage on the suction side of the runner could easily be calculated. These calculations were made for all rings tested at four speeds and the pump normal capacity, and the results are tabulated in Fig. 31, where the leakage is expressed as percentage. From this table it is seen that the leakage loss varied from 1.52 to 20.0 per cent.

From the curves in Figs. 46 to 65 it is seen that for the same pressure the coefficient of discharge decreased slightly as the peripheral velocity of the runner ring increased (increase in r.p.m.). This was probably due to the fact that the mean absolute velocity of the flow through the clearance was greater for greater relative velocities, causing the resistance to the flow to become greater and the coefficient of discharge to become smaller. The effect of the relative velocity on the coefficient of discharge varied slightly for different wearing rings; the general trend was, however, the same for all of them—that is, toward a higher coefficient of discharge for lower speeds.

To study the effect on the coefficient of discharge of the width of the wearing ring, different radial clearances and various resistances in the form of grooves, turns, sudden enlargement of area, etc., it is convenient to choose the points of comparison with the same pressure across the clearance and the same speed. The points at normal head and capacity have been chosen for this purpose and the leakage in per cent of the normal capacity has been calculated and is given in Fig. 31, with the corresponding coefficients of discharge. give the normal head and capacity of the pump at different speeds with a runner of $10^1/_8$ in. diameter. The pressures across the clearance are also given. It is to be noted that these are 63 per cent of the pump total head for all speeds. The same ratio holds for the diameter cut to $8^1/_2$ in., indicating that this ratio is determined by the volute mean radius and the diameter of the wearing rings.

From the data in Fig. 31 it is seen that the percentage of leakage increases slightly for higher speeds. This is because the pump head and the pressure across the clearance increase as the square of the speed, while the capacity of the pump increases directly as the speed. Now, if the discharge through the clearance between the wearing rings were proportional to the square root of the pressure difference on both sides of the rings, then the percentage of leakage would be the same at all speeds, as the leakage would vary in the same ratio as the pump capacity. But since the flow through the clearance is proportional to the $1/n$ power of the head, where n is less than 2, the leakage increases faster than the capacity.

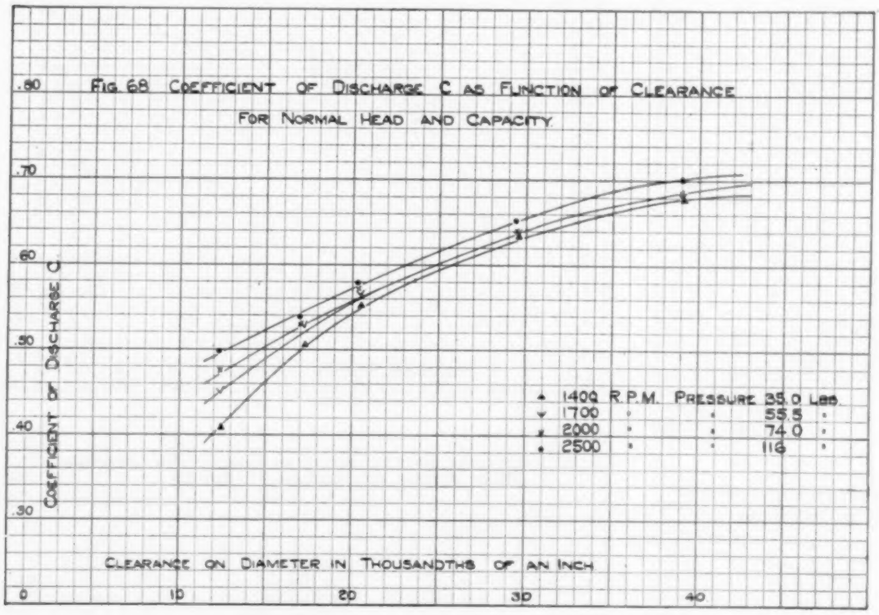

Fig. 68 Coefficient of Discharge C as Function of Clearance for Normal Head and Capacity

Referring to the rings Nos. 1 and 2 in the table, it will be noticed that cutting off the labyrinth increased the leakage from 41.0 to 46.6 per cent of its value with the labyrinth. In this ring the radial clearance on the smaller diameter was slightly greater than that on the large diameter. The overlap on the smaller diameter was $^3/_8$ in. The axial clearance was $^1/_{16}$ in.

Referring to rings Nos. 2, 4, and 6, it will be noticed that the leakage increased as the width of the ring was cut from $1^1/_{16}$ in. to $^{11}/_{16}$ in. A further cut to $^1/_2$ in. was tested, the results of which are not given in the table, but are given in Fig. 59. These are in agreement with those listed in the table. The coefficient of discharge plotted against width of the wearing ring for the points under consideration is given in Fig. 66.

Referring to rings Nos. 3, 4, 5, and 6, it is seen that projection of the runner ring against the case ring and vice versa has very little, if any, effect on the coefficient of discharge. However, in the case of the runner ring projecting outside the case wearing ring, the effect of the different runner speeds disappears (see Fig. 48). This is probably due to a slight pumping action of the projecting portion of the runner wearing ring.

By comparing the leakage for the rings Nos. 6, 7, 8, 9, and 10, the effect of the radial clearance can be seen. The percentage of leakage loss increased due to an increase of the discharge coefficient and an increase of the leakage area. The change of the coefficient of discharge with the clearance for the same points is shown in Fig. 68. It is seen that the rate of change increased for smaller clearances. The change of the coefficient of discharge with clearance can be explained as follows: As the clearance is decreased, the Reynolds number $R = dv/\nu$ (where d is the pipe diameter in the case of pipe flow or mean hydraulic radius for any other form of section, v is the mean velocity of flow, and ν is the kinematic viscosity) decreases for the same velocity of flow and the same liquid. Referring to the curve in Fig. 67, it will be seen that the coefficient of friction for pipe flow increases as the Reynolds number decreases; hence the coefficient of discharge will decrease, as the coefficient of resistance and the coefficient of discharge are related:

$$1 + f = 1/C^2$$

where f is coefficient of friction. This follows from

$$Q = CA\sqrt{(2gH_L)}$$

or

$$V = C\sqrt{(2gH_L)}$$

or drop in pressure

$$H_L = \frac{V^2}{C_2{}^2 g} = fV^2/2g + V^2/2g$$
$$= (1 + f)V^2/2g$$

It is interesting to note that with the rings set eccentrically (due to inaccuracy of machining or shaft deflection), although the clearance area remains the same, the leakage is smaller. This was observed several times during these tests. The reason for this fact is that the increase in coefficient of discharge in the portion with larger than the mean clearance is more than counterbalanced by the decrease of the coefficient of discharge for the portion of the ring with a clearance smaller than the mean clearance.

The effect of circular grooves is shown with rings Nos. 11, 12, and 13. The first one is ring No. 7, with three circular grooves cut $^1/_{16}$ in. wide, $^3/_{64}$ in. deep, and $^1/_8$ in. apart, and with the edges as they come from the lathe, bearing minute burrs, measuring not over 0.001 in. Ring No. 12 is the same as No. 11 with the burrs taken off but with sharp edges. It is seen that ring No. 11 shows a reduction in leakage from 32.2 to 35.5 per cent over ring No. 7. This reduction dropped to from 16.7 to 20.0 per cent after the burrs were taken off.

The advantage of circular grooves almost disappears for large clearances, as is shown by ring No. 13. With a radial clearance of 0.0294 in., the gain is only from 2.2 to 4.0 per cent.

Referring to rings Nos. 15, 16, and 17, it is seen that the spiral grooves reduce the leakage considerably. Compared to a ring without grooves, the leakage is reduced from 20.8 to 27.0 per cent with a single threaded ring and from 33.0 to 36.8 per cent with a triple (higher pitch) thread. The fact that the gain is considerably greater with the triple thread suggests that the reduction in leakage is not solely due to an increase in the resistance to the flow, but that actual pumping of the leakage water back to the case takes place. The effect of the spiral grooves is reduced with large clearances, but not to such an extent as in

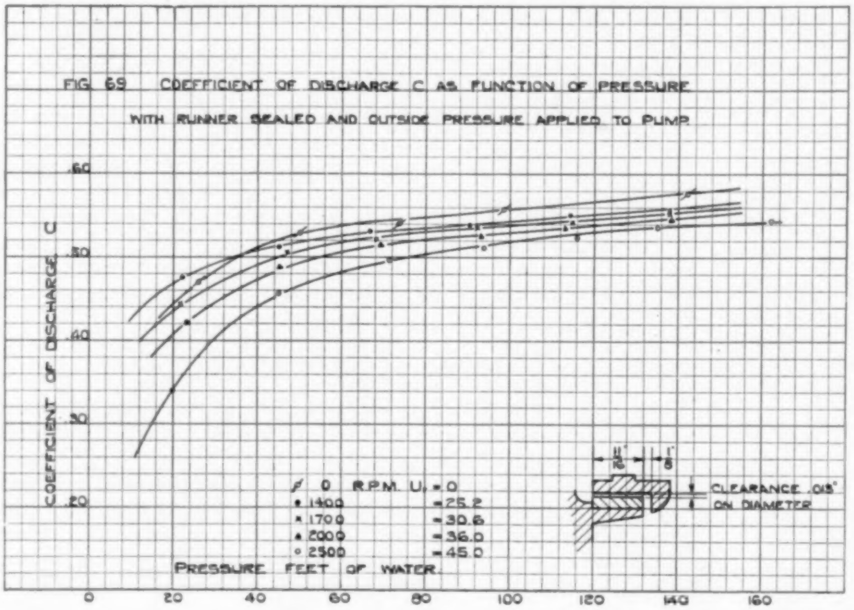

FIG. 69 COEFFICIENT OF DISCHARGE C AS FUNCTION OF PRESSURE WITH RUNNER SEALED AND OUTSIDE PRESSURE APPLIED TO PUMP

the case of the plain circular grooves. This is seen from the results with rings Nos. 18 and 19, the clearances being 0.0215 against a clearance of 0.0115 in. for rings previously referred to.

Although the spiral grooves show a decided advantage over plain circular grooves, the net gain is probably less than that given by the figures in the table, since, naturally, some power is required to pump the leakage by spiral grooves.

The figures for rings Nos. 15, 18, and 22 in the table are marked "calculated." By this is meant that no test has been made with the rings using the clearances specified for these rings in the table; the figures given were obtained for the sake of comparison by interpolating between the five clearances tested. However, these figures may be considered as accurate as the original.

The effect of a step in the wearing ring diameter may be seen from figures given for rings Nos. 20, 21, and 22. The reduction in leakage with a stepped ring against a plain one of the same width and clearance is from 24 to 33 per cent. Rings Nos. 20 and 21 differ in that in the first the runner wearing ring at the entrance projects $^3/_{16}$ in. against the case wearing ring. This ring shows a leakage loss slightly less than with the runner ring, the edges of which were flush with the edge of the case wearing ring.

A series of tests was made with outside pressure applied to the pump case, the runner outlet being sealed by a band. The runner was driven at 1400, 1700, 2000, and 2500 r.p.m. The coefficients of discharge were calculated and plotted in Fig. 69. Comparing these with the results given for the same ring with the pump's own pressure, it is seen that they are almost identical. These curves show that the direction of the curves for the coefficient of discharge at low speeds and high pressure, which could not be obtained with the pump's own pressure, is the same as that for 2500 r.p.m. The power required to drive the rotating element was independent of the pressure in the pump case and was lower than that at pump shut-off. The curves in Fig. 70 show the power required to drive the rotating element with the runner sealed, the power to pump the leakage at shut-off, and the sum of the two with the power at pump shut-off.

It will be noticed that the power at shut-off is considerably greater than that necessary to drive the rotating element with the runner sealed plus the power to pump the leakage. The difference is wasted by internal circulation and eddies in the pump case near the runner periphery. It should be noted that the power to drive the rotating element with no discharge varies as a certain power of the speed, the exponent for higher speeds being approximately 2.8 and for lower speeds about 2.25. This is due to the fact that at high speeds the disk friction, which varies as the cube of the speed (theoretically, the exponent found by experiment is slightly lower), is the main loss; while at lower speeds the friction in the stuffing boxes and bearings, which varies as the square of the speed, constitutes a greater portion of the total power than at the high speeds.

12 PROCEDURE FOR CALCULATION OF LEAKAGE LOSS

The following procedure is recommended for calculating the leakage loss. Usually pumps are designed and sold to operate at the normal head and capacity or at the maximum efficiency point. It is in the attainment of this end that the designer is mostly interested and for which he makes the analysis of losses due to various causes. Therefore, the procedure for calculation of the leakage at this point will be outlined:

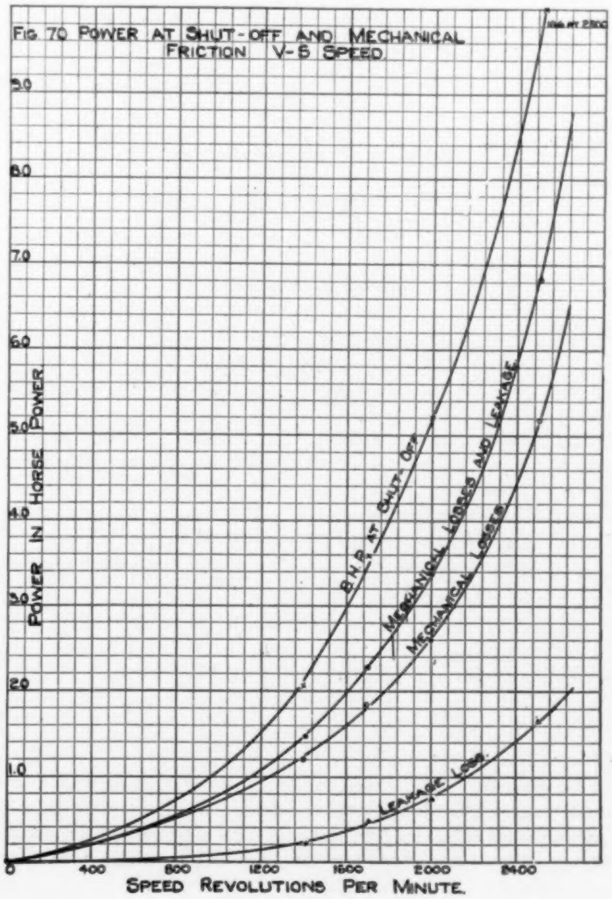

FIG. 70 POWER AT SHUT-OFF AND MECHANICAL FRICTION V-S SPEED

(1) Calculate the volute pressure from a given total head, estimating the efficiency of discharge nozzle, which in the case of the tested pump was 60 per cent. The volute pressure is calculated from

$$H_d = K_n(V_v^2/2g - V_d^2/2g) + H_v$$

where

H_d = the pressure at discharge flange, equal to $H_d = H - V_d^2/2g$
H = pump total head
V_v = velocity in the volute case
V_d = nozzle velocity at the discharge flange
K_n = efficiency of the nozzle.

(2) For the volute pressure thus obtained, calculate the pressure at the wearing ring from

$$H_L = H_v - \varphi^2(u_3^2 - u_r^2)/2g$$

For the tested pump φ was found to vary from 0.456 to 0.488.

If u_2 is used instead of u_3, the value 0.5 can be used for the coefficient φ.

As an alternative the pressure at the wearing ring may be calculated directly from the total head by estimating the factor K_r in the formula

$$H_L = K_rH$$

For the pump tested, this factor was 0.63 and did not depend upon the small variation of the runner diameter. For the analysis of the performance of existing pumps, the volute pressure and pressure at the wearing ring can be obtained by measurement, and the factors K_n and K_r can be calculated.

Probably the quickest way to calculate the pressure at the wearing ring is by using formula [29], Section 10:

$$H_L = \frac{3}{4}\,\frac{(u_2^2 - u_1^2)}{2g}$$

(3) Correct the pressure at wearing ring H_L for velocity head at the runner eye

$$H_L' = H_L + \frac{V_e^2}{2g}$$

where V_e is velocity through the runner eye.

(4) From a given speed and wearing ring diameter, calculate the runner wearing ring peripheral velocity u_r.

(5) For calculated u_r and a given type of the ring, choose the coefficient of discharge for the pressure across the wearing ring as found in (3).

If the design of the wearing ring is different from those for which the test data are available, use the data of the type nearest to it and increase or reduce the coefficient of discharge to correspond to the difference in design. For values of u_r not given in the data available, interpolate between the given values.

(6) With the coefficient of discharge and the pressure across the clearance found, calculate the leakage from

$$Q_L = CA\sqrt{(2gH'_L)}$$

(7) Calculate the volumetric efficiency

$$e_v = \frac{Q}{Q + Q_L}$$

Allowing in these calculations an error not greater than 5 per cent, and in a modern pump a leakage loss of not more than 5 per cent, the total error will be only 0.25 per cent of the pump's input. This is smaller than the error in measuring the input and the output of the pump.

PART II AXIAL THRUST

13 AXIAL THRUST IN CENTRIFUGAL PUMPS

WHILE in the double-suction pumps, due to symmetry of construction, the runner is balanced for the axial thrust, in the single-suction runners some means should be provided to take up the runner axial thrust. This thrust is due to the fact that the pressure in the pump case acts on a larger area on the back side of the runner than on the front side. This thrust is partly balanced by the force to the right, in Fig. 30, due to the change in momentum of the incoming water which results from the change in direction of the flow from the axial to radial.

$$\text{Force to right} = WV_e/g = AV_eV_e\gamma/g = 2A\gamma V_e^2/2g$$

where A is the runner-eye area, V_e is the velocity in the runner eye, γ is the density of water, and W is the weight of water per unit time.

Axial thrust may be taken up by a thrust bearing or it may be reduced or entirely eliminated by hydraulic means. The most widely used method of balancing axial thrust in the single-suction, single-stage pumps consists in providing another wearing ring on the runner back. In the chamber thus formed the suction pressure is admitted. The latter is obtained either by drilling holes through the runner web into the suction (Fig. 2) or by connecting this chamber by a pipe or a channel cast on the pump case to the suction nozzle. Thus, to balance the axial thrust, a portion of the pump capacity is sacrificed by allowing water to leak through an additional clearance. Concerning the amount of axial thrust, there is available no information checked by actual measurements. The difficulty in calculating the axial thrust lies in the fact that the pressure on the portion of the runner shroud opposite the suction is considerably smaller than that of the pump discharge or even the volute pressure, due to rotation of water in the space between the runner and the case walls. Sometimes runners are provided with the radial ribs on the back side of the runner to increase this rotation (see Fig. 12). To study the pressure distribution in the pump case, to measure the axial thrust of a single-suction pump, and also to investigate to what extent the axial thrust may be balanced by different means are the objects of this investigation.

The pressure distribution in the space between the runner and the pump case depends on the clearance between the runner and the stationary walls. The pressure is smaller for smaller clearances.[28] It is therefore important with small clearances to have the runner exactly in the middle position in the pump case, because otherwise, even in the case of a double-suction pump, there will be an axial thrust due to a difference in the angular velocity of rotation of water on the two sides of the runner. This was checked experimentally in the laboratory of the University of California by J. N. LeConte.[29] In modern pumps there is usually provided an ample clearance on both sides of the runner so that slight displacement of the runner from the middle position does not produce an axial thrust.

It should be noted that when holes are drilled through the runner hub to reduce the pressure in the balancing chamber on the back of the runner, the runner performance may be impaired by the flow through these holes directed against the main flow in the runner. The outside connections are to be preferred.

The pressure in the balancing chamber will always be slightly higher than in the runner eye, since some pressure is necessary to produce the velocity and to overcome the resistance through the balancing holes. Furthermore, since the flow into the runner is directed against the holes, the pressure in the chamber will be higher than that in the runner eye by the amount of the kinetic head of the flow impinging against the holes ($V_s^2/2g$); and if the diameter of the wearing ring on the back of the runner is the same as that on the front, the total force due to this head is equal to $AV_s^2/2g$, or equal to one-half of the force in the opposite direction, due to change in momentum of the flow into the runner. Hence, to obtain a perfect balance by means of the balancing chamber on the back of the runner, the diameter of the chamber should be larger than the wearing ring diameter on the suction side.

[29] J. N. LeConte, "Hydraulics," McGraw-Hill Book Company, 1926.

In the case of the open runners (Figs. 12 and 15), the axial thrust is still greater because the pressure on the suction side of the runner varies from suction pressure to discharge pressure, while on the opposite side there is a full volute pressure reduced only by rotation. To reduce the thrust with the open runners, a portion of the back shroud may be cut out (Fig. 15) without seriously affecting the pump performance.

In the vertical pumps the weight of the rotating element adds to the axial hydraulic thrust. This weight may become quite large in deep-well turbine pumps. It is possible to reduce the load on the thrust bearing by making the hydraulic thrust work against the weight of the rotating element, in which case the runners should be turned with the suction side upward.

In addition to what may be termed external sources of the axial thrust, there are internal causes. To these belong the following:

(*a*) The water reaction on the vanes set at an angle different from 90 deg. to the plane of rotation, as is found in the propeller of screw pumps and to a smaller degree in any mixed-flow, single-suction runner. This thrust is of the same nature as that on a ship propeller and is considerable for the large propeller pumps.

(*b*) The axial thrust caused by uneven pressure on the two runner shrouds inside the runner. The causes of the difference in pressure are the difference in the head produced along two stream lines near the shrouds due to a difference in the outside diameter, vane angularity (in mixed-flow runners), the length of the stream lines, and the difference in the radial velocities near the shrouds. Of these the uneven radial velocity is the most important, since in almost all pumps, except the pure-axial-flow pumps, water is turned through 90 deg. just near the points where it comes under the influence of the vane. The effect of the turn is twofold: (1) The pressure near the outer wall of the turn becomes higher than that near the inner wall, thus producing the thrust directed from the suction. This thrust is the same as that due to change of momentum of the incoming flow described before, and equal to WV_s/g. (2) The uneven velocity distribution. Now, since the diameter and the vane angle are the same for the two stream lines, the head produced by the vane is higher where the radial velocity is smaller, as is seen from the velocity triangle (Fig. 21). For a radial inlet the head produced is

$$H_t = \frac{u_2 c_{2u}}{g}$$

For a smaller radial velocity c_{2m}, the value of c_{2u} is greater; hence the head produced is larger. The thrust due to this cause is variable, depending on the pump capacity, since the velocity distribution in a 90-deg. turn depends upon the mean velocity of the flow and the radius of curvature. Under certain conditions this may be reversed, as discussed in detail in Section 4.

Because double-suction runners are symmetrical in construction, the thrust due to this last cause is absent. However, if for some reason the symmetry of the flow in a double-suction pump is destroyed, considerable axial thrust will result caused from inside of the runner. The most common cause for non-symmetrical flow in the runner is a non-symmetrical approach such as is found when an elbow is put next to the suction flange in the plane different from the plane of symmetry of the pump, as is usually the case when two pumps are operated in series.

(*c*) The cavitation, or local formation of vacuous spaces inside the runner, results in a heavy axial thrust. Depending on the runner profile and working capacity, these vacuous spaces may form at the vane entrance tips near the front or back shrouds; then the unbalanced pressures on the opposite shroud inside the runner produce axial forces. Owing to the character of the cavitation, the axial thrust caused by it varies considerably in magnitude and also may vary in direction.

It should be noted that in some instances a moderate axial thrust is desired to keep the rotating element from floating or whipping. Accordingly, it has been found that in the deep-well pumps the bearings wear less if the column shaft is running under tension due to thrust. Of course, this thrust must be provided for when selecting the thrust bearing.

14 AXIAL THRUST IN MULTI-STAGE PUMPS

In the case of multi-stage pumps the end thrust is of more importance on account of the higher pressures involved and the summation of the thrust of several stages. If the number of stages is even, the pump can be made inherently balanced by arranging runners in groups, with suctions in opposite directions. Due to symmetry of construction the pump is hydraulically balanced. But this scheme requires expensive pattern work. If the runners are arranged with suctions in the same direction, the stages may be cast separately and a pump with any required number of stages assembled, or the pattern may be made in sections and a one-piece casting may be made with the required number of stages. In both cases the thrust in all stages is in one direction, and special means should be provided to take care of this thrust.

The balancing of every runner by means of a chamber on the back of the runner and drilled holes through the runner web is secured in multi-stage pumps also. It takes much room in the axial direction, however; it increases the span between the bearings; it is expensive; and it tends to lower the pump efficiency.

The old and very effective methods of balancing a considerable thrust are the use of a balancing disk and a drum. Both methods sacrifice a portion of pump capacity to eliminate the thrust.

The balancing disk operates as follows: In Fig. 72 the thrust is to the right. A balancing chamber is provided on the back of the last stage runner, separated from the pump case by a disk keyed to the shaft. The disk rotates with the shaft, with a small clearance from the case wearing ring. The balancing chamber is connected to the pump suction or is vented to atmosphere. The pressure in the chamber can be regulated by a valve. If the pressure on the runner backs exceeds that on the disk, the disk is moved to the right, the clearance between the disk and the case wearing ring becomes smaller, and the pressure drops in the balance chamber until the pressure on the disk moves it to the left, making the clearance larger. Now the pressure builds up in the balance chamber, and the disk is moved to the right until an equilibrium is reached, when forces to the right balance those to the left.

Fig. 71 shows a balance disk with two active throttling surfaces floating between two fixed seatings with very slight clearance. If the pressure on the high-pressure side of the disk exceeds the axial thrust to the left, the piston moves to the right, increasing the clearance between the large wearing ring and the piston and

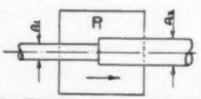

FIG. 74b END THRUST = $P_1(A_2-A_1)$

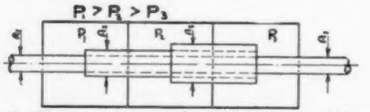

FIG. 74c END THRUST = $(P_1-P_3)(A_2-A_1)+(P_2-P_3)(A_3-A_2)$.

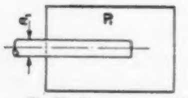

FIG. 74d END THRUST = P_1A_1

SIMPLE CASES OF THE END THRUST DUE TO SHOULDERS ON SHAFTS

decreasing the clearance between the small wearing ring and the piston. The pressure in the balance chamber builds up more quickly than in the case of a single throttling surface, and the rotating element is brought to a balance with a considerably smaller leakage than with a single-faced disk.

The disadvantages of this method of balancing are that (1) a portion of the pump capacity is wasted, (2) some power is consumed on the disk friction of the balancing disk, and (3) it requires a certain amount of axial play for the rotating element. The advantages are (1) the complete automatic balance (no thrust bearing is necessary), and (2) the elimination of the high-pressure stuffing box. The calculation of the amount of leakage in these balancing methods is complicated by the variation of clearances and pressures. However, the leakage can easily be measured. This kind of leakage will not be considered in this investigation. The balancing drum is used to reduce or eliminate small end thrust when the thrust bearing employed does not allow any axial play. It consists of a drum keyed to the shaft (Fig. 73) fitted with a small clearance in the case wall. The last stage pressure acts on one side of the drum, while the other side is under suction pressure. Thus a force to the right is obtained which will partly or completely balance the pump hydraulic thrust to the left. The pressure on the low-pressure side can be regulated. The disadvantages of this method are that (*a*) it is not automatic, (*b*) the pump may be perfectly balanced for one capacity and unbalanced for another, (*c*) the balance is destroyed after the clearance is increased on account of wear, (*d*) the greater span between bearings which results increases the tendency toward deflection and vibration, necessitating the use of a larger shaft.[30]

While multi-stage pumps with runners arranged in two equal groups with suctions in opposite directions are considered to be hydraulically balanced, this is true only for pumps with two stuffing boxes and with shafts of a constant diameter through the whole pump and runner hubs not extending through the walls separating the two adjacent stages. Usually the span between the bearings in multi-stage pumps is large and shafts are made heavier at the middle portion for strength. The shoulders on the shaft and the runner hubs produce axial thrust which may be considerable. It is probable that neglecting this fact has caused the failure of many high-speed pumps. The thrust capacity of ball bearings decreases rapidly with the speed of rotation. Multi-stage pumps running at 3600 r.p.m. are coming into general use now. Such pumps, to operate safely, must have axial pressures balanced as closely as possible in order to minimize end thrust.

To show how the end thrust for a pump with runners arranged back to back can be calculated, a few elementary examples will be considered which will illustrate clearly the principle involved. Fig. 74 shows several closed vessels filled with liquid under pressures P_1, P_2, and P_3 above atmosphere, and shafts pass through the walls of these vessels of diameters D_1, D_2, and D_3 and areas A_1, A_2, and A_3, respectively. The end thrusts are calculated, the direction being shown by arrows. Now consider a four-stage pump with runners arranged as shown in Fig. 75. Let

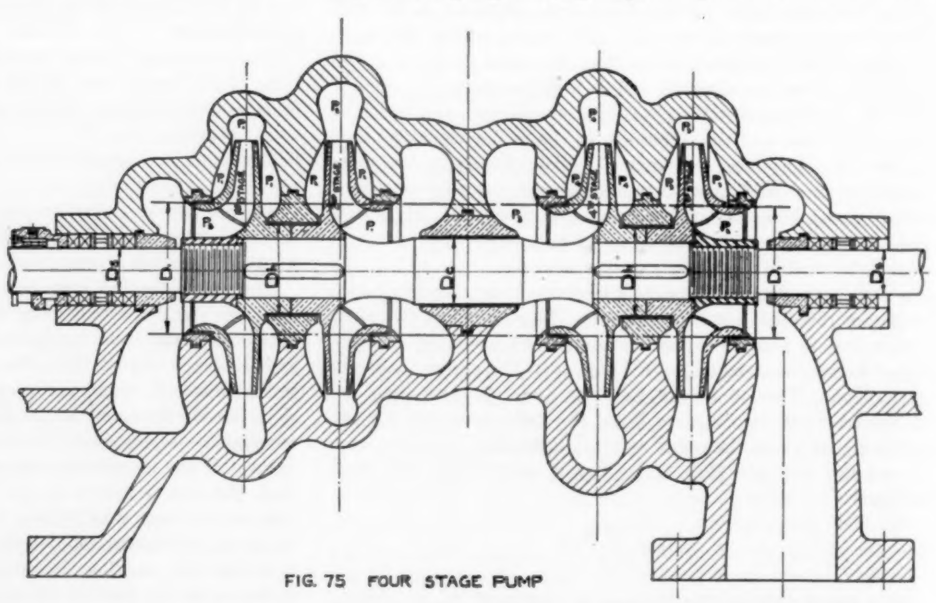

FIG. 75 FOUR STAGE PUMP

---

[30] For description of numerous modifications of the balancing devices, see C. Pfleiderer, "Die Kreiselpumpen," pp. 237–259.

P_s = suction pressure

P_1 = volute pressure in the first stage = $P_s + P$, where P is the pressure produced by one stage

P_2 = volute pressure in the second stage = $2P + P_s$

P_3 = volute pressure in the third stage = $3P + P_s$

P_4 = volute pressure in the fourth stage = $4P + P_s$

D_s = diameter of shaft or shaft sleeve at the stuffing box, equal on both sides

D_h = runner hub diameter

D_c = shaft diameter at the center

D_1 = runner wearing ring diameter

A_1, A_s, A_h, A_c = areas of the circles corresponding to diameters D_1, D_s, D_h, and D_c.

Assume that the pressures in the clearances between the pump case and the runner shrouds are uniform and equal to that of the corresponding volute pressure. Assume also that the suction pressure of the second stage is the same as volute pressure of the first stage and that the suction pressure of the third stage is the same as the discharge pressure of the second, etc. These assumptions do not affect the final result, since there is always a one-stage pressure difference P between two similar points in two successive stages.

It is evident that the pressures on both sides of the runner shrouds from the diameter D_2 to diameter D_1 are equal and balanced. Consider now the pressures on each runner after exclusion of areas between D_2 and D_1. Call pressures to the left positive, those to the right negative. Then the forces on the rotating element are:

$$\begin{aligned}
(A_1 - A_h)P_1 - (A_1 - A_s)P_s &= \text{first stage}\\
(A_1 - A_c)P_1 - (A_1 - A_h)P_2 &= \text{second stage}\\
(A_1 - A_h)P_4 - (A_1 - A_c)P_3 &= \text{fourth stage}\\
(A_1 - A_s)P_2 - (A_1 - A_h)P_3 &= \text{third stage}
\end{aligned}$$

The axial thrust is equal to the sum of these forces. Adding and rearranging:

$$\begin{aligned}
T &= A_1(2P_1 + P_3 + P_4 - P_s - P_2 - 2P_3)\\
&\quad + A_h(P_2 + P_3 - P_4 - P_1) + A_c(P_3 - P_1)\\
&\quad + A_s(P_s - P_2)
\end{aligned}$$

Substituting for P_1, P_2, P_3, and P_4 their values $P + P_s$, etc., and reducing:

$$T = 2P(A_c - A_s) = 2P(D_c^2 - D_s^2)\,0.785 \ldots\ldots [30]$$

It is seen that, due to symmetry, D_1 and D_h do not appear in the final result. The whole system can be represented diagrammatically as equivalent to a simple case shown in Fig. 76. This result holds for the arrangement of stages as shown, 1, 2, 4, 3, which gives a minimum thrust. By reasoning similar to the above, the thrust for the arrangement of stages 1, 2, 3, 4 is found to be

$$T = 3P(A_c - A_s) + 2P(A_h - A_c) \ldots\ldots\ldots [31]$$

This is identical with a scheme shown in Fig. 77. The end thrust for this diagram is equal to

$$\begin{aligned}
T &= (A_c - A_s)(P_4 - P_1) + (A_h - A_c)(P_2 - P_1)\\
&\quad + (A_h - A_c)(P_4 - P_3)\\
&= 3P(A_c - A_s) + 2P(A_h - A_c)
\end{aligned}$$

To obtain an idea of the magnitude of the thrust produced in this way, take a numerical example. A 4-in. four-stage pump with an arrangement of stages as shown in Fig. 75 and 100 lb. pressure per square inch per stage has the dimensions, D_s = $1^3/_4$ in., D_h = $3^1/_4$ in., and D_c = $2^5/_8$ in. Substituting these values into formula [30], we get:

$$T = 2 \times 100 \times 0.785(2.625^2 - 1.75^2) = 597 \text{ lb.}$$

For the arrangement of stages 1, 2, 3, 4, the thrust is:

$$T = 100 \times 0.785(2.625^2 + 2 \times 3.25^2 - 3 \times 1.75^2) = 1475 \text{ lb.}$$

The runner dimensions (except the hub diameter) do not affect the result because of the symmetry of construction. In the first case the pressures on the shoulders formed by the runner hubs are opposite in direction and cancel each other, while in the second case these terms are of the same sign and add to the thrust due to the increase in the shaft diameter in the middle. From Equation [31] it is seen that with the arrangement of stages 1, 2, 3, 4 (not symmetrical) an axial thrust is obtained even with the shaft of constant diameter, due to runner hubs, making $A_c = A_s$. Formula [31] becomes

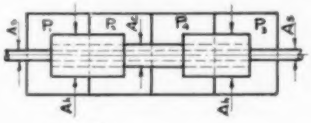

FIG. 76

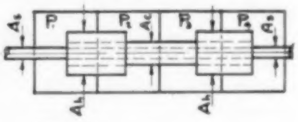

FIG. 77

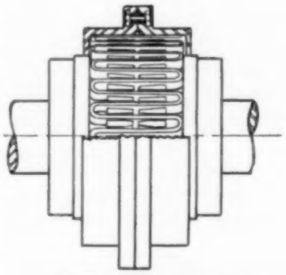

FIG 78 FLEXIBLE COUPLING WITH A SPRING

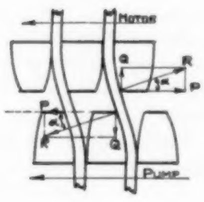

FIG. 79 AXIAL AND TANGENTIAL COMPONENTS TRANSMITTED BY A COUPLING

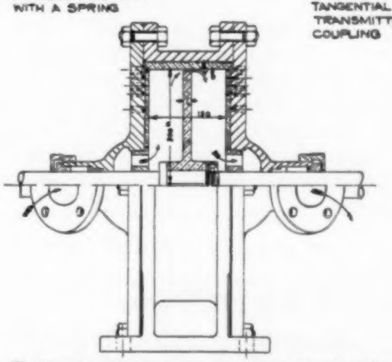

FIG. 80 DR YENDO'S APPARATUS FOR MEASURING LEAKAGE THROUGH THE RADIAL CLEARANCES

$$T = 2P(A_h - A_s) \ldots\ldots\ldots\ldots\ldots\ldots [32]$$

Take for another example a six-stage pump, Fig. 81. By the procedure outlined, the thrust is calculated for the arrangement of stages 1, 2, 5, 6, 4, 3 to be

$$T = 2P(A_c - A_s) + P(A_h - A_c) \ldots\ldots\ldots [33]$$

For the arrangement 1, 2, 6, 5, 4, 3, the thrust is equal to

$$T = 2P(A_c - A_s) - P(A_h - A_c) \ldots\ldots\ldots\ldots [34]$$

For the same values for D_s, D_h, and D_c, as in the previous example, and for a stage pressure of 100 lb. per sq. in., the first arrangement gives an axial thrust of 890 lb., while the second arrangement gives only 310 lb.

In a multi-stage pump with one stuffing box and one internal bearing there is a thrust due to the pressure acting on the enclosed shaft end, which should be added to the thrust due to shoulders on the shaft and runner hubs. Suppose in the pump shown in Fig. 75 the right-hand stuffing box is replaced by a closed bearing. The pressure on this end of the shaft is $2P$, the area is A_s, and the additional thrust is:

$$T' = P_2 \times A_s = A_s(2P + P_s) \ldots\ldots\ldots\ldots [35]$$

For P_s equal to the atmospheric pressure this gives

$$T' = 200 \times 0.785 \times (1.75)^2 = 480 \text{ lb.}$$

From the expression [35] it is seen that the thrust due to an internal bearing depends upon the suction pressure on the first stage. The thrust increases as the suction pressure increases, and it may reach a great value if the pump is operating under considerable positive head (if, for instance, two pumps are working in series). Since the main object of making pumps with one stuffing box is to eliminate the high-pressure stuffing box, the thrust due to this cause is always toward the first-stage suction, or in the same direction as the thrust due to shoulders on the shaft.

The thrust on the enclosed shaft end may be reduced or eliminated by using an uneven number of stages and grouping them so that the thrust due to one stage will balance that due to the enclosed bearing.

The thrust due to shoulders on the shaft and runner hubs can be balanced by making the runner hubs of different diameters in such a way that the pressure on the shoulder formed is opposing the end thrust. Thus, if the runner hubs on stages 3 and 4 are made larger than those on stages 1 and 2 (Fig. 75) (D_{h1} denoting diameter of the runner hubs for stages 1 and 2, D_{h2} the diameter of the runner hubs for stages 3 and 4, and A_{h1} and A_{h2} denoting the corresponding areas) and the calculations are repeated with these changes, the following expression is obtained for the axial thrust:

$$T = 2P(A_c - A_s) - P(A_{h2} - A_{h1}) \ldots\ldots\ldots [36]$$

By equating the thrust to zero we get:

$$2(A_c - A_s) = (A_{h2} - A_{h1}) \ldots\ldots\ldots\ldots\ldots [37]$$

For the same values of A_c and A_s and $D_{h1} = 3^1/_4$ in., A_{h2} is equal to 14.3 sq. in., or $D_{h2} = 4.27 \sim 4^1/_4$ in.

In a similar manner the balance can be obtained by making the runner wearing rings of different diameters. It is evident that in the case of a two-stage pump this is the only way to eliminate the axial thrust due to runner hubs, as there is only one group of runners. This balancing method can be used for reducing or eliminating moderate thrust, whatever its cause, by underbalancing or overbalancing the thrust due to shoulders on the shaft and runner hubs.

In addition to the hydraulic thrust from the pump, the thrust-bearing capacity should be ample to take from the coupling the thrust caused by misalignment of the rotating element of the pump and driver even if a flexible coupling is used. The ideal coupling should transmit the torque from the driver to the pump and allow a certain amount of end play for the driven shaft. Pure torque can be transmitted only if axes of rotation of both elements coincide; otherwise the coupling will produce a radial and axial load on the bearings of both pump and driver. The amount of thrust is proportional to the degree of misalignment. For high-speed pumps the choice of the coupling is of importance. Certain types of couplings, even with perfect alignment, produce axial thrust in both directions. Figs. 78 and 79 show a type of coupling with a tape put between the teeth cut on the coupling flanges as a flexible member. Since the pressure between the tape and the teeth is at an angle to the plane normal to the axis of rotation, components P-P transmit the torque, while components Q-Q produce the axial thrust.

15 Unbalanced Axial Forces on Pump Casing

When considering the axial thrust in centrifugal pumps, the attention is usually confined to the unbalanced axial forces on the rotating element, while in all cases there is an unbalanced and opposing force on the pump case, which is almost self-evident. However, to illustrate the point involved a simplified case will be considered. In Fig. 85 a body with two cylindrical portions of diameter D_1 and D_2 and a shaft of diameter d is enclosed in a casing under pressure P_2, while that outside of the casing is P_1. It is evident that an unbalanced force $(P_2 - P_1)\pi/4$ $(D_1^2 - d^2)$ will act on the body directed downward and at the same time an equal and opposite force will be exerted on the casing wall directed upward. In pumps the case is complicated by the fact that the pressure in the pump case is not uniform and the runner is revolving; however, in all cases there is a force on the pump case exactly equal to the axial thrust on the rotating element due to external pressure. Normally this force on the pump case is of no consequence as the case is rigid enough to stand this force without deformation. In the case of deep-well pump (Fig. 86) this force should be considered if the number of stages is great (say, 25). In this case the force on the pump case becomes of the order of several thousand pounds, and the pump casing (outer column) is not rigid enough to stand it without deflection. This deflection, together with the shaft elongation due to hydraulic thrust which is in the opposite direction, may be more than the running clearance in the stages, and the rubbing of runners against the pump case (bowls) will result. These conditions are more pronounced at the starting of the pump. Suppose that the rotating element was adjusted so that the runners are in the middle position in the pump case. When the pump is not running, the shaft is under tension due to the weight of the runners and shaft, and the outer column is under its own weight and that of the bowls. When the pump is started, the head is very nearly zero. Under these conditions the axial thrust may be considerably higher than at normal operating conditions, and the shaft will be subjected to an additional tension equal to the thrust of all stages. With a very great length of the shaft (several hundred feet) this extension may be of the order of $^1/_4$ to $^1/_2$ in., while the pump cases will be subjected to an equal lifting force. Due to a greater strength of the casing (outer and inner column) the deflection of the casing will be a small portion of the shaft extension. When the outer column is filled with water, the head on the pump is built up and the conditions approach normal. The thrust will be reduced as will the reaction on the pump case, and the weight of the water column in the casing will more than counterbalance the lifting force due to reaction. The problem of the column and shaft extension in deep-well pumps with a great number of stages is a very serious one. The normal clearances between the pump case and the runners may not be sufficient, due to shaft extension under hydraulic load. The rotating element should be adjusted so that, when stationary, the runners are near the top case wall and when the pump is running will be placed in the middle position in the case. The lifting of the rotating element due to shaft whipping is hardly possible under a load of several thousand pounds and close bearing spacing.

16 Description of the Apparatus for Measuring Axial Thrust

For measuring the axial thrust in a single-stage pump a special thrust ball bearing was designed, shown in Fig. 30-*a*. The axial thrust from the runner was transmitted through the shaft and ball bearing to a piston which was free to move axially in the bearing housing. To prevent the oil from leaking from the housing through the clearance between the sliding piston and the housing, an oil guard was provided and filled with oil to the same level as the oil in the bearing housing. The axial motion of the piston could be limited to a predetermined value by setting a stop bolt with a lock nut; otherwise the piston could move out more than would be allowed by the axial clearances between the rotating element and the stationary parts inside of the pump. The pressure due to axial thrust was transmitted by means of a bell crank with a 1 to 1 ratio of the arms directly on to the platform scales as shown in Fig. 32. The platform scales had a reduction of 40 to 1, and the scale beam had about 1 in. travel; the maximum travel for the piston was about $^{1}/_{40}$ in. The pump construction allowed the rotating element to move not less than $^{1}/_{8}$ in. toward the suction and over $^{1}/_{4}$ in. in the opposite direction. In the middle position the piston face was flush with the finished face of the bearing housing. The slightest displacement of the piston from this position could be seen by eye. In this way it was always possible to see if the rotating element was free to move, and in which direction it was thrusting.

An important item in the equipment for measuring the axial thrust was the flexible coupling. Such a coupling should allow the free axial motion of the pump rotating element and should transmit the torque without producing any radial or axial thrust load on the pump bearings. This was accomplished very satisfactorily by a coupling with leather disks as a flexible member floating on pins screwed into both coupling halves. For the axial thrust of from 200 to 400 lb., 5 lb. was sufficient to bring the system out of balance.

It should be noted that near the shut-off the axial thrust was very unsteady, the jumps being of the order of plus or minus 10 per cent. The values recorded are the average estimated values. To take up the lost motion and deflection of the scales, beams, and rods, adjusting screws were provided in both arms of the bell crank.

The axial thrust was measured with the following arrangements:

1 Runner diameter $10^{1}/_{8}$ in.:
   (*a*) No balancing means, with the case wearing ring on the back of the runner removed
   (*b*) With six radial ribs on the back of the runner, 8 in. from tip to tip, $^{3}/_{16}$ in. high and $^{5}/_{8}$ in. wide
   (*c*) With the balancing chamber connected to the suction nozzle by a 1-in.-diameter hole drilled through the casing wall opposite the $1^{1}/_{2}$-in. leakage nozzle, with a wearing ring on the back of the runner and no radial ribs
   (*d*) Same as (*a*), with the runner displaced $^{3}/_{16}$ in. from the middle position away from the suction.

2 Runner diameter $8^{1}/_{2}$ in.:
   (*a*) No balancing means
   (*b*) Six radial ribs on the back of the runner 7 in. from tip to tip
   (*c*) With balancing chamber connected to the suction nozzle by a 1-in.-diameter hole
   (*d*) With nine $^{3}/_{8}$-in. holes drilled through the runner web to connect the balancing chamber to the runner suction
   (*e*) Same as (*a*), with the runner displaced from the middle position toward the balancing chamber.

The runner could be displaced from its middle position by replacing the adjusting collar on the shaft in the thrust bearing by one $^{3}/_{16}$ in. wider, the rest of the assembly not being affected by this change.

A series of tests on axial thrust in multi-stage pumps were made at the testing department of Byron Jackson Company, Berkeley, Calif. The object of these tests was to measure the axial thrust in multi-stage pumps with runners arranged in two opposing groups and thus to check the statements arrived at analytically. The pumps tested belong to the high-speed (3600 r.p.m.) oil-pipe-line type built in sizes 3, 4, and 6 in. The capacities ranged up to 1500 g.p.m., the pressures developed were up to 1000 lb. per sq. in., with maximum power of 400 hp., special equipment being built for these tests.

Fig. 81 shows a 4-in. six-stage pump with runners arranged in pairs set back to back. The arrangement of stages is 1, 2, 6, 5, 4, 3. In Section 14 it was pointed out that this arrangement gives minimum thrust due to shoulders on the shaft and runner hubs extending through the walls separating two adjacent stages. The runner hubs of the third and fourth stages are of a larger diameter to eliminate the thrust due to this cause.

Fig. 81*a* shows a 4-in. four-stage pump with stage arrangement 1, 2, 4, 3. To balance the axial thrust caused by the shoulders on the shaft, balancing collars are provided on the runner hubs of the third and fourth stages.[31] The tests on these pumps included the measurements of the axial thrust without any balancing means and runner hubs of the same diameter. After that the pumps were balanced either by increasing the runner hub diameters of one group or by providing collars on the runner hubs. The tests were repeated with a positive head on the suction of the first stage. All tests were run at 3600 r.p.m.

The bearing for measuring the axial thrust in multi-stage pumps is essentially of the same design as that shown in Fig. 30*a*, only of a larger size and modified to take thrust in both directions. The bell crank also has been changed to transmit the thrust in both directions directly on scales. It is mounted on a special stand independent of the pump base. The height of the supporting cross-member can be adjusted to suit the pump. The picture in Fig. 82 shows the set-up for measuring the thrust outside (to the right). For thrust in opposite direction a tension link is substituted for the compression rod between the bearing and the bell-crank arm.

17 Discussion of Results of Axial Thrust in Single-Stage Pump

From what has been stated in Section 13, it is evident that, unless the pump shown in Fig. 30 has some balancing means, it will thrust to the left, and the piston holding the thrust bearing in Fig. 30*a* will move outside. Figs. 87, 88, and 89 show the axial thrust actually measured with a runner $10^{1}/_{8}$ in. in diameter, plotted against pump capacity. The head-capacity and efficiency curves are also shown for reference. Figs. 90, 91, and 92 show the same with the runner cut to $8^{1}/_{2}$ in. An inspection of these curves shows that the axial thrust varies for different capacities, being minimum at about 1.35 of the normal capacity. From this point the thrust increases both ways, and near shut-off it decreases again. The sharp-pointed minima for the thrust curves in Figs. 89 and 92 are due to an abrupt drop of the head-capacity curves at high speeds. If run with a positive head on suction, the head-capacity curve would take its normal shape and the thrust curve would be similar to those in Figs. 87, 88, 90, and 91. The shape of the axial thrust curves cannot be explained from the shape of pressure curves in Figs. 33 to 36 and 42 for points *A*, *B*, *C*, and points on the diameter of the wearing ring. These show a continuous drop of pressure from

FIG. 81a SECTIONAL ELEVATION 4-STAGE O. L. MULTIPLEX-PUMP

the shut-off point to the point at which the discharge valve is wide open. There is a small increase in the thrust with the increase of capacity. This is due to a decrease in pressure in the runner eye on account of the increase of the velocity head through the runner eye $V_e^2/2g$. This, however, is more than counterbalanced by the increase in the component of thrust which is due to a change of momentum in the axial direction of the incoming flow and which is directed opposite the first. This is equal to WV_e/g or $A\gamma V_e^2/g$, which is twice the thrust due to velocity head. Thus the net effect of the two is a decrease of the thrust to the left, with an increase of capacity equal to $V_e^2/2g$ per unit area of the runner eye. To give an idea of the magnitude of the forces corresponding to WV_e/g and $V_e^2/2g$, these are calculated for the following normal capacities and speeds:

Speed, r.p.m.	Capacity, g.p.m.	V_e, ft-sec.	$V_e^2/2g$, ft.	WV_e/g, lb.	Measured thrust, lb.
1400	270	10.35	1.66	12.0	190
1700	325	12.5	2.4	17.0	265
2000	375	14.4	3.22	23.3	420
2500	475	18.2	5.1	37.3	...

From these considerations it is seen that the shape of the thrust curves cannot be explained by the change of pressure outside the runner. However, considering the causes of the axial thrust inside the runner, a satisfactory explanation can be found. It is the aim of a good pump design to shape the vanes and runner profiles so that an equal head is produced along all the stream lines so that the losses due to cross-flows and back-flow will be eliminated. For a runner with a plain vane and the length of the stream lines near the shrouds approximately equal, this is possible if the radial velocity is the same for all stream lines. With a 90-deg. turn in front of the vanes, neglecting the effect of friction near the runner walls, this is possible only for one value of the radial velocity, and hence for one pump capacity. On both sides of this point, since the radial velocities are different near the runner shrouds, the pressures produced along these stream lines are not equal. This causes unbalanced forces on the runner shrouds inside. Since the axial thrust is to the left (Fig. 30) for small capacities near shut-off, there must be higher pressure on the back shroud than on the front shroud, the difference between the two producing the drop of axial thrust near shut-off. For large capacities the reverse is true. The pressures on the front shroud are higher than those on the back shroud; the difference between the two produces the increase of the axial thrust for high capacities regardless of the rapid decrease of pressures in the pump case. The velocity distribution necessary to produce this effect is as follows: At small capacities, higher radial velocities are near the inner wall of the turn (at front shroud) and low velocities are at the outer side of the turn (Fig. 22). Then the head produced at the back shroud will be higher than that at the front shroud, as explained in Section 13. At high radial velocities (large capacities) the picture is reversed. Higher velocities are at the back shroud and low at the front (Fig. 23).

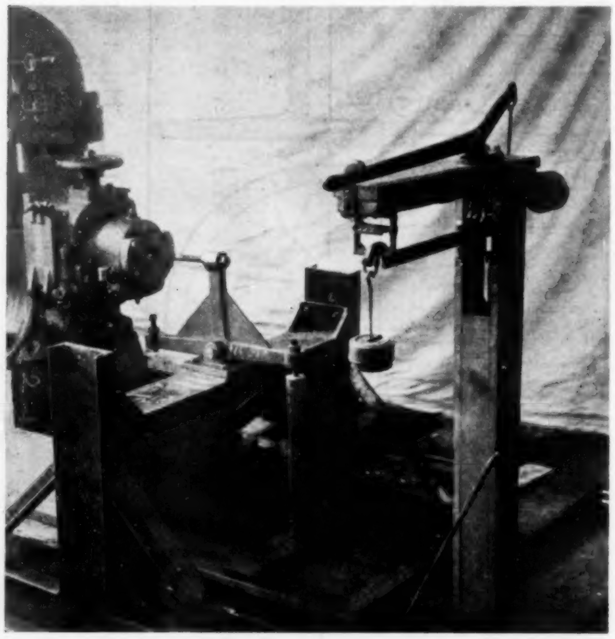

FIG. 82 SET-UP FOR MEASURING AXIAL THRUST OF A SIX-STAGE PUMP

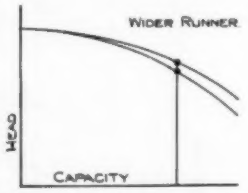

FIG. 83 DIFFERENCE IN HEAD DUE TO A DIFFERENCE IN RUNNER WIDTH

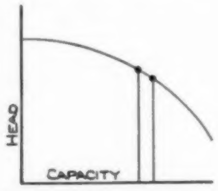

FIG. 84 DIFFERENCE IN HEAD DUE TO A DIFFERENCE IN LEAKAGE

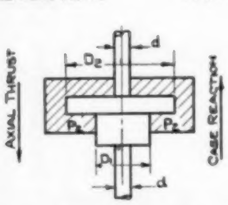

FIG 85 CASE REACTION AND AXIAL THRUST $T = .785(D_1^2 - d^2)(P_2 - P_1)$

Irregularities in the form of sudden breaks and bumps in the shape of the head-capacity curves which are often observed with the wide runners (high specific speed) are usually explained by cross-flows and back-flows at the runner discharge, as a result of a difference in the head produced along the stream lines near the runner shrouds. But it has never been mentioned that these conditions cause an axial thrust from the inside of the runner.

From Figs. 87 to 92 it is seen that at shut-off, when the mean radial velocity through the runner is negligible (only the leakage water being circulated through the runner), the axial thrust is due only to the external pressure on the runner. Taking the pressure on the back side of the runner over the area opposite the runner eye equal to that at the wearing ring, which is approximately true (Figs. 33, 34, 35, 36, and 42), and multiplying it by the net area of the runner eye (12.0 sq. in.) gives very closely the thrust as measured:

Speed, r.p.m.	Runner diameter, in.	Pressure at ring, ft.	Thrust calculated, lb.	Thrust measured, lb.
1400	$10\frac{1}{8}$	48.5	252	255
1700	$10\frac{1}{8}$	71.0	370	360
2000	$10\frac{1}{8}$	96.0	500	500
1700	$8\frac{1}{2}$	...	...	280
2000	$8\frac{1}{2}$	69.0	360	375
2500	$8\frac{1}{2}$	107.5	560	560

For all other capacities the thrust calculated in this way is smaller than that actually measured, approximating it for capacities between those corresponding to the maximum efficiency and minimum thrust. With the valve wide open (maximum capacity), the thrust calculated is considerably smaller

than that obtained by measurement,[32] as is seen from the following table:

Speed, r.p.m.	Runner diameter, in.	Capacity, g.p.m.	Pressure at ring, ft.	Calculated thrust, lb.	Measured thrust, lb.
1400	$10^1/_8$	450	22.5	117	180
1700	$10^1/_8$	525	30.0	155	260
2000	$10^1/_8$	575	42.5	221	325
1700	$8^1/_2$	450	....	...	250
2000	$8^1/_2$	475	31.0	160	305
2500	$8^1/_2$	570	40–45	220	400

It is believed that the difference between the thrust calculated and the thrust measured is due to the uneven pressure on the runner shrouds inside. This is caused by the difference in the head produced as a result of the uneven radial velocities along the stream lines near the shrouds.

Comparing the thrust at shut-off and maximum efficiency of the same runner at different speeds, it will be noticed that the thrust varies approximately as the square of the speed. This is because the pressures produced vary approximately as the square of the speed.

Figs. 96, 97, and 98 show the axial thrust for a $10^1/_8$-in. runner with the balancing chamber connected to the pump suction by means of one 1-in.-diameter hole drilled through the case wall opposite to the leakage nozzle. In Fig. 30 a set of wearing rings with a close clearance and of the same diameter as those on the suction side was provided on the back side of the runner. From these curves it is seen (1) that the thrust is reduced considerably but not eliminated, (2) that the shape of the thrust curves is similar to the shape of those for the pump with no balancing means (Figs. 87, 88, and 89), (3) that the minimum thrust with no balancing is reduced to about one-half and takes place at the same capacity, (4) that the thrust at the shut-off is reduced to about 0.25 of that with no balancing means. The reason for this is that the increase of pressure in the pump case with the decrease in capacity does not affect the pressure in the balancing chamber, while with no balancing means the pressure on this portion of the runner shroud increases toward the shut-off point.

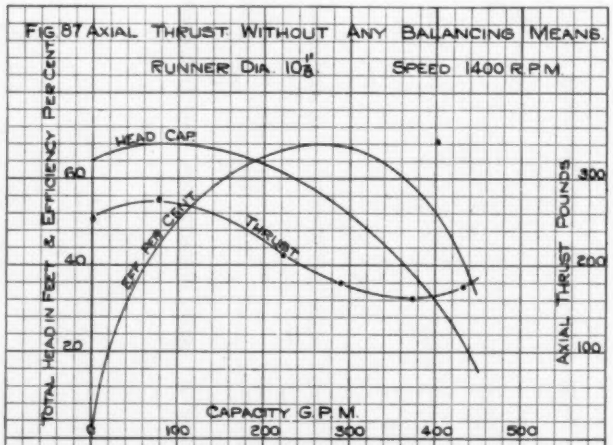

FIG 87 AXIAL THRUST WITHOUT ANY BALANCING MEANS. RUNNER DIA. 10 1/8" SPEED 1400 R.P.M.

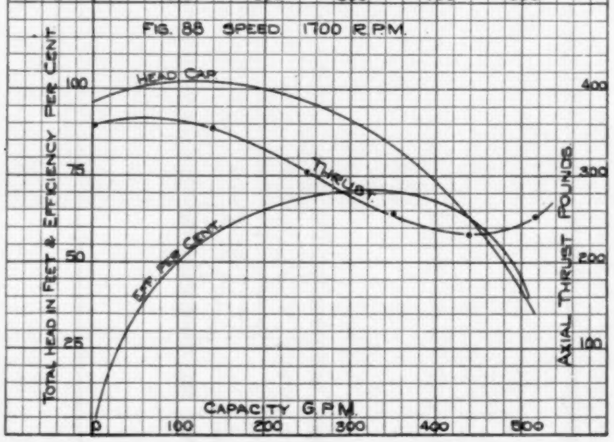

FIG. 88 SPEED 1700 R.P.M.

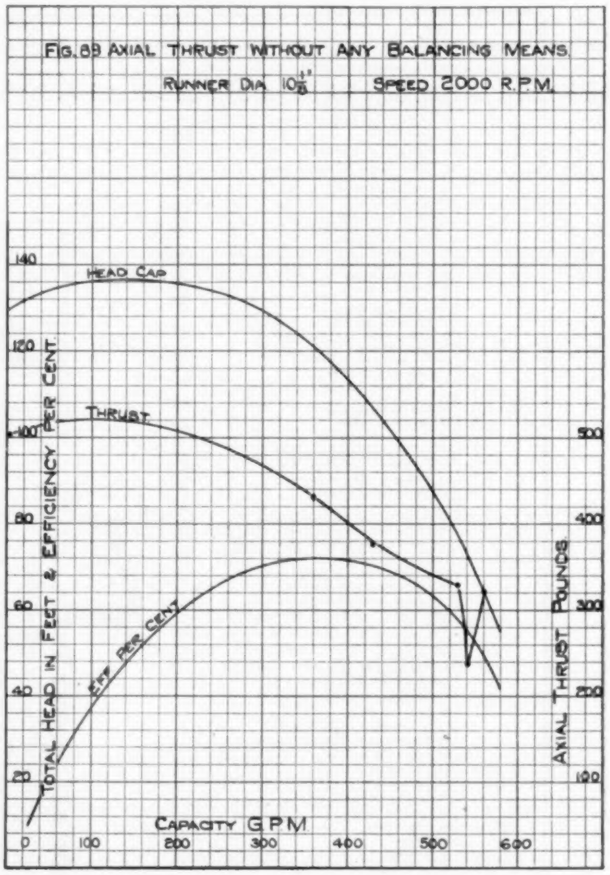

FIG. 89 AXIAL THRUST WITHOUT ANY BALANCING MEANS. RUNNER DIA. 10 1/8" SPEED 2000 R.P.M.

It should be noted that the thrust at shut-off is lower than the minimum at capacities over the normal. In Section 13 it has been shown that the pressure in the balancing chamber cannot be equal to that in the runner eye. The difference in pressure due to stated causes is, however, not sufficient to account for the thrust obtained with this method of balancing. Apparently a portion of the thrust originates inside of the runner.

Figs. 99, 100, 101, and 102 show the thrust measured with the balancing chamber connected to the runner suction by means of nine $^3/_8$-in. holes drilled through the runner web. The shape of these curves is similar to the shape of those obtained with one 1-in. hole drilled to the pump suction; but the minimum thrust is smaller with nine holes, being approximately 0.25 of that without balance. This is because the total area of nine $^3/_8$-in. holes (equal to 0.99 sq. in.) is greater than that of one 1-in. hole (which is 0.785 sq. in.), which makes pressure in the balance chamber nearer that in the runner eye.

Figs. 93, 94, and 95 show the axial thrust curves with an $8^1/_2$-in. runner and six radial ribs $^5/_8$ in. wide, $^3/_{16}$ in. thick, and 7 in. from tip to tip. From these tests it is seen that, as far as the elimination of the axial thrust is concerned, this method is

---

[32] The assumption that the pressure on the back of the runner over the area opposite the runner suction is equal to that at the wearing ring, and the failure to consider the effect of variation of the pressure at the runner eye with capacity, make the calculated thrust slightly higher.

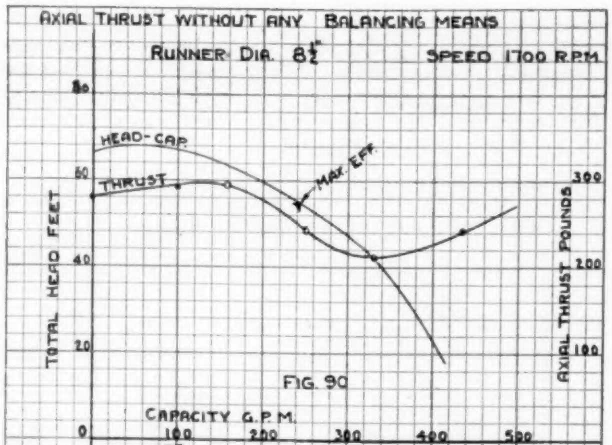

FIG. 90

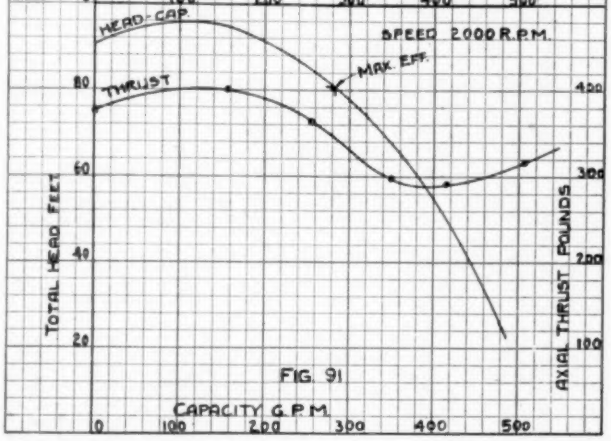

FIG. 91

most efficient. The thrust is not only eliminated but reversed in many cases. The effect of the radial ribs on the back side of the runner is to increase the angular velocity of rotation of water in the space between the runner and case walls. This reduces the pressure on this side of the runner so that the difference between the pressures on the two runner shrouds from the outside reduces or balances the thrust caused by unbalanced pressure on the back side of the runner over the area opposite to the runner suction. In some cases this difference produces a thrust in the opposite direction. The thrust occasioned by the pressure on the back side of the runner over the area opposite the runner suction is considerably lower with the radial ribs on the runner than without them because the pressure at the wearing ring is reduced approximately in the ratio of 1 to 0.62. The mean angular velocity of water in the space between the runner and case without ribs is calculated to be 0.467 ω, where ω is the runner angular velocity. With radial ribs the angular velocity increased to 0.632 ω for *A*, 0.568 ω for *B*, and 0.512 ω for *C*.

The shape of thrust curves for runners with radial ribs is similar to those for runners without any balancing means, the thrust being reduced approximately by the same amount for all capacities. The amount of reduction of thrust caused by ribs on the runner backs varies as the square of the speed.

It should be mentioned that for small capacities approaching the shut-off the thrust is very unstable, especially with the radial ribs on the back of the runner. The probable reason for this is that this portion of the head-capacity curve is unstable.

Figs. 43, 44, and 45 show the axial thrust with six radial ribs $^5/_8$ in. wide, $^3/_{16}$ in. thick, and 8 in. from tip to tip for the runner $10^1/_8$ in. in diameter. The shape of the curves is similar to the shape of those discussed, and what has been said about the first applies to the latter.

A series of tests with the runner displaced from the middle position $^3/_{16}$ in. away from the suction does not show any appreciable difference in the axial thrust, the difference being within the error of observation. The explanation of this is probably in the fact that, even with the runner displaced $^3/_{16}$ in., there is still a clearance between the runner and the case of about $^1/_4$ in., and according to Newton's assumption that if the space between the two surfaces, one stationary and one moving, is filled with liquid, the liquid velocities vary linearly from zero at the stationary surface to a maximum equal to the velocity of the moving surface. Thus the mean velocity in both cases is the same, equal to one-half of that of the moving surface. It is interesting to note that with the runner displaced from the middle position $^3/_{16}$ in., the rotating element has a tendency toward axial vibration, which can be seen by eye or felt by hand at the movable bearing of the pump. This is due to jet reaction of the runner discharging against the case wall on one side.

18 Discussion of Tests on Axial Thrust in Multi-Stage Pumps

The calculations of the axial thrust in multi-stage pumps with runners arranged back to back, as advanced in Section 14, are based on the assumption that every runner produces an equal portion of the total head. While this is aimed at in the normal design, in practice, however, the heads produced in various stages may differ, due to several causes, the most common of which are as follows:

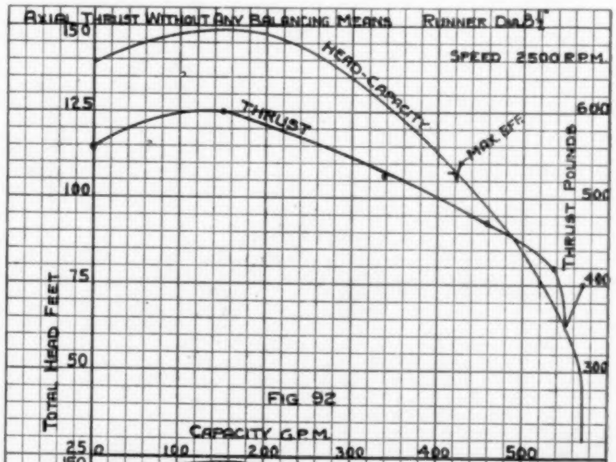

FIG. 92

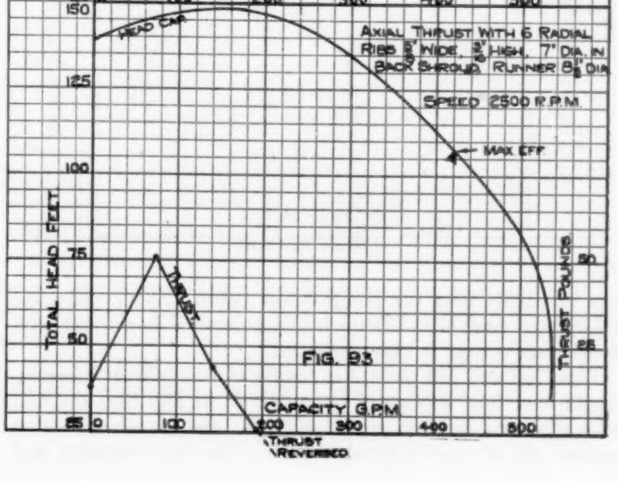

FIG. 93

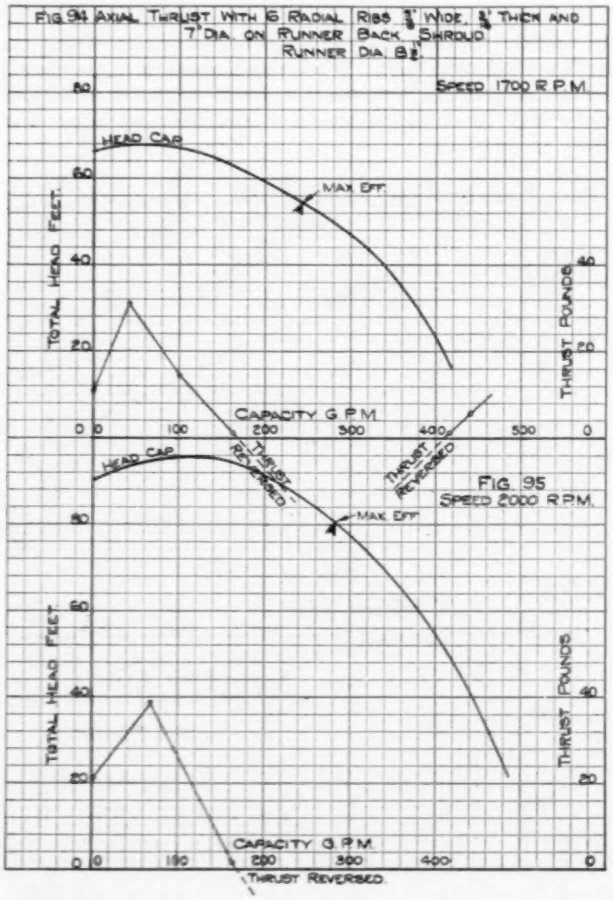
(1) A difference in the runner width due to inaccuracy of castings. With runners of different widths having different head-capacity curves and working at the same capacity, the wider runner will work at a higher head, as shown in Fig. 83.

(2) With the identical runners, if the leakage from stage to stage or through the stuffing boxes or leak-offs is different, some runners will work at a higher capacity and hence a lower head, as is seen from Fig. 89.

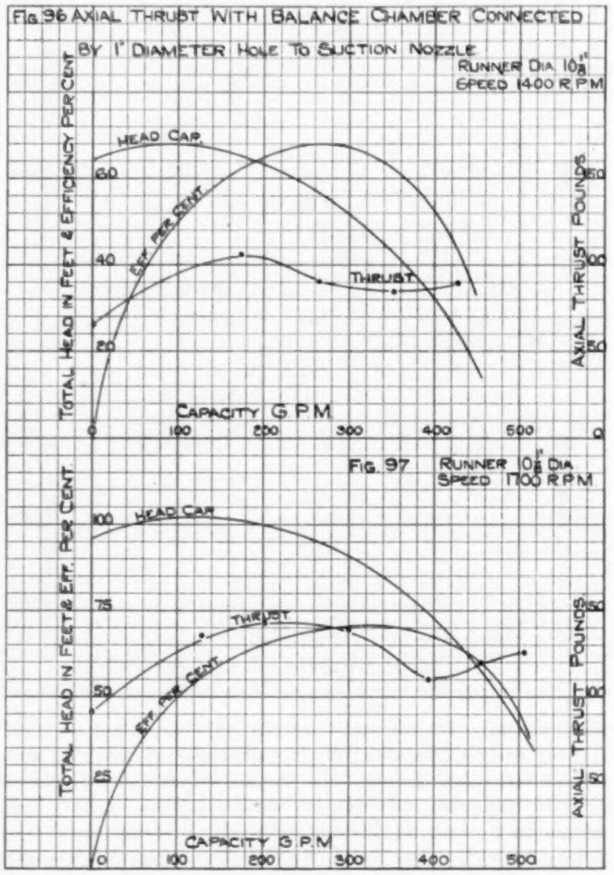
(3) If the pump is working under suction lift, the head-capacity curve for the first stage may be different from that for the rest of the runners, depending on the amount of the suction lift. This difference is greater for larger capacities and may be quite considerable near the pump cut-off, as the first stage may cut off earlier than the rest of the stages.

(4) For mechanical reasons in multi-stage pumps the form of the suction nozzle for different stages is very often made differently. Since the position of the stop and the shape of the channel of approach to the runner entrance affect the amount of pre-rotation of incoming water, the head produced will vary, and unbalanced axial forces will result.

The variation in the head produced by different stages due to all the foregoing causes is more pronounced at high capacities, and especially near the pump cut-off point. This explains the unexpected axial thrust frequently encountered in practice with multi-stage pumps at high capacities.



Figs. 103 and 104 show the results of axial thrust measurements of a 4-in. four-stage pump shown in Fig. 81*a*, the first with a positive head on suction of 60 lb., and the second with a suction lift of approximately 10 ft. The head-capacity and efficiency curves are also given for reference. The results represented by these curves are typical for the whole line of pumps of this kind. From inspection of these curves it is seen that the variation of the thrust for different capacities is mainly due to causes from inside the runner, but to these are added several new, peculiar to multi-stage pumps.



From these tests it is seen that without balancing rings the axial thrust for capacities near the normal is over 600 lb. with a suction lift and over 700 lb. with a positive head on suction, the direction of thrust being toward the first stage suction in both cases, as anticipated. With the balancing collars the thrust is brought practically to zero in both cases. The reduction of thrust is approximately the same for all capacities. The difference in the thrust with suction lift and positive head on suction is probably due to the fact that with the suction lift the first stage produced a head slightly lower than the rest of the stages; hence the pressure on the back of the runner of the second stage is not quite balanced by that of the first stage, causing the total thrust toward the first stage suction to decrease. This becomes more pronounced at capacities over 800 g.p.m., and at capacities near cut-off the thrust is reversed. The measurements of pressure between the stages show that near cut-off the head produced by the first stage drops considerably faster than in the rest of the stages. The unbalanced thrust produced by the second stage becomes more than enough to balance the thrust caused by the shoulders on the shaft and runner hubs. The pressure measurements between the stages for the points other than near cut-off did not allow the making of any definite conclusions because the readings were taken on the curved interstage piping with different velocities.

The increase of axial thrust at capacities over 1100 g.p.m. with a positive head on suction may be caused by the local vacuous spaces (cavitation) inside the runner near the back shroud at the vane entrance tips. This local cavitation is not followed by a sudden drop in the head produced by the first stage; otherwise, the pressure on the back of the runner of this stage would be lowered and the thrust toward the first stage suction would be smaller, as takes place with the suction lift.

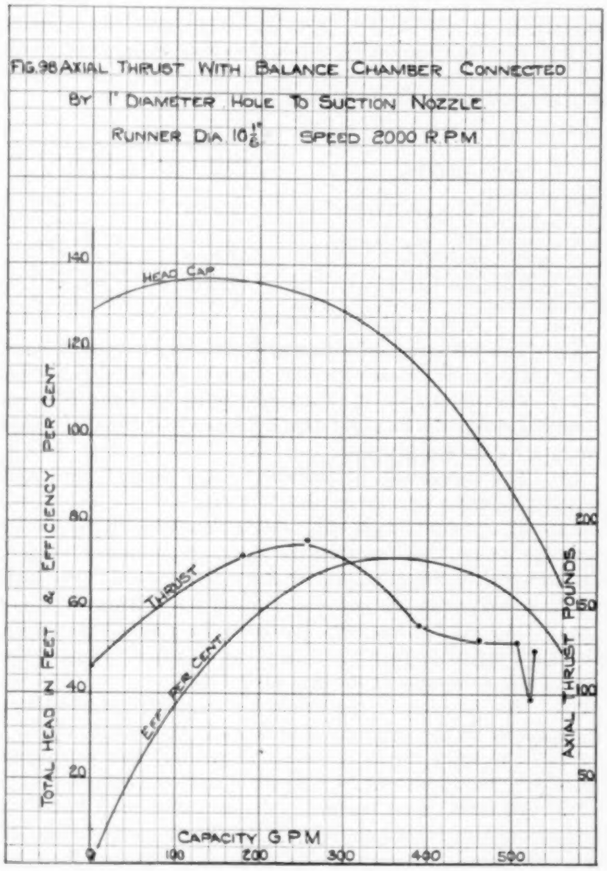


FIG. 98 AXIAL THRUST WITH BALANCE CHAMBER CONNECTED BY 1" DIAMETER HOLE TO SUCTION NOZZLE RUNNER DIA $10\frac{1}{8}$" SPEED 2000 R.P.M.

The cause of the cavitation at the vane tips at the entrance lies in the fact that at high capacities water enters the vane with a high velocity and at a higher angle than that of the vane, producing dead vacuous spaces on the front side of the vane. Air and vapor bubbles appear and collapse in these spots, producing noise and causing pitting of the vane. Depending on the runner profile and form of the approach to the runner, the cavitation may take place either near the front or the back runner shrouds. The axial thrust caused by the cavitation varies between the wide limits, sometimes changing the direction, setting the whole pump in vibration. It is quite probable that the increase of the thrust at high capacities in the case of the single-stage pump, as discussed in Section 17, is also due to cavitation.

It should be noted that the pump efficiency with the suction lift is one point higher than with a positive head on suction for capacities near that at which the cavitation starts (800–900 g.p.m.). This was confirmed by repeated tests and was observed on several single-stage double-suction pumps. This is in agreement with water turbine practice as described in "Hydraulische Probleme."[33] The explanation is found in the fact that, at conditions of approaching cavitation, water leaves the runner walls, and the friction and shock losses are thus reduced and the efficiency is improved.

PART III CONCLUSIONS

WHILE some of the conclusions based on these tests are quite general and hold for all types of centrifugal pumps, the others are limited in their application to the conditions duplicating or approaching those under which these tests were made. Briefly the results of this study can be summarized as follows:

(1) In a centrifugal pump with a volute case, the maximum pressure is at the discharge flange for capacities lower than the normal. For capacities greater than the normal, the pressure, in the volute case, is higher than that at the discharge flange. The reason for this lies in the case design.

(2) The pressures at different points of the volute are equal at the point of maximum efficiency. There is no side thrust on the runner from the volute case under these conditions. On both sides of this point pressures vary along the volute.

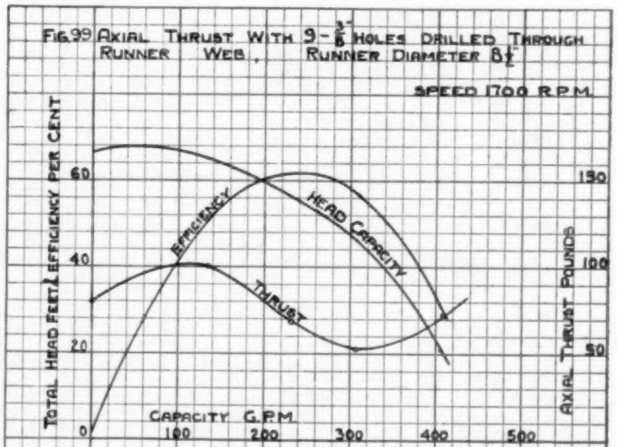

FIG. 99 AXIAL THRUST WITH 9 - $\frac{3}{8}$" HOLES DRILLED THROUGH RUNNER WEB. RUNNER DIAMETER $8\frac{1}{2}$" SPEED 1700 R.P.M.

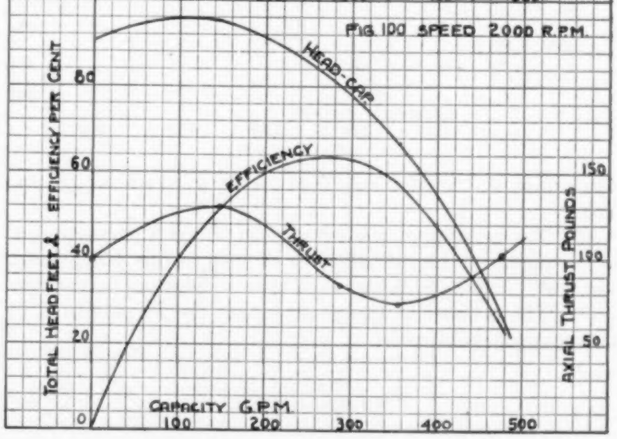

FIG. 100 SPEED 2000 R.P.M.

(3) The volute pressure at the point of maximum efficiency can be determined with a sufficient degree of accuracy from the pump discharge pressure by assuming the nozzle efficiency. For the pump tested the nozzle efficiency was found to be 60 per cent.

(4) The pressures at different radii in the space between the runner and case walls can be expressed by the formula:

$$H_a = H_v - \varphi^2 \frac{(u_2{}^2 - u_a{}^2)}{2g}$$

---

[33] V.D.I. Verlag, 1926, Berlin.

For notation see Section 9. The coefficient φ was found to be 0.467 and is constant for all speeds, diameters, and small runner cuts.

(5) With radial ribs on the back of the runner, the angular velocity of rotation of water in the space between the runner and the case is increased considerably. This reduces the pressure on this side of the runner according to the preceding formula.

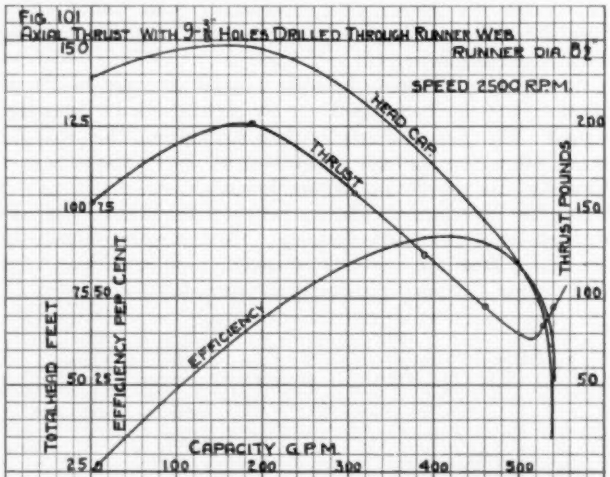

FIG. 101

AXIAL THRUST WITH 9-⅜" HOLES DRILLED THROUGH RUNNER WEB

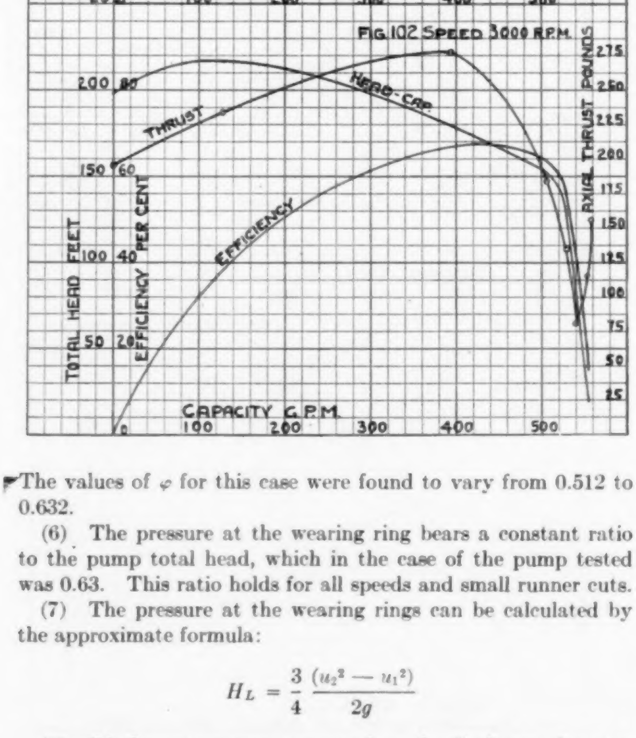

FIG. 102 SPEED 3000 R.P.M.

The values of φ for this case were found to vary from 0.512 to 0.632.

(6) The pressure at the wearing ring bears a constant ratio to the pump total head, which in the case of the pump tested was 0.63. This ratio holds for all speeds and small runner cuts.

(7) The pressure at the wearing rings can be calculated by the approximate formula:

$$H_L = \frac{3}{4}\,\frac{(u_2^2 - u_1^2)}{2g}$$

(8) Discharge pressures measured on the discharge pipe at a distance of from 5 to 10 pipe diameters from the discharge flange are higher than those at the discharge nozzle for capacities over the normal. The reason for this is that the actual velocity at the flange is higher than that corresponding to the discharge area, a portion of the section being occupied by dead turbulent water.

(9) If the amount of leakage is represented by the formula $Q_L = CA\sqrt{(2gH_L)}$, the coefficient of discharge varies as follows: (*a*) For the same speed the coefficient C increases with the pressure H_L. (*b*) For the same pressure it decreases slightly with the increase of speed. (*c*) For the same clearance, speed, and pressure the coefficient C increases as the width of the wearing ring decreases (Fig. 66). (*d*) For the same width, speed, and pressure the coefficient C decreases as the radial clearance is decreased (Fig. 68).

(10) The following table shows the advantages of the different types of wearing rings tested over a plain ring of the same width and radial clearance, for operation at the point of maximum efficiency and for speeds from 1400 to 2500 r.p.m.:

Type of ring	Radial clearance on diameter, in.	Saving in leakage in per cent of that for a plain ring
Single labyrinth	0.0122	41.0 to 46.6
Circular grooves with rough edges	0.0170	32.2 to 35.5
Same with smooth edges	0.0170	16.7 to 20.0
Circular grooves with smooth edges	0.0294	2.2 to 4.0
Spiral grooves, single thread	0.0115	20.8 to 27.0
Spiral grooves, triple thread	0.0115	33.0 to 36.8
Spiral grooves, triple thread	0.0215	24.7 to 26.8
Stepped ring	0.0100	24.0 to 33.0

(11) The advantage of a ring with circular or spiral grooves over a plain one decreases with an increase of the radial clearance.

(12) The spiral grooves of a higher pitch are more effective in cutting down the leakage; this indicates that there is actual pumping by the spiral groove.

(13) The percentage of leakage for the normal head and capacity increases with an increase of speed.

(14) The power to drive the rotating element with the runner discharge sealed, together with the power to pump the leakage, is considerably lower than that at the pump shut-off. For high specific speed pumps the power at shut-off is a maximum.

(15) The axial thrust with no balancing means varies with the pump capacity, showing a minimum at capacities over the normal and a decrease at the shut-off point.

(16) The increase in the thrust for large capacities cannot be explained by the variation of pressure in the pump case.

(17) The axial thrust measured is greater than calculated considering the forces due to pressure outside the runner.

(18) In addition to the thrust due to unbalanced forces on the runner shrouds from the outside, there is an axial thrust due to a difference in pressure on the inside of the runner shrouds, which results from a difference in the head produced along the two stream lines near the runner shrouds and cavitation. Of the several causes of this, the uneven radial velocity distribution is most important.

(19) The balancing of the axial thrust by means of a chamber on the back of the runner of the same diameter as the runner suction does not eliminate the axial thrust, but reduces it to about 25 per cent for the useful part of the head-capacity curve.

(20) With an ample clearance between the runner and the pump case, a small runner displacement from the middle position does not affect the axial thrust.

(21) Multi-stage pumps with runners arranged in two groups back to back, and usually considered hydraulically balanced, have an axial thrust due to a variation in the shaft diameter and the runner hubs extending through the walls separating two adjacent stages. The amount of thrust due to this cause depends on the arrangement of stages.

(22) The axial thrust due to the shoulders on the shaft and runner hubs can be balanced by making the runner hubs of different diameters.

(23) In multi-stage pumps with runners arranged in two opposing groups, the variation in the head produced by different stages causes axial thrust, as symmetry is destroyed under these conditions.

(24) The cavitation or formation and collapsing of vapor-filled vacuous spaces inside the runner, manifested by noise, vibration, and runner pitting, is always followed by a consider-

able change in the axial thrust. The direction of the thrust due to this cause depends on the location of vacuous spaces, which in turn depends upon the runner profile and form of the approach to the runner. Causes of cavitation are high suction lift, high velocities (overspeeding), and difference between the direction of the incoming water and the vane angle at the entrance.

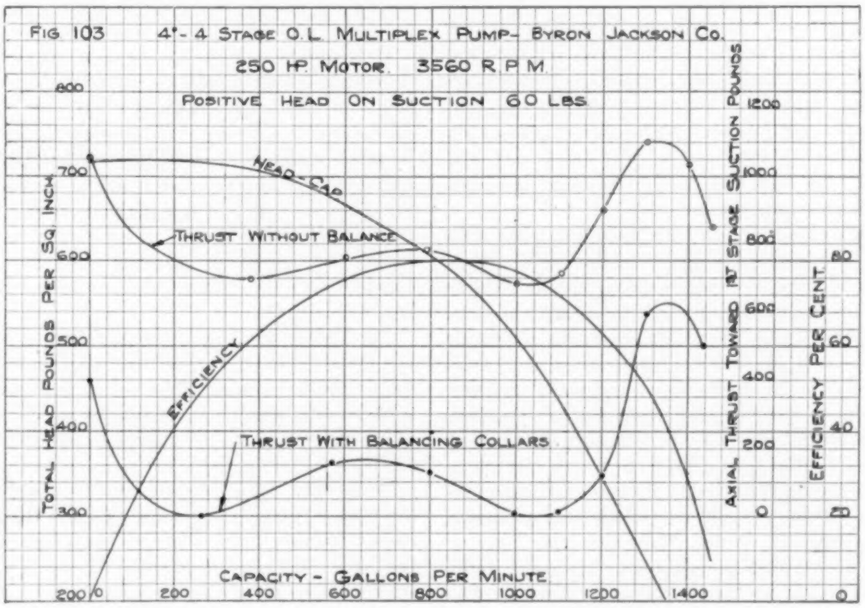

Fig 103

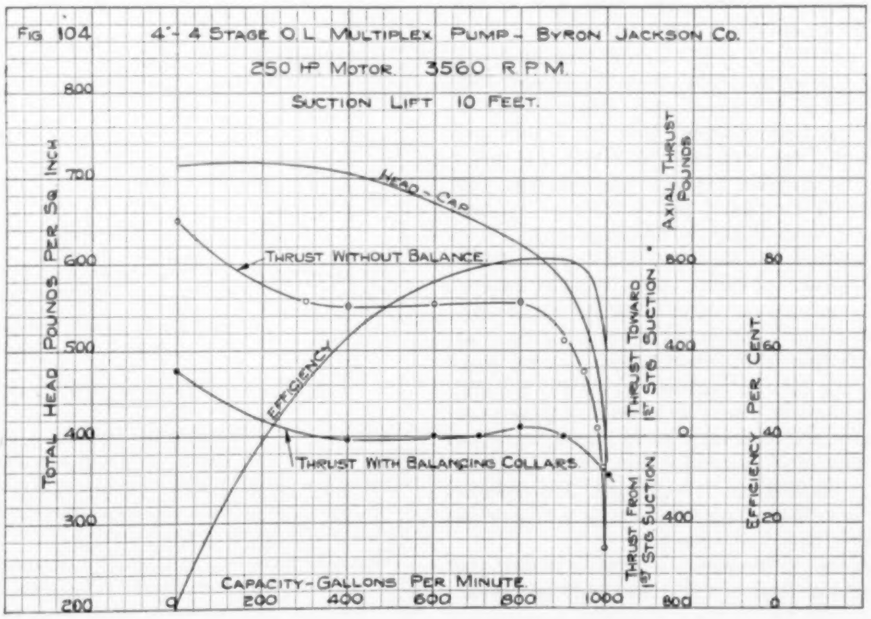

Fig 104

(25) Pumps with one stuffing box and one internal bearing have additional thrust due to unbalanced pressure on the enclosed shaft end. The magnitude of this thrust depends on the suction pressure of the pump.

(26) The theoretical head produced by a runner with an uneven radial velocity distribution is smaller than that given by the elementary theory.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to all those who, by suggestions and criticism, helped the completion of this work. Particularly he is indebted to Prof. M. P. O'Brien and Mr. E. D. Howe, of the Department of Mechanics of the University of California, for their assistance and cooperation in the actual tests involving special "set-ups" and equipment without interfering with the regular laboratory procedure.

The author is also indebted to Byron Jackson Company for the loan of equipment and to Messrs. R. Schurman, Vice-President, and A. Hollander, Chief Engineer, of the Byron Jackson Co., whose interest and support in this study made this work possible.

Discussion

F. G. Switzer.[34] Such research work as this is exceedingly interesting. It is through this kind of thing that the centrifugal pump has reached its present importance. As we learn more about the details of its characteristics we will find that this type of pump will be gradually still further improved, giving it an ever-widening field of application. Many commercial-pump users are hesitant in adopting the centrifugal pump until they can be assured of the high efficiencies which other types of pump are capable of developing, particularly in the range of high head and low capacity. But when multi-stage centrifugals can show 80 per cent efficiency at heads as high as 1200 ft. and capacities as low as 1000 g.p.m., the lower cost and simplicity of construction and operation will make the centrifugal pump of increasing importance.

For some time past the writer has been spending what time he could find available in work of a nature similar to Mr. Stepanoff's. With the cooperation of Goulds Pumps, Inc., there have been made available pumps, pump parts of special design, and complete testing equipment. These were installed in the hydraulic laboratory at the School of Mechanical Engineering at Cornell University. The work done there has been under the direction of the writer. This work has not duplicated any of the work of the author, but the trails have crossed. Pressure distribution in the volute has been looked into a little, not with respect to leakage, but for the purpose of trying to learn something more about volute design. Had the author taken measurements at more than three points (*D*, *E*, and *F*) in the main body of the volute, it is not believed that he would have made the statement he does in the second of his conclusions. Considerable change can often be made in the volute proportions, changing therefore the velocities and hence the pressures, without any great change in efficiency. Pressure variations around the volute may be quite large, and occur in quite a short section of the volute. This is particularly true near the beginning and again near the end of the volute. The effect of increased flow which is illustrated in Fig. 40 can be still further explained. The writer has rather conclusive evidence that flow in a certain portion of the small end of the volute may be reversed in direction under these conditions of high capacity, and this alone will go much further toward explaining the conditions observed than any comparatively small change in discharge angle. It is too bad that efficiencies are not indicated, in addition to leakage. The writer is of the opinion that certain of the types of wearing ring used which showed marked reduction in leakage would show little if any gain in efficiency. This would have been discovered if similar changes had been made in the front wearing ring.

The use of radial ribs for the purpose of reducing leakage, and hence wear in clearances, seems to be well established in the dredge-pump field, while practically never used in any other types. The writer has often wondered why they were not more generally used, particularly in high-head, low-capacity pumps. Here more is to be gained by reducing leakage than in other combinations of head and capacity.

Another explanation for the decrease in coefficient of discharge with increasing peripheral speed of the runner may be offered. It has been found that the flow in these clearance spaces is not axial; it is spiral. The drag of the runner causes tangential motion. Hence the length of path may change somewhat. Put in another way, we may reason that for ring No. 10, say, increasing pressure at constant peripheral speed causes an increased axial component of velocity with about the same tangential component. Hence the spiral of flow becomes steeper and the length of path shortens. The shorter path means increased total flow and is shown by the increasing coefficient of discharge. Also, with fixed pressure and varying peripheral speed, there is a nearly constant axial component of velocity and an increasing tangential component with higher speeds. At higher speeds the path is then longer and the discharge coefficient should go down, which it does.

It would have been exceedingly interesting and informative if tests had been made on narrower rings. Fig. 66 shows the trend of discharge coefficient with width of ring. If these curves could be projected backward to zero ring width, it would be much easier to separate the effects of friction from entrance and discharge losses. Also it might be expected that the curves for different speeds would converge there to a single value independent of speed. This same idea may be expressed by saying that increasing the ring clearance as shown in Fig. 68 should cause the curves to converge at greater clearances, as they actually do.

Fig. 70 shows some interesting data, too. In trying to separate the losses of pumps at or near maximum efficiency, the writer has found that the so-called mechanical losses often appear to be considerably greater than can be accounted for by the sum of bearing and gland frictions and disk friction. No explanation has been found for this.

While the actual measurement of end thrust is not new, the work reported here is more inclusive than any other published records known to the writer. For some years, Goulds Pumps, Inc., has been measuring end thrust. As a result of these studies, very simple means have been found for reducing end thrust. In Fig. 105 is shown a test curve of end thrust of such a pump. It is seen that the arrangement used is effective in reducing end thrust in a new pump and keeping it at a reasonable value with an old pump which is worn beyond the point where the wearing rings should be renewed.

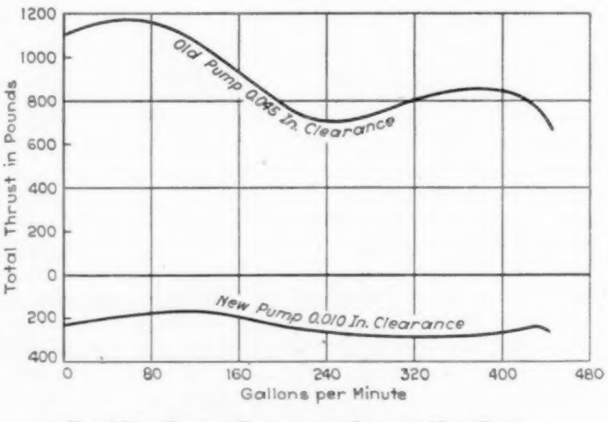

Fig. 105 Thrust Curves for Old and New Pump

That there can be any marked differences of pressure on the front and back shrouds inside an impeller as narrow as the one tested seems unlikely. Any tendency to such differences would be the cause for cross-flow within the impeller and reduced efficiency. Had the author measured pressures in the clearance spaces at the front of the impeller, he would no doubt have found sufficient differences there to account for considerable unbalance. He apparently assumes the same pressures on the outside of both shrouds. Tests have shown that this may not be true. Differences as much as 30 or 40 lb. per sq. in. have been observed between front and back clearance spaces.

---

[34] Professor of Hydraulic Engineering, Cornell University, Ithaca, N. Y., and Consulting Engineer for Goulds Pumps, Inc. Mem. A.S.M.E.

Michael D. Aisenstein.[35] The data collected on measuring the thrust of Byron Jackson pumps and a companion of the different types of wearing rings are interesting. It is, however, regrettable that in no place does the author refer to the original experiments on leakage by Prof. A. F. Sherzer,[36] whose experiments on leakage were along the same line and whose methods were followed.

The opening statement in the introduction, that with modern efficiencies of 90 per cent, leakage losses take an important aspect, is not correct.

It is because of the tendency on the part of some designers to improve the efficiency of centrifugal pumps by reducing the clearance joint that some pump manufacturers have resorted to advertisements such as to "beware of close clearances" or advertised that the efficiencies as obtained by them were not due to close clearances. This situation has made many prospective users of pumps very suspicious when any improvement in efficiency is claimed, as immediately close clearances, thin shafts through the stuffing boxes, etc., are thought of as the reasons for this improvement.

The high efficiencies that are obtained by some of the leading manufacturers is the result of reduction of the hydraulic losses owing to a better understanding of the phenomena of hydrodynamics, due to the selection of specific speeds for which the disk friction becomes a minimum for the same head produced by the impeller. Take for example a highly efficient double-suction pump of medium specific speed, a capacity of 9000 g.p.m., pumping fresh water at 75 lb. per sq. in. pressure difference across the clearance. The pump efficiency is 90 per cent. The diameter of the ring is 12 in. and the clearance 0.016 in. on the diameter, using the table on the fourth page. Then from the equation the leakage in gallons per minute for two suctions will be:

$$GPM_L = 2\pi DSC\sqrt{2gH_L}$$

We have, assuming $C = 0.55$,

$$GPM_L = \frac{2\pi \times 12 \times (0.016/2) \times 0.55\sqrt{64.4 \times 2.31 \times 75} \times 448}{144}$$

$$GPM_L = 109$$

and volumetric efficiency

$$l_v = \frac{9000}{9109} = 98.9 \text{ per cent}$$

and if the whole leakage should be eliminated, the limit of increase of pump efficiency due to the absence of leakage loss would be

$$l = \frac{90.0}{98.9} = 91 \text{ per cent}$$

Since the accuracy of any commercial test is not greater than 1 per cent, it would be difficult to determine the gain in efficiency if the entire leakage loss should be eliminated.

On the tenth page the author criticizes Dr. Pfleiderer's Equations [17], [18], [19], and [20] as not being practical; particularly, Equation [20] is claimed as not accurate enough. Mr. Stepanoff's Equation [29] is the same as Equation [17], with the exception that the volute pressure H_p is called $\frac{u_2^2 - u_1^2}{2g}$, and it so happens that in this form it agrees closer with the particular test.

As to the computation of the head H_p, with the present knowledge of centrifugal pump theory it can be calculated very accurately without much difficulty.

The author's criticism that most of the textbooks in illustrative design roughly estimate the leakage losses rather than calculate them is without foundation. It is well known to every designer, as well as to the criticized authors of the textbooks, that to start a new design certain factors are to be assumed. The total volume of liquid, which includes the leakage that should pass through the suction pipe and impeller, should be assumed, since on this capacity the whole design is based and dimensions and angles of the impeller and size of the volute are determined. For instance, if a single-suction pump should deliver 340 g.p.m., assuming 5 per cent leakage, the delivered volume through the impeller will be

$$GPM = 340 \times 1.05 = 357$$

Assuming a 4-in.-inside-diameter suction pipe, the velocity through the suction pipe will be

$$c_s = \frac{357 \times 0.409}{4^2} = 9.1 \text{ ft. per sec.}$$

If the velocity in the impeller eye is taken as 12 ft. per sec. and the hub of the impeller from the horsepower requirements is determined to be $1^3/_8$ in., from equation,

$$C_e = \frac{GPM \times 0.321}{\pi/4\,(d_e^2 - d_h^2)}$$

or

$$d_e = \sqrt{\frac{357 \times 0.321}{12 \times 0.785} + 1^3/_8{}^2} = 3.75 \text{ in.}$$

After d_e is determined and the proper thickness, say $^3/_8$ in., is allowed for metal, the different formulas as given in the textbooks could be used to check the leakage loss, using the ring of diameter $3^3/_4 + {}^3/_4$ in. and whatever clearance it is decided to use. The statement on the fifth page that the main reasons for the low efficiency of small pumps is an excessive leakage loss is incorrect. As shown by the author himself, in considering the small pump as tested by the author, on the eleventh page, it is found for a clearance of 0.012 in. for plain wearing rings in case [6] or [4] that the leakage loss varies from 3.16 to 4.5 per cent, which, considering the pump efficiency of 68 to 72 per cent, is a relatively small loss, and very little improvement should be expected in this direction.

The main reason for low efficiency of high-pressure (low-specific-speed) small-volume, small pumps is the disk friction and unfavorable hydraulic design due to too large impeller hub for relatively small impeller diameter because of required size of the shaft, narrowness of the port width, etc. So far as small, low-head pumps are concerned, the mechanical losses, such as stuffing-box tightness, may overshadow all other losses and account for an efficiency drop of 20 per cent.

With reference to the derivation of equations for theoretical head with non-uniform radial velocity (see seventh page) the whole integration is incorrect. As long as velocity $v_r = v_1 + ax$ is variable, the angle β_2, or rather the corrected true angle β'_2, which should have been used (see Fig. 20), is also variable, and the term $\frac{u_2}{g \tan \beta_2} = B$ could not be treated as a constant; consequently the whole discussion has no theoretical or practical meaning.

So far as Equation [36] is concerned, the assumption that when the runner hubs D_{h2} and D_{h1} are of different size, the thrust pressure per stage P is the same in each case is incorrect, and therefore the resulting Equation [37] is in error.

---

[35] Chief Engineer, United Iron Works, Oakland, Calif. Jun. A.S.M.E.

[36] *Engineering News-Record*, vol. 92.

Another disadvantage of having hubs of different diameter is that the peripheral velocity will be greater for larger hubs and still greater unbalancing will take place due to wear, increasing rapidly with time. A much better way to balance a four-stage pump would be to make the shaft through the stuffing box of the same size, that is, $D_s = D_c$, which would also increase the rigidity of the shaft in the packing box, which is a desirable feature as it would increase the life of the packing.

On the ninth page the author discusses characteristics of a centrifugal pump when pumping viscous oils without reference to the article on "Characteristics of Centrifugal Oil Pumps," by the writer, published in Trans. A.S.C.E., Vol. 94, 1930, page 437, in which the same phenomena are discussed and the same explanations are offered.

To determine what actually takes place so far as different flows are concerned, velocities should have been measured at many points and checked against velocity diagrams as obtained from theory. The method of measuring static pressure in different places in the casing, without recording the velocities, as followed by the author, is very unsatisfactory, and the deductions based on such methods are unreliable so far as conditions of flow are concerned in passages of such shape as exist in a centrifugal pump, and should be taken with a grain of salt.

A point which the writer wishes to stress is that however well a multi-stage pump is balanced hydraulically when new, it will become unbalanced in time due to wear; further, heavy thrust due to momentary obstructions or faulty suction conditions may always take place; and for these reasons an adequate thrust bearing of ample capacity should be provided.

It is a well-known fact that the thrust capacity of ball bearings is reduced with speed. According to reputable ball-bearing manufacturers, at 3600 r.p.m. the largest double-row ball bearing that could be safely used would be a No. 409, with a thrust capacity of about 1740 lb. at 3450 r.p.m., for periods of 5000 to 25,000 hours. This is not enough to take care of any contingencies which may occur in an oil pipe line of any size, say, 4 or 5 in. discharge diameter. For this service bearings of the Kingsbury type with thrust capacities increasing with speed should be used.

Of course, for relatively small pumps or slow-speed pumps, ball-bearing-fitted pumps are satisfactory, and as they are much cheaper than the combination of sleeve and Kingsbury-type bearings, there is some advantage in the use of the former type of bearing.

Most of the oil companies resent the use of ball bearings in high-speed pipe-line pumps. They are cheaper so far as initial cost is concerned, but they are expensive to maintain, and expenditures due to shutdowns prove to be many times the additional cost of the pump when fitted with an adequate bearing.

For this reason the writer disagrees with that portion of the paper which claims (on the twenty-sixth page) that the pipeline pumps as shown on the thirtieth and thirty-first pages can be safely operated if the axial pressures were balanced when the pumps were new.

In conclusion, the writer wishes to warn any designer of centrifugal pumps not to get on the dangerous ground of improving efficiency by decreasing the running clearances to improve the volumetric efficiency (0.008 or 0.010 in. for rings of 6 in. in diameter as recommended on the fourth page is dangerous), to thin out the shaft through the stuffing boxes so as to reduce the friction losses, and use the ball bearings where they should not be used to reduce bearing losses and be able to keep smaller clearances at the running joints.

A. PETERSON.[37] This paper should prove of considerable value to manufacturers of centrifugal pumps who have not made or who do not have facilities to conduct such painstaking experiments.

The table, Fig. 31, giving the leakage loss for different kinds of wearing rings, is extremely interesting and valuable. The author's tests confirm similar tests carried out about 25 years ago by the company with which the writer is associated.

Contrary to the author's assertion that years ago very little attention was paid to leakage losses in centrifugal pumps, it may be of interest to bring out that as early as 1905 very complete tests were made by the De Laval Steam Turbine Company to determine leakage through wearing rings, both of the plain type and the labyrinth type, and the apparatus used was very similar to the one shown in Fig. 27, as used by Professor Susuki of the Tokyo University in 1929.

As a result of these tests, the company about a year later, or in 1906, adopted as standard the double-labyrinth ring shown in Fig. 7, and it has been used ever since practically without any modifications.

The writer does not believe that many pump builders or users appreciate the tremendous advantage of labyrinth rings over plain rings, because if they did, labyrinth rings would be more extensively used.

The author's tests indicate that for the same clearance the single-labyrinth ring, as shown in Fig. 6, gives from 41 to 46.6 per cent less leakage than the plain ring. The results of our tests were that the double-labyrinth ring, as shown in Fig. 7, gives about one-third the leakage of the plain ring.

This is of considerable importance in centrifugal-pump design, because not only does it result in higher initial efficiencies, but also in better sustained efficiencies. In view of the one-third lower velocity of the water through the labyrinth ring, there naturally will be less wear of this type of ring than of the flat ring, and this stands out particularly in the case of pumps handling gritty water.

Practically the only reason why the efficiency of a centrifugal pump drops off by use is wear in the rings, and therefore anything that can be done to reduce the amount of wear is of considerable advantage.

Leakage losses are something that cannot be seen, and unless the pump is tested at regular intervals, it may be operated for a considerable time with worn rings and at very much reduced efficiency.

As a rule labyrinth rings are not used so much for the purpose of obtaining a higher initial efficiency as for the purpose of permitting larger clearances without a sacrifice in efficiency. This is also important, as it is not then necessary to resort to the means outlined at the bottom of the fourth page—that is, to machine the revolving ring after it is put on the impeller. This is objectionable, because it is not always convenient for a customer, in case he orders a replacement ring, to take the pump rotor to a machine shop to have a finishing cut taken on the impeller ring.

Another advantage that stands out in connection with large-clearance labyrinth rings is that for a certain fixed amount of wear the leakage increases a smaller percentage than for the same amount of wear in the small-clearance plain rings.

Assuming that a plain ring with 0.012 in. clearance on the diameter has a leakage of 5 per cent and that the same amount of leakage is obtained with a labyrinth ring with 0.030 in. clearance on the diameter and that both rings have worn 0.012 in. on the diameter, we have a loss in efficiency in the case of the flat ring of 5 per cent and with the labyrinth ring a loss of only 2 per cent, assuming no change in coefficient of discharge. This example clearly demonstrates the great advantage of the labyrinth ring.

---

[37] Chief Engineer Pump and Compressor Department, De Laval Steam Turbine Company, Trenton, N. J. Mem. A.S.M.E.

The pressure readings taken by the author at various points in the volute are of considerable interest, and they also agree with similar tests conducted by the De Laval Company.

On the fifteenth page there is brought out the importance of designing the volute so as to obtain uniform pressure in it, and the author also shows that the pressure can only be uniform at one point, that is, at maximum efficiency. For other conditions the pressure distribution is unequal, and this throws additional load on the shaft that may result in breakage, if the shaft is not strong enough to withstand such load. The author refers to this load as side thrust or side pressure. It seems to me more logical to consider it as a radial load.

On the same page in the first column reference is made to pressure at E being higher than at D due to E being on a larger diameter than D, making the average peripheral velocity of the water particles higher. Is not the peripheral velocity of the water at E lower than at D, and is not this the reason for the pressure at E being higher than at D?

In the second column of the sixteenth page the statement is made that the pressure H_L should be corrected for velocity head in the runner eye, since the pressure in the runner eye is lower than the suction lift by the velocity head. It is not believed that this is quite correct, because the pressure at the runner eye is as a rule equal to the suction lift less friction in the suction passages up to that point. If the runner eye should happen to be of smaller area than the area where the suction-lift reading is taken, correction should be made for only difference in velocity heads at the two points and not for the entire velocity head at the runner eye.

In his calculations of pressure at the wearing ring in terms of volute pressure, the author, on the seventeenth page, states that the relative velocity w_1 at the inlet is equal to or slightly greater than the relative velocity w_2 at the outlet. In most centrifugal pumps, particularly those operating at comparatively high r.p.m., there is a considerable difference between these velocities, the relative velocity at the inlet often being more than twice as great as the velocity at the outlet. Judging by the proportions of the pump as shown on the tenth page, a ratio of about 2 to 1 exists, and even higher ratios are not uncommon. This means that the term $\frac{w_1^2 - w_2^2}{2g}$ may be quite an item, and dropping it may in some cases affect the results materially. For the pump shown on the tenth page the term $\frac{{}_1{}^2w - w_2^2}{2g}$ is at least 21 for 2500 r.p.m., and if this figure were used in the formula at the bottom of the seventeenth page the calculated pressure at the wearing ring would be 140 instead of 119 ft. Therefore, in order to have the calculated results agree with test results, a constant other than 0.50 for φ would have to be used.

Without doubt there will be conditions where dropping of the term $\frac{w_1^2 - w_2^2}{2g}$ will affect the results even more than in this particular case.

The writer would like to ask if, when conducting the leakage tests, any pressures were taken in the chamber on the back side of the runner. Judging from statement on the nineteenth page, the pressure was assumed to be equal to that of the atmosphere. This assumption, however, may lead to some errors, particularly where the leakage through the rings was great, as in the case of ring 10 with a leakage of 10 per cent, or 47.5 g.p.m. It would require a velocity head of almost 4 ft. to discharge this amount of water through the $1^1/_2$-in. orifice, and possibly the back pressure due to other restrictions may have been even higher; and for this reason the actual pressures in the balancing chamber should have been measured in order to obtain accurate figures for the coefficient of discharge.

In the second part of the paper, on axial thrust, reference is made to hydraulically balanced single-suction multi-stage pumps. Such pumps are not built, as indicated on the twenty-fifth page; that is, with a valve in the balancing pipe for regulating the pressure. The balancing arrangement is always made automatic, either similar to Fig. 71 or with a leak-off through a small annular clearance around the shaft. Although these balancing arrangements may have their disadvantages, they are, however, superior to practically any on the market today, simply because they work automatically and no unknown factors enter into the design.

As to the disadvantage pointed out by the author, that a portion of the pump capacity is wasted, this applies just as much to the pump with impellers arranged back to back.

Take, for instance, the six-stage pump shown in Fig. 81, if this pump were designed for a total pressure of 900 lb. there would be a drop in pressure in the clearance space between the sixth and second stage of 600 lb., which would result in an appreciable leakage and loss of capacity if the bushing and shaft should become even slightly worn.

One advantage of the automatic hydraulic-balancing arrangement is that means can be provided in the balancing pipe for continuous measurement of the leakage, and adjustments and replacement of parts can therefore be made as soon as the leakage is found to be excessive.

With internal-tightening joints subjected to considerable pressure drops, such as in the back-to-back impeller pump, there is no way to determine the leakage except by either taking the pump apart and measuring the clearance or by running a complete test, which is not always convenient.

With the high pressures as nowadays encountered in connection with boiler-feed pumps and high-pressure oil pumps, the item of leakage through balancing rings and through bushings separating stages on back-to-back impeller pumps may be of considerable magnitude, and anything that can be done to check this leakage should be of value in maintaining the original efficiency of the pump, either by adjustment or replacement of parts.

The power requirements of modern high-pressure boiler-feed pumps are such that even a comparatively small percentage loss in efficiency becomes an item of great importance.

At the bottom of the first column of the thirty-seventh page reference is made to increase in efficiency of a high-pressure pump with suction lift as compared with pressure on the suction. This is something that the writer has not found in his experience with centrifugal pumps, and he would be interested to know if there are any other centrifugal-pump manufacturers who have found a condition similar to that which the author has obtained in his tests.

It is rather difficult to reconcile the two head-capacity curves in Figs. 103 and 104. Plotting the two curves on the same sheet, it is found that between 560 g.p.m. and 960 g.p.m. the curve with suction lift is higher than the one with pressure on the suction, the maximum difference being around 20 lb., which seems to require an explanation other than that given at the bottom of the thirty-seventh page. It is doubtful if the condition approaching cavitation with the water leaving the runner walls accounts for the difference in head and efficiency. It is difficult to conceive how the pump could be operating at conditions approaching cavitation over such a great range of capacity as from 560 g.p.m. to 960 g.p.m. There must be some other explanation for the increase in efficiency and head when the pump is operating at 10 ft. suction lift.

The writer would like to ask why only a 250-hp. motor was used to drive this pump. The horsepower required by the pump is such that the motor would be overloaded almost 50 per cent if the pump were handling water, and this overload seems high for the present-day electric motor.

In going back to the second column of the twenty-second page, it is stated that, with the rings set eccentrically, the leakage is smaller for the same clearance area.

The writer has not had an opportunity to verify this by tests, but he happened to run across a reference to such tests in *Zeitschrift des Vereines deutscher Ingenieure* in the April 12, 1930, issue, according to which the leakage through rings set eccentrically is greater than with concentric rings, and with full eccentricity the leakage under some conditions was $2^1/_2$ times as great as with concentric rings. The writer would like to know if the author can offer some explanation for this discrepancy.

John Mann.[38] Some of the discussers seem to think that pump builders are going to a lot of unnecessary trouble in balancing for end thrust when Kingsbury bearings could be built to carry any end thrust which might occur in an unbalanced pump.

Their remarks would possibly apply to the propeller type of pump, but in the radial-vane type of pump there is no loss in efficiency due to balancing, and practically no extra cost.

The pumps under discussion were mainly 3600 r.p.m. and up to eight stages, developing pressures of approximately 100 lb. per sq. in. per stage. These pumps, with impellers back to back and having their areas balanced, can have end-thrust loads as high as 5000 lb. This end thrust can be balanced by the Goulds method of making suction impellers slightly smaller in diameter than the discharge impellers, or by the Byron Jackson method of changing impeller-hub diameters. Pumps so built and balanced have a light end-thrust load. Ball bearings can then be used to locate the rotating element endwise. These bearings over a wide range of speeds are reliable, require very little attention, and are of comparatively low cost, whereas if no effort is made to balance the pumps for axial thrust, and Kingsbury bearings are used, these bearings would be costly and require a lot of attention at the higher speeds to keep them running.

The author has contributed to the improvement of centrifugal pumps by the publication of his comprehensive tests on wearing-ring leakage and axial thrust.

Referring to his statement that there is no available information on axial thrust checked by actual measurements, Goulds has been making such measurements continuously since 1927 and has collected a large amount of data on axial thrust on many types of pumps, such as: Double-suction, single-stage; single-suction, single-stage (as in Fig. 30), with wearing-ring clearances varied; single-suction, single-stage, open impellers; single-suction, multi-stage, runners grouped one way; single-suction, multi-stage, runners in two groups, opposed. These tests have not been published. (As a result of these tests, end thrust in Goulds pumps is known and provided for in the design.)

The machine used to measure thrust consists of a cylinder and plunger, the end thrust being balanced by hydraulic pressure on the plunger, the pressures being read directly from a pressure gage.

Various tests made since 1927 would seem to indicate that the main cause of axial thrust other than unbalanced areas is due primarily to a difference in pressure on the two sides of a runner. It is believed that if the author, in his tests on axial thrust, had obtained pressures on both sides of the runner, he would have come to quite different conclusions in regard to the unknown causes of thrust other than unbalanced areas. This difference in pressure is caused by a difference in leakage. For example, if there is excessive end thrust on a double-suction pump, this thrust would be due to the clearance space on the wearing ring on one side of the runner having worn more than the wearing ring on the opposite side of the runner. While the other causes mentioned by the author may be present, they are so small that they can be neglected.

A two-stage pump with runners back to back will have a leakage from the second-stage chamber to the first-stage chamber. This will cause a slight drop in the average pressure on the back of the second-stage runner and a slight increase in pressure on the back of the first-stage runner. Although this pressure change is low, the area on which the pressure acts is great. The thrust in this two-stage pump, and in the multi-stage pumps with runners grouped back to back, is balanced by making the suction runners smaller in diameter than the discharge runners.

The difference in head developed by the runners is then an unbalanced pressure on the suction-eye areas of the runners in a direction from suction to discharge.

Pumps similar to Fig. 30 have a greater leakage from the front shroud of the runner to the suction chamber than from the back shroud to the discharge chamber. This difference in leakage causes a difference in pressure on the two shrouds of the runner and a thrust toward the suction.

To balance this thrust, the discharge wearing ring is made larger in diameter than the suction wearing ring. The pressure on the discharge shroud of the runner is then on a smaller area than the pressure on the suction-side shroud. In the first paragraph on the twenty-fifth page, the author seems to have neglected the effect of this large thrust load in the opposite direction when increasing the wearing-ring diameter to balance for impact. The shape of the thrust curve and the amount of balancing to be done on this pump depend on the means taken to transfer the leakage from the discharge chamber to the suction side of the pump.

Referring to the conclusions on axial thrust, conclusion (16) can be explained by the change in pressure on the full shroud diameter due to leakage.

As to conclusion (17), the major portion of axial thrust should be calculated on pressure change due to leakage loss.

As to conclusion (18), it is very doubtful that uneven radial velocity distribution in the runner is a cause of axial thrust in the pumps under discussion in the paper.

As to conclusion (23), pumps with runners arranged in two opposing groups have an unbalanced end thrust as per Equation [30]. This is the same as pumps with runners arranged in pairs back to back, as in Fig. 75.

Symmetry is no more a factor in axial thrust in the group arrangement than in the pair arrangement of Fig. 75. That this is so is shown by the thrust curves without balance, as in Figs. 103 and 104.

[Discussion of this paper jointly with that of J. W. Macmeeken by A. J. German will be found following the latter paper.]

AUTHOR'S CLOSURE

The author wishes to thank the discussers for their contributions to this paper. He feels flattered that Professor Switzer and Messrs. Peterson and Mann have gone through the paper with such extreme care. Their points of view, different from the author's in some cases, are appreciated.

Referring to Professor Switzer's valuable discussion, the author thinks that any decrease in leakage is a net saving, and that the pump efficiency will improve with improved volumetric efficiency. Such minute increase in power as that caused by the increased skin friction (steps or grooves on the rings and decrease in clearance) or power used to pump the leakage back by spiral grooves, could not be detected by these tests.[39] The author agrees with Professor Switzer that the radial ribs on the impeller shrouds are the most effective means to reduce the leakage, or even to eliminate it at high speeds, as was observed in these tests. The danger, however, is that the radial ribs will throw the pump out of balance for axial thrust. The general belief that radial ribs take much power seems to be greatly exaggerated. Investigation in this direction would be of value. The author uses radial ribs occasionally for balancing axial thrust. Professor Switzer's explanation of the decrease of the coefficient of discharge through the wearing rings with increased peripheral speed is essentially the same as the author's, only differently worded.

---

[38] Chief Engineer, Goulds Pumps, Inc., Seneca Falls, N. Y.

Messrs. Switzer and Mann are inclined to think that the major cause of axial thrust other than the unbalanced areas is the difference of pressure on the two sides of the impeller from outside rather than from inside. The author would agree with that if these discussers would show what causes this difference in pressure on the two sides of the impeller with such ample clearances around the impeller as are found in modern pumps. On page 35, the author has mentioned that he conducted a series of tests (40 runs) with the impeller displaced from its central position in the casing $^3/_{16}$ in., thus making a difference in the clearance space of $^3/_8$ in., and did not find any appreciable change in the axial thrust. Thus this cause for the difference in pressure on two shrouds of the impeller is hardly possible with large clearance spaces. To what extent may the difference in leakage affect the pressures in the clearance spaces? Not more than the difference in the velocity head in these spaces, the leakage only flowing through—which is really negligible. This does not apply to the pressure in the balancing chamber on the back of the impeller, which depends greatly upon the amount of throttling in the wear ring, and as this is decreased with worn rings, the pressure in this chamber increases, resulting in increased axial thrust as shown in Fig. 105. The form of the thrust-capacity curves (increase of thrust at high capacities) is substantially the same with no balancing chamber on the back of the impeller, as seen from Figs. 87–94. It has been shown in the paper that the amount of balancing required depends upon the way the balancing chamber is connected to the pump suction. No explanation accounts for the increase of thrust at low pressures (high capacities) except the supposition of different internal pressures at the two shrouds. The variation in thrust at conditions approaching cavitation, when local low-pressure spots are formed inside the impeller, can hardly be questioned.

The case of a double-suction pump with different clearances in wearing rings quoted by Mr. Mann may serve very well to prove the author's point of view, because with different amounts of leakage on the two sides of the pump, the impeller halves work at different capacities, and hence at different heads, which causes axial thrust from inside the impeller. The author is very anxious to know some details about the pump with a difference in pressure on both sides of the impeller of 30 or 40 lb. as mentioned by Professor Switzer. This must be some unusual case. In the case of a dredge pump tested by J. H. Polhemus and J. Healy (see footnote 28) with an impeller 70 in. in diameter, a head of 92 lb., and a clearance of $^1/_{32}$ in. at the front shroud and of $^8/_{32}$ in. on the back, the maximum difference in pressure observed was 24.5 lb.; but when the clearances were changed to $^9/_{32}$ in. on the front shroud and $^1/_{32}$ in. on the back, the difference decreased to 4 lb. Note the relatively small clearances and the size of the impeller used in these tests.

Professor Switzer will notice that author's readings taken at various points in the volute agree with similar tests by the DeLaval Company, as stated in Mr. Peterson's discussion. As to the possibility of cross-flows inside the impeller caused by the difference in pressure near the two shrouds, it should be noted that there are many examples in hydraulics illustrating that the pressure alone does not determine the direction of the flow—the flow through the elbow being one. At points removed from the point of the peak efficiency, these cross-flows no doubt exist, and account for the drop in efficiency on both sides of the peak.

The author shares Mr. Peterson's enthusiasm about the labyrinth rings, which are standard with the Byron Jackson pumps except on very small, cheap ones, where other means to reduce leakage are used. As to the radial load on the pump shaft caused by uneven pressure distribution in the volute casing, the author prefers the term "side thrust" to distinguish it from the radial load due to weight of the rotating element and to suggest the hydraulic nature of this load. Mr. Peterson's explanation of the difference in pressure at points *D* and *E* in the volute case seems very probable, depending, however, on the volute proportions.

If the suction lift is measured with a monometer on the suction nozzle, then this reading should be corrected for the difference in the velocity heads at the point where the reading is taken and at the impeller eye to obtain the difference in pressure across the clearance, as pointed out by Mr. Peterson. H_L in this paper is the static head above the pump-suction level as clearly defined in the first paragraph of sec. 9, page 14, and it should be corrected for the full velocity head at the impeller eye, the loss of the suction pipe being neglected.

The ratio of the relative velocities at the inlet and outlet $w_1/w_2 \geqq 2$ seems unusually high. Probably the discrepancy is explained by the difference in location of points to which these velocities refer. The author calculates these velocities at the vane tips where the vane overlapping starts at entrance and stops at discharge (dotted line through *A*, Fig. 19) and not from the theoretical velocity triangles. R. Defeld[40] gives for this ratio values ranging from 1.0 to 1.5, which agree with the author's observations. Furthermore, [27] refers to the theoretical head; the actual head is lower by the amount of hydraulic losses, but dropping of the term $(w_1^2 - w_2^2)/2g$ will partly account for these hydraulic losses, as mentioned in the first paragraph of page 17. The size of the special nozzle through which the leakage was discharged was not $1^1/_8$ in., as appeared by mistake in preprints of the paper at the bottom of the first column, page 12, but $1^1/_2$ in. as shown clearly in Fig. 32 on the same page. In all cases, except those with the two largest clearances, this nozzle was not running full, thus assuring atmospheric pressure in the chamber on the back of the impeller.

It seems that the automatic feature of the balancing disk was sufficiently emphasized in the paper. As to the leakage loss in pumps with impellers arranged in two opposing groups as compared with those using balancing disks, the first have the advantage that the clearances are on a small diameter and the throttling surfaces are wide and can be provided with steps and grooves to reduce the leakage.

As to the possibility that pumps approaching cavitation conditions show slightly better efficiency than when operating with a positive head on suction, the author never gave this any thought until he had learned that it was an established fact in hydraulic-turbine practice as reported by J. Ackeret referring to Thoma and

---

[39] Professor Howe and Mr. Ponomareff of the University of California are experimenting now with a very delicate apparatus which will enable them to throw some light on the questions of the effect of the clearance, eccentricity, and viscosity upon the power consumption for close-running fits.

[40] Raymond Defeld, "A Practical Treatise on Single and Multistage Centrifugal Pumps," Chapman & Hall, 1930, p. 45.

Schilhansl's observations, in "Hydraulische Probleme," V.D.I. Verlag 1926, page 105. H. Föttinger confirmed the same fact on page 110 of the same work. After that the author had the occasion to observe the same phenomenon on three different pumps tested at different times.

A 250-hp. motor was used in these tests because the pumps were built for light gasoline and mounted on a base to take a motor of this size. These motors stand an overload of 50 per cent for an hour without excessive heating.

As to the discrepancy between the author's experience with the eccentric clearances and those of Dr. Schneckenberg briefly reported in the April 12, 1930, issue of *Zeitschrift des Vereines deutscher Ingenieure*, called to the author's attention by Mr. Peterson, the following comments will be made. After a study of the Dr. Schneckenberg article, it seems that the discrepancy is caused by a difference in the test conditions and methods of observation and may be apparent only, as will be seen from the following:

(1) Both throttling surfaces of the Dr. Schneckenberg apparatus were stationary, while in the author's set-up one surface was revolving.

(2) The maximum difference in the leakage between the concentric and eccentric clearances was observed by Dr. Scheckenberg with the smallest clearances 0.01 mm. (0.0004 in.) and 0.1 mm. (0.004 in.), referring to the viscous flow, this difference almost disappearing with 0.4 mm. (0.016 in.) and 1 mm. (0.040 in.), the flow being turbulent in this case. Only the last two clearances are comparable with those used by the author. The rotation of one of the throttling surfaces accompanied by the microscopic vibration tends to set up turbulent flow much earlier than with both surfaces stationary.

(3) In the author's arrangement the resistance to the flow or pressure drop on the two sides of the wearing rings included the entrance and exit losses and was uniform around the wearing ring, while Dr. Schneckenberg's throttling surfaces were 181.5 mm. long (7.25 in.) and pressure readings were taken a certain distance from the ends, thus excluding the entrance and discharge losses. This difference in the arrangement is important because the leakage (or coefficient of discharge) was plotted against the pressure in both cases.

(4) In the case of eccentric clearance in Dr. Schneckenberg's tests, the pressure readings were taken in the middle between the maximum and minimum clearances, where the clearance was practically equal to that with concentric location. The leakage measured was the total for the whole circumference and was plotted against the pressure difference thus obtained. No doubt the pressure drop varied for different points on the circumference, and so did the velocities. The pressures measured as explained above could hardly be used as a basis for comparison of leakage with concentric clearances and a uniform pressure for all the points on the circumference.

The author's experience with eccentric clearances was limited to a few cases where rubbing in the wearing rings was observed and inconsistent results were obtained. The trouble was removed in all cases after the concentricity of the clearances was restored. No doubt, in all cases when no rubbing in the rings was observed, a certain amount of eccentricity was present, affecting adversely the accuracy of the results.

The author is glad to find an able supporter in Mr. Mann on the question of the use of ball bearings in high-speed multi-stage pumps. The Byron Jackson Company in a period of less than two years has installed over one hundred 3600-r.p.m. multi-stage pumps in sizes up to 500 hp. Some of these pumps have been in continuous service for twenty months. During this time only one trouble with ball bearings has been reported. On inspection of this bearing, a broken thermometer was found in the bearing housing, partially ground to fine dust which was deposited on the balls. After cleaning, this bearing was reinstalled and is running to entire satisfaction. The wearing rings and stage pieces were replaced in some cases where the pipe line was not initially free from sand and scale. The cheapness of the ball bearings is a secondary consideration. The deciding factors in their favor are their efficiency, reliability, minimum attention required, and reduction of the shaft span between the bearings.

In conclusion (23) the expression "runners arranged in two opposing groups" was intended to cover both the runners set in pairs back to back and set in two opposing groups with runners of each group facing in one direction. Naturally, as far as the axial thrust is concerned, the two schemes are identical.

The reference by Messrs. Peterson and Mann to the experimental work performed by their respective companies, the results of which have not been published, leaves the author's statement that there is little or no information available on leakage loss and axial thrust still in force. After the submission of this paper for publication the author learned about two works on leakage loss, one by A. F. Sherzer, briefly reported in *Engineering News-Record*, Vol. 92, pages 1056–58, and another one by M. Hannocq, of Liége University, reported in *Revue Universalle des Mines*, Vol. 6, and mentioned in Defeld's book previously referred to. Both of these investigators experimented with pumps with impeller suctions sealed and measured the leakage at the suction nozzle with an outside pressure applied to the volute case. Professor Sherzer tested plain rings with different clearances, and his results are in close agreement with those presented in this paper. The author was unable to obtain a copy of the publication containing the results of Mr. Hannocq's tests.

Referring to Mr. Aisenstein's criticism—it would seem that this discusser did not take into consideration the simple theoretical propositions advanced in sections 4 and 14, the first one dealing with the theoretical head developed by an impeller with uneven radial velocity distribution and the latter about the axial thrust caused by the shaft shoulders and impeller hubs in multi-stage pumps. The material contained in this paper is essentially the thesis submitted by the author to the University of California, which brought to him a doctor's degree and resulted in his advancement to his present position. To this discusser the integration seemed to be incorrect because the term $u_2/(g \tan \beta_2) = B$ on page 7 could not be treated as a constant on account of variation of the angle β_2. It would seem that he overlooked the author's statement in the first paragraph of section 4 that the deduction is intended for "the theoretical head for an infinite number of vanes," and that thus any variation of the angle β_2 is excluded, which is perfectly consistent with the radial velocity's not being the same for different water particles. With this in mind the whole development stands the most searching scrutiny.

The best proof of the usefulness and correctness of the principles involved in the calculation of the axial thrust due to the shaft shoulders and impeller hubs is on the testing stand. Numerous tests, of which Figs. 103 and 104 are illustrations, proved not only the existence of the axial thrust due to this cause, but that its value can be calculated accurately for the useful range of the head-capacity curve. A slight correction may be necessary to account for the difference in the head produced by different stages, as discussed on page 35.

It may be a matter of opinion whether an improvement of 1 per cent in efficiency of a 90-per cent pump is worth while or not, but certainly the endeavor to attain it should not be stopped by fear of inaccuracy in testing, as this is no worse for a pump of 91 per cent efficiency than it is for one of 90 per cent.

The author is not in favor of advertising injunctions such as "beware of close clearances," which is just another talking point similar to the stereotyped "extra long stuffing box," the latter being applied now to every pump in which no one expects to find more than five packing rings. But for a stuffing box of a hot-oil pump working at 1500 lb. and a temperature of 600 deg. fahr., the term "double extra long" would by no means be strong enough. The small clearances consistent with a perfect mechanical operation free from seizing or rubbing are entirely justified, but they do require skilled labor and cost money. Mr. Peterson pointed out, and rightly, that the reduced leakage not only improves the initial efficiency but also the sustained efficiency on account of greatly reduced wear.

Dr. Schneckenberg, in the article previously referred to, states that in modern high-pressure boiler-feed pumps the clearances between the throttling surfaces are made very small, in fact, smaller than those in the bearings. This of course means that these surfaces themselves serve as bearings. Apparently, the German engineers are not afraid of close clearances.

It would seem that the object of the tests on leakage has escaped Mr. Aisenstein's attention. It was not the author's intention to develop some new formula to calculate the leakage through the clearances in the wearing rings. He used the oldest formula of hydraulics, $v = \sqrt{2gh}$, dating back to Torricelli's time (1643). To find the experimental coefficients for this formula for various types of rings and the ways to estimate the pressure across the clearance was the object in view. The author also appreciates very well the necessity of making certain assumptions and estimates in any kind of engineering calculations, and lengthy arithmetical figuring was hardly necessary to prove that. To guide the design in making these assumptions and estimates was the thought when these data were offered for publication. Dr. Pfleiderer's classical work on centrifugal pumps and textbooks previously published does not contain this information.

It is to be regretted that Mr. Aisenstein did not give particulars regarding the easy method of calculating the volute pressure H_p mentioned in his discussion.

In this discusser's statement of the reasons for the low efficiency of small pumps, the author did not find anything not contained in the last paragraph on page 5, where it is stated in the first item that the "low-specific-speed type of pump is inherently less efficient."

It was hardly necessary to give references on all the questions touched in the introductory and descriptive part of the paper, but if the author were to mention any reference on pumping oils, it would be R. L. Daugherty's reports contained in the Goulds Bulletins 126 and 130.

The experience of several leading pump manufacturers has fully demonstrated that 3600-r.p.m. ball-bearing pumps intelligently designed are just as reliable as 1750-r.p.m. pumps with Kingsbury bearings were in the past, and Mr. Aisenstein's warning in the last paragraph of his discussion might have had weight fifteen years ago, but not now.

Hydraulic Jump in Sloping and Horizontal Flumes

Investigation of a Rational Solution Offering Formulas for the Tail-Water Depth

By ROBERT W. ELLMS,[1] PHILADELPHIA, PA.

The formulas presented in this paper were developed on a rational basis by the author in an attempt to solve for the tail-water depth of the hydraulic jump when it is produced in either sloping or horizontal flumes. A recent study of the mathematical analysis of this phenomenon has brought to light certain interesting relationships which are discussed in this paper. The conclusion drawn from this investigation is that Prof. W. C. Unwin's momentum formula is really a special case of a more general formula which can be used to include jumps produced in both sloping as well as horizontal flumes. Data from a paper by the author entitled, "Computation of the Tail-Water Depth of the Hydraulic Jump in Sloping Flumes"[2] are used to substantiate the theoretical conclusions reached herein.

ONE of the most interesting phenomena included in the study of hydraulics is the passage of water moving at a high velocity and below the critical depth into a stream of water moving at a considerably reduced velocity above the critical depth. This condition of flow has generally been termed the "hydraulic jump," and for over one hundred years there have been many experiments conducted upon it to determine its characteristics. In 1819 Bidone made experiments with a laboratory model in an attempt to discover, if possible, the relation between the depth of water before the jump to the depth of water after the jump. His work, like that of his followers, Gibson, Ferriday, and Lane, was done on small-scale models with jumps produced in horizontal flumes. While their work was very important, it was difficult to tell much about the nature of the action of the jump from their experiments. Prof. W. C. Unwin was the first to correctly analyze the mathematics of jumps produced in horizontal flumes on a rational basis, and his work is recorded in the Encyclopedia Britannica.

With the increasing demand for water power in industry, the necessity of large dams and levees to prevent destruction of property from river floods, and the new application of the jump to the process of water purification, it became imperative to determine more about the laws governing the production of the jump so that its occurrence could be predicted with certainty and the limits of its action more easily controlled. Kennison and Hinds followed in this work with observations on large jumps produced in a horizontal position only, but it was not until 1917 that Riegel and Beebe, of the Miami Conservancy District, extended the study to include jumps produced in sloping flumes. These two latter men were interested in properly controlling the flood run-off waters leaving large retarding basins placed beside the Miami River. In 1920 J. W. Ellms and A. G. Levy conducted a series of experiments on jumps produced in sloping and expanding flumes. Their work was done on a full-sized model flume in which a jump was produced prior to the installation of three such flumes in the Baldwin Filtration Plant at Cleveland, Ohio. In 1927 the author and J. R. Fleming conducted experiments on jumps produced in a sloping and expanding flume capable of carrying 1.5 cfs of water and the slope of which could be varied from approximately 9 to 17 deg.

The results of all the work done on jumps produced in sloping flumes proved conclusively that it was incorrect to apply Professor Unwin's classical momentum formula to this condition of expanding flow. It appeared necessary to develop another formula along rational lines which would have included in it a factor to take care of any variation in the slope of the flume. Several empirical formulas were developed by the author, and the work was described in a paper.[2] Since its publication a further study of the mathematics of the jump has been made and a plausible rational solution developed. Before going directly to the mathematical solution for the jump produced in sloping flumes, a history of the mathematics for jumps produced in horizontal flumes will be briefly reviewed.

History of the Mathematics of the Jump for Horizontal Flumes

During the past century many interesting attempts have been made to obtain the proper mathematical formula which would express the conditions of flow observed. As mentioned before, Bidone's experiments were made in small laboratory model flumes, and it was therefore very difficult to measure accurately the depths of water before and after the jump. This inaccuracy led to the application of false principles and the development of formulas from non-identities.[3]

Belanger attempted to compute the depth of tail water of the hydraulic jump in a horizontal flume by solving the equation

$$d_1 + \frac{v_1^2}{2g} = d_2 + \frac{v_2^2}{2g}, \text{ for } d_2$$

---

[1] Mechanical Engineer. Jun. A.S.M.E. Mr. Ellms was born in Cincinnati in 1903. In 1926 he was graduated from Baldwin-Wallace and in 1927 from Case School of Applied Science. He received his M.E. degree from Case in 1930. He designed traveling cranes in Cleveland, and subsequently became connected with the Pennsylvania Water & Power Company, Baltimore, as hydraulic test engineer. He had charge of model laboratory tests on the turbine units now installed at Safe Harbor. In 1930 he was appointed head of research work on coke crushers by the Koppers Research Corporation, Pittsburgh. This work led to the introduction of new crushing methods that would reduce the quantity of coke breeze, but work was discontinued due to economic conditions.

[2] Robert W. Ellms, "Computation of the Tail-Water Depth of the Hydraulic Jump in Sloping Flumes," Trans. A.S.M.E., paper HYD-50-5, 1927–1928.

Contributed by the Hydraulics Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, andnot those of the Society.

[3] Throughout this paper all flumes will be considered to have unit width and rectangular section. Here, also, g will equal 32.2 fps and w equal 62.5 lb.

In Fig. 1, and the foregoing formula:

d_1 = depth of water before jump
d_2 = depth of water after jump
v_1 = velocity of water before jump
v_2 = velocity of water after jump
g = acceleration due to gravity, fps.

From this false equation he easily derived the formula

$$d_2 = \frac{v_1^2}{4g} \pm \sqrt{\frac{v_1^2}{2g}\left(d_1 + \frac{v_1^2}{8g}\right)} \quad \ldots\ldots\ldots\ldots [1]$$

According to this, energy losses occurring from impact or sudden expansion were considered by him to be negligible, but it is now known that the term $d_2 + \frac{v_2^2}{2g}$ should have had added to it the h_e losses to make the equation a true identity. Here the h_e represents the loss of head due to impact.

Professor Merriman considered that "the lost velocity head is $\frac{(v_1^2 - v_2^2)}{2g}$, and that this is lost in two ways: first, by impact $h' = \frac{(v_1 - v_2)^2}{2g}$ and, second, by the uplifting of the whole quantity of water through the height $1/2(d_2 - d_1)$." From this he found that

$$d_2 = \pm\sqrt{2d_1 \frac{v_1^2}{2g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

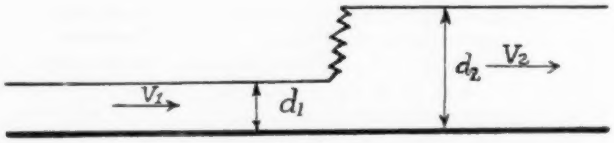

FIG. 1

It has been proved that the loss in head by "sudden expansion" is not equal to $\frac{(v_1 - v_2)^2}{2g}$, but is probably this quantity multiplied by a constant. The lifting of the mass of water through the distance stated is incorrectly applied in this equation.

Mr. Andrews mentioned that possibly "the difference between the velocity heads should be equated to the difference between the height of the center of gravity of the water masses in the two phases of flow, rather than the difference between the elevation of the two water surfaces." Thus

$$\frac{v_1^2 - v_2^2}{2g} = \frac{d_2 - d_1}{2}$$

The resulting equation solved for d_2 is

$$d_2 = \frac{v_1^2}{2g} \pm \sqrt{\frac{v_1^2}{g}d_1 + \left[\frac{v_1^2}{2g}\right]^2} \quad \ldots\ldots\ldots\ldots [A]$$

Considering the center of mass as a measure of the potential energy of water has caused more than one such error in hydraulics.

Professor Unwin seems to have properly analyzed the forces acting in this phenomenon when he suggested that it might be regarded as a case of Newton's second law of motion. He therefore equated the static force acting on the water to the loss of momentum that a unit mass of water would experience in changing its velocity from V_1 to V_2 in unit time. As Newton expresses this law, "The rate of change of momentum is proportional to the applied force and takes place in the direction in which the force acts." Stated in algebraic terms $F \propto \frac{M \cdot v}{t}$, or $Ft = M(V_1 - V_2)$, in which F is the dynamic force that causes the change of momentum from MV_1 to MV_2 in the time t. Professor Unwin considered the dynamic force in this problem as being equal to the difference between the pressure exerted by two columns of water equal in height to d_1 and d_2, respectively.

Thus from Fig. 1 the total force in favor of the flow is $w\int_0^{d_1} d_1$ and the total force of the water opposing the flow is $w\int_0^{d_2} d_2$.

Integrating these forms between their limits and taking their differences will give $\frac{wd_1^2}{2} - \frac{wd_2^2}{2}$, or $w\left(\frac{d_2^2 - d_1^2}{2}\right)$, the latter expression giving a positive sign to the form. Equating this to the change of momentum $\frac{wQ}{g}(V_1 - V_2)$, where $M = \frac{wQ}{g}$, and placing $Q = d_1V_1$, will give

$$\frac{w(d_2^2 - d_1^2)}{2} = \frac{wd_1V_1}{g}(V_1 - V_2) \quad \ldots\ldots\ldots\ldots [3]$$

Substituting $V_2 = \frac{d_1V_1}{d_2}$ and solving for d_2, gives the three roots

$$d_2 = \pm\sqrt{\frac{2d_1V_1^2}{g} + \frac{d_1^2}{4}} - \frac{d_1}{2} \quad \ldots\ldots\ldots\ldots [4]$$

$$d_2 = d_1$$

Equation [3] is a cubic with two positive roots and one negative root.

Table 1 shows how the four equations just developed compare with Bidone's original measurements.

TABLE 1

d_1	V_1	Observed d_2 (Bidone)	Belanger	Merriman	Andrews' Equation [A]	Unwin
0.149	4.59	0.423	0.424	0.439	0.781	0.373
0.155	4.47	0.423	0.438	0.437	0.749	0.367
0.208	5.59	0.613	0.642	0.636	1.148	0.537
0.242	6.39	0.764	0.811	0.777	1.436	0.663
			No energy loss	Sudden expansion	Center of mass	Momentum

It is interesting to note that Bidone conducted his experiments in a flume which had a slope of approximately one-tenth of a foot per foot, and as a result all his measurements are higher than the momentum formula gives. Without discussing the discrepancies in Table 1, it will suffice to mention that even rationally developed formulas are subject to serious error if the problem is not properly analyzed and that to attempt to fit a formula to poorly taken data will prove just as disastrous.

The truth of Professor Unwin's formula has been proved beyond any question or doubt. Many experiments covering a large variation in the value of d_1 and V_1 have been made and checked with this formula, so that its application to a jump produced in a horizontal flume may be made without fear of using it incorrectly. The 1929 edition of Professor King's "Handbook of Hydraulics" has a special chapter devoted to the hydraulic jump that covers the subject so completely that any one may readily apply the principles stated therein to his particular problem.

MATHEMATICS OF THE JUMP IN SLOPING FLUMES

With the extended application of the jump it became desirable to more easily control its action. This was accomplished by causing it to occur in a sloping flume. By so doing the mathematics required to compute the resulting tail-water depth became greatly involved. Introducing this additional variable caused a complete failure of the classical momentum formula when applied to this flow condition. Empirical formulas now developed, however, give accurate results for the range of all present data on sloping flumes.[4]

The real difficulty encountered in the development of a rational formula was to find a satisfactory explanation of the action taking place within the jump and to determine just how this action should be expressed mathematically. An attempt is here made to apply the principles which underlie the conservation of linear momentum and to correlate flow conditions for jumps produced in both horizontal and sloping flumes.

Analysis From Newton's Second Law of Motion

The first step in the solution of this problem is to determine the value and direction of the applied forces acting on the water.

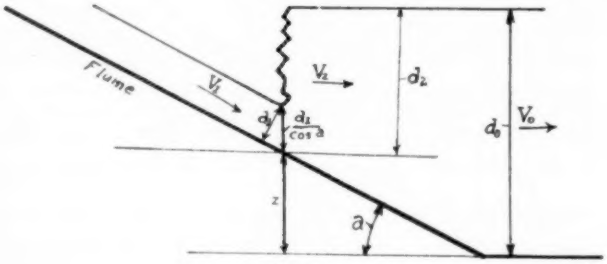

FIG. 2

If we consider Professor Unwin's case of a jump in the horizontal position, it will be observed that the dynamic forces acting on the water may be correctly translated into equivalent static forces. Fig. 2 is a diagram showing the profile of a jump produced in a sloping flume of rectangular cross-section and unit width.

The depth of the stream before impact is d_1 measured normal to the bottom of the flume, and its corrected vertical depth is $\frac{d_1}{\cos a}$, where a is the angle of inclination of the flume with the horizontal. The depth of water after impact is d_2. While the water does not rise immediately to this value as drawn in Fig. 2, still it is this depth which is effective in opposing the flow. The hydrostatic force in favor of the flow is $w \cdot \int_0^{\frac{d_1}{\cos a}} \frac{d_1}{\cos a}$, and the force opposing the flow is $w \cdot \int_0^{d_2} d_2$.

Integrating these functions, subtracting their limits, and taking the difference between them will give $\frac{wd_2^2}{2} - \frac{wd_1^2}{2 \cos a}$. Simplifying this, we have a statement of the force which causes the change of momentum from before to after impact. It is $w \frac{d_2^2 - \frac{d_1^2}{2 \cos a}}{2}$ in magnitude, and its direction is in a horizontal plane. **This assumes cos a to have constant values.**

The effective value of the momentum of the water before impact is the product of its mass times its velocity times the cosine of the angle at which it strikes. This is $Mv(\cos a)$, and for our case it is $\frac{wQV_1 \cos a}{g}$, where a is the angle from normal at which the water before the jump would impinge on a supposedly vertical tail-water wall. Fig. 3 shows this condition.

The velocity vector ($V_1 \cos a$) is co-linear with the tail-water velocity vector (V_2). This is exactly the condition that occurs during the production of the hydraulic jump in a sloping flume.

The instant impact occurs, the water flows practically horizontal. Hence we may therefore state that the value of the momentum after impact is simply equal to wQV_2/g, where V_2 equals the velocity of the tail water which corresponds to the height d_2 to which the water jumps. We are not concerned with the indeterminate flow conditions in the turbulent part of the jump or further down the flume, but only with the forces acting and the resulting theoretical change of momentum which takes place the instant impact occurs.

From the foregoing steps the final basic equation for jumps produced in either a sloping or horizontal flume may be developed, as follows. Starting with the original momentum equation $Ft = MV_1 - MV_2$ and making the proper substitutions will give $w \cdot \frac{d_2^2 - \frac{d_1^2}{\cos^2 a}}{2} \cdot t$ as the magnitude of the impulse and $\frac{wQV_1}{g} \cos a - \frac{wQV_2}{g}$ as the change of momentum.

Equating these two expressions, substituting $Q = d_1V_1$, and t to be unity, will give

$$w \cdot \frac{d_2^2 - \frac{d_1^2}{\cos^2 a}}{2} = \frac{wd_1V_1}{g} \cdot (V_1 \cos a - V_2) \ldots\ldots [5]$$

This is the final equation for a jump produced in either a sloping or horizontal flume. If the flume has zero slope, the cosine of the angle becomes unity and this formula reduces to Professor Unwin's familiar formula, Equation [3] of this paper. We are chiefly interested, however, in its treatment for jumps produced in sloping flumes. In order to more clearly understand the nature of this mathematical problem, it is best that Equation [5] be reduced to a cubic equation which can be readily plotted. This is done in the following steps.

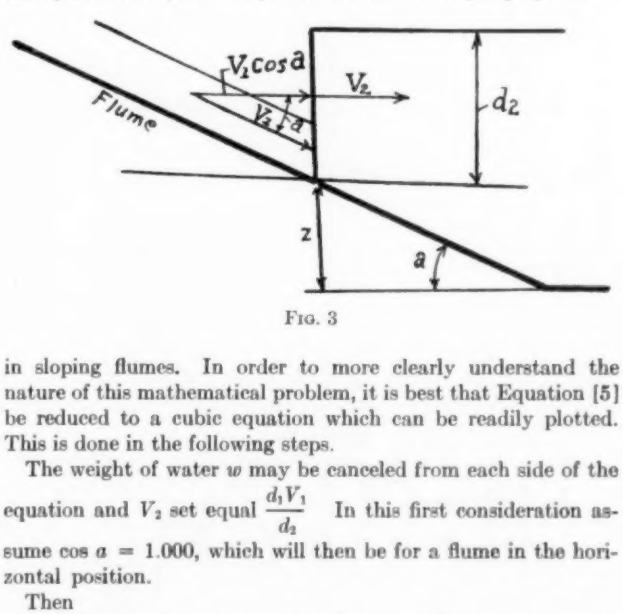

FIG. 3

The weight of water w may be canceled from each side of the equation and V_2 set equal $\frac{d_1V_1}{d_2}$ In this first consideration assume $\cos a = 1.000$, which will then be for a flume in the horizontal position.

Then

$$\frac{d_2^2 - d_1^2}{2} = \frac{d_1V_1}{g}\left(V_1 - \frac{d_1V_1}{d_2}\right) \ldots\ldots\ldots\ldots [6]$$

$$d_2^3 - d_2d_1^2 = \frac{2d_1V_1^2d_2}{g} - \frac{2d_1^2V_1^2}{g}$$

$$d_2^3 - \left[\frac{2d_1V_1^2}{g} + d_1^2\right] d_2 + \frac{2d_1^2V_1^2}{g} = f(d_2) \ldots\ldots [7]$$

The independent variables in this function are d_1 and V_1, while d_2 is the only dependent variable. If d_1 is set equal to unity and

---

[4] **The statement and discussion of these formulas are given in the author's previous paper.**

V_1 assumed to have various positive values above zero, Equation [7] may be reduced to any of the following forms:

Let $V_1 = 4.02$, then Roots for $f(d_2) = 0$
$d_2^3 - 2d_2 + 1 = f(d_2)$...... $+1, +0.6, -1.6$....[8]

Let $V_1 = 5.67$, then
$d_2^3 - 3d_2 + 2 = f(d_2)$...... $+1, +1.0, -2.0$....[9]

Let $V_1 = 8.03$, then
$d_2^3 - 5d_2 + 4 = f(d_2)$...... $+1, +1.6, -2.55$..[10]

Let $V_1 = 11.35$, then
$d_2^3 - 9d_2 + 8 = f(d_2)$...... $+1, +2.4, -3.4$...[11]

For the conditions chosen in [8] no jump will occur, because V_1 is less than the critical velocity.

The conditions for [9] are for critical flow, and no jump can be produced.

Equations [10] and [11] are for conditions favorable to produce a jump.

These formulas are plotted on the graph, Fig. 4. It will be noted that since d_1 was chosen equal to unity, all the curves pass through $d_2 = +1$, and that when the velocity V_1 reaches the critical velocity the curve $f(d_2)$ has just become tangent to the d_2 axis.

From this it will be seen that it is necessary to select the proper value of d_2 when solving Equation [5], or Equation [3] which is derived from [5], for the particular flow conditions being studied.

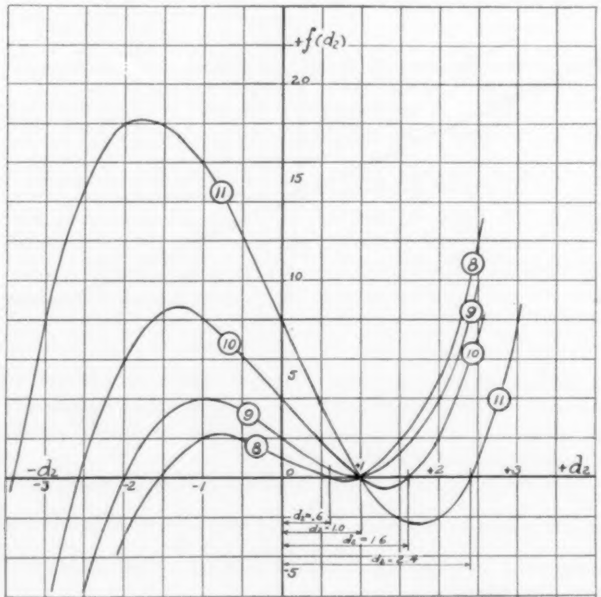

FIG. 4 HORIZONTAL FLUME DEPTH GIVEN BY POSITIVE ROOT OF $f(d_2)$, EQUATION [5]

$$d_2 = +\sqrt{\frac{2d_1V_1^2}{g} + \frac{d_1^2}{4}} - \frac{d_1}{2}$$

$$d_1 = +1.0, \cos a = 1.000$$

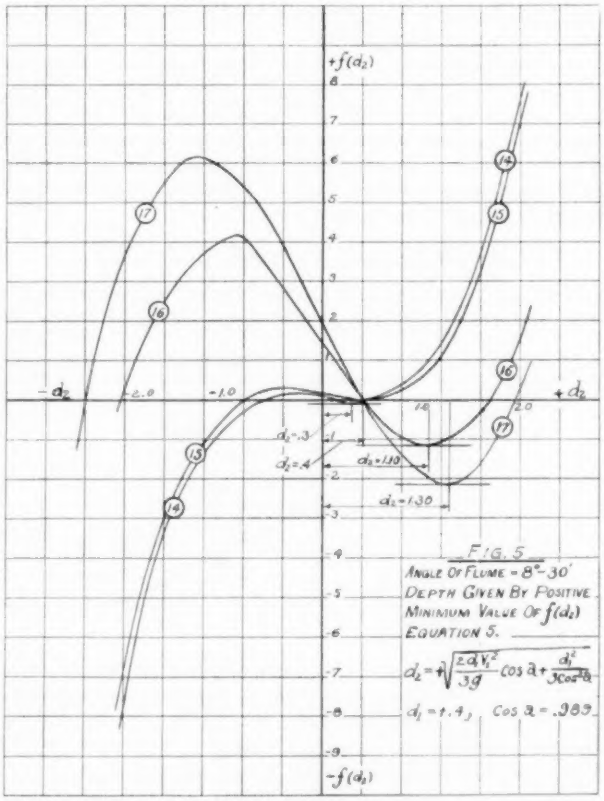

FIG. 5 ANGLE OF FLUME = 8° 30′. DEPTH GIVEN BY POSITIVE MINIMUM VALUE OF $f(d_2)$, EQUATION [5]

$$d_2 = +\sqrt{\frac{2d_1V_1^2}{3g}\cos a + \frac{d_1^2}{3\cos^2 a}}$$

$$d_1 = +0.4, \cos a = 0.989$$

It is now of interest to see what takes place when the jump is produced in a sloping flume, or in other words where a is not equal to zero. Canceling w from Equation [5], as before, and substituting $V_2 = \frac{d_1V_1}{d_2}$, we have

$$\frac{d_2^2 - \frac{d_1^2}{\cos^2 a}}{2} = \frac{d_1V_1}{g}\left(V_1 \cos a - \frac{d_1V_1}{d_2}\right) \ldots\ldots [12]$$

which may be reduced to

$$d_2^3 - \left[\frac{2d_1V_1^2\cos a}{g} + \frac{d_1^2}{\cos^2 a}\right]d_2 + \frac{2d_1^2V_1^2}{g} = f(d_2) \ldots [13]$$

Assume $\cos a = 0.989$, or $a = 8° 30'$. Also assume $d_1 = 0.4$ ft.

Let $V_1 = 2.00$, then Roots for $f(d_2) = 0$
$d_2^3 - 0.262d_2 + 0.040 = f(d_2)$.... $+0.4, +0.18, -0.55$..[14]

Let $V_1 = 3.58$, then
$d_2^3 - 0.478d_2 + 0.127 = f(d_2)$.... $+0.4, +0.4, -0.80$..[15]

Let $V_1 = 12.09$, then
$d_2^3 - 3.58d_2 + 1.45 = f(d_2)$.... $+0.4, +1.7, -2.05$..[16]

Let $V_1 = 14.10$, then
$d_2^3 - 4.87d_2 + 1.98 = f(d_2)$.... $+0.4, +1.95, -2.40$..[17]

For the conditions chosen in [14] no jump can be produced, because V_1 is less than the critical velocity.

The conditions for [15] are for critical flow, and no jump will occur.

Equations [16] and [17] are for conditions favorable to produce a jump.

These formulas are plotted on Fig. 5. Since d_1 was chosen equal to 0.4 ft., all the curves pass through $d_2 = +0.4$ ft. Here again the curve $f(d_2)$ is tangent to the d_2 axis just when V_1 equals the critical velocity.

Since Equation [5] has been developed along rational lines, it is only logical to believe that the larger positive root and value of d_2 would be the height to which the water would rise for jumps produced in a sloping flume. An attempt to use this value for data already obtained on jumps produced in sloping flumes failed completely and resulted in a calculated value approximately twice as large as the measured one. By substituting the measured value of d_2 obtained from previous experimental data in Equation [5], it was observed that the function of d_2 was very close to its positive minimum value. This immediately suggested the thought that the value for d_2 which would satisfy present experimental data was such a one that the value of the momentum equation would be a minimum. Thus in Equation [16] the $f(d_2)$ is a minimum when $d_2 = 1.12$ ft. Actual measurements for flow under the conditions of this formula give a measured height of 1.10 ft. Similarly, for Equation [17] the function is a minimum when $d_2 = 1.30$ ft., while the measured height of the jump was found to be 1.43 ft.

It is to be understood that Equation [5] has been developed entirely along rational lines and that experimental data have been used only to bring out and fortify the reasoning and conclusions herein disclosed. Since we have selected the positive minimum value of Equation [5] as that value of d_2 which accurately states the height to which the water will rise for jumps produced in sloping flumes, it becomes a simple matter to derive by calculus a proper formula which will accurately state this value. It is only necessary to take the first derivative of Equation [5], set it equal to zero, and solve for d_2. For convenience we may use Equation [13], which was derived directly from Equation [5], and write:

$$d_2^3 - \left[\frac{2d_1V_1^2}{g}\cos a + \frac{d_1^2}{\cos^2 a}\right] d_2 + \frac{2d_1^2V_1^2}{g} = f(d_2)$$

$$\frac{d(f \cdot d_2)}{dd_2} = 3d_2^2 - \frac{d_1^2}{\cos^2 a} - \frac{2d_1V_1^2}{g}\cos a \,.\,. [18]$$

Setting this function equal to zero and solving for d_2 gives:

$$3d_2^2 = \frac{2d_1V_1^2}{g}\cos a + \frac{d_1^2}{\cos^2 a}$$

and the two roots of this quadratic equation are:

$$d_2 = \pm\sqrt{\frac{2d_1V_1^2}{3g}\cdot\cos a + \frac{d_1^2}{3\cos^2 a}}\,.\, [19]$$

This formula is not a root of Equation [5]. It simply gives the value of d_2 which will make Equation [5] have a minimum positive value.

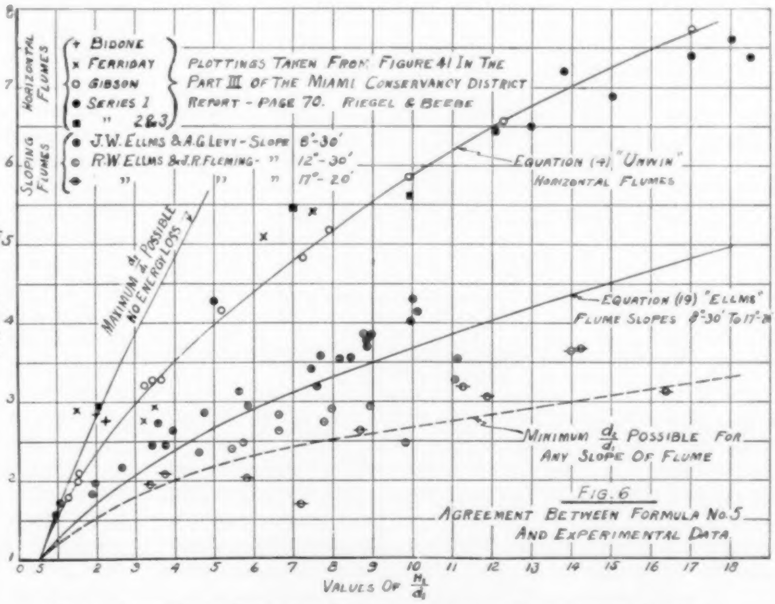

FIG. 6 AGREEMENT BETWEEN EQUATION [5] AND EXPERIMENTAL DATA

This formula has been used to compute all the data available on jumps produced in sloping flumes, and the extraordinary agreement between computed and observed values for d_2 are presented in Table 2. Runs Nos. 1 to 22, inclusive, were made in a small-capacity flume the angle of which was set at 17° 20′ for one set of tests and then changed to 12° 40′ for another set of tests. These readings made by the author are nearly all lower than the calculated value. The remainder of the runs listed in the table were made by J. W. Ellms and are nearly all a little higher than the calculated value. The flume used in these tests was non-adjustable and of high capacity. Its slope was 8° 30′ with the horizontal. Columns 6 and 7 give the computed and observed tail-water depths for the conditions of flow listed, while the last two columns give the depth of tail-water corrected for station elevation.

A further agreement between experimental data and Equation

[19] is shown in Fig. 6. Here are plotted the values of $J = d_2/d_1$ against the value of $\frac{H_1}{d_1} = \frac{V_1^2}{2gd_1}$. This method of comparing data with computed values is given by Messrs. Riegel and Beebe in a report entitled "The Hydraulic Jump as a Means of Dissipating Energy," which is a Technical Report of the Miami Conservancy District, Part 3, issued 1917. The plotted values of Bidone, Ferriday, Gibson, and Series 1, 2, and 3 are picked directly from Fig. 41, p. 70, of this report and are spotted along the theoretical "momentum curve" stated by Unwin for horizontal flumes merely to readily compare on the same graph the data now available for sloping flumes.

The curve farthest to the left represents "no energy loss," and therefore gives exceptionally high values for J. It will be observed that some early experiments of Ferriday, Bidone, and Series 2 and 3 fell to the left of the "no energy loss" curve, indicating a gain in energy which is impossible. The curve marked "Equation [19]" is really three separate lines representing three flume slopes. These lines are so close together that only one is drawn here. The dotted line is a boundary line for the minimum d_2/d_1 possible for any slope of flume and any value of d_1 or V_1. The points which are below this line are obviously in error. Likewise the points which fall above the Equation [4] line, and incidentally on the "no energy loss" curve, are impossible data. Regardless of the points in experimental error, these data taken in two widely different flumes by different experimenters remarkably substantiate the validity of Equation [19]. It may also be noted that all curves intersect where $(d_2/d_1) = 1$ and $(H_1/d_1) = 0.5$; that is, at the condition for critical flow.

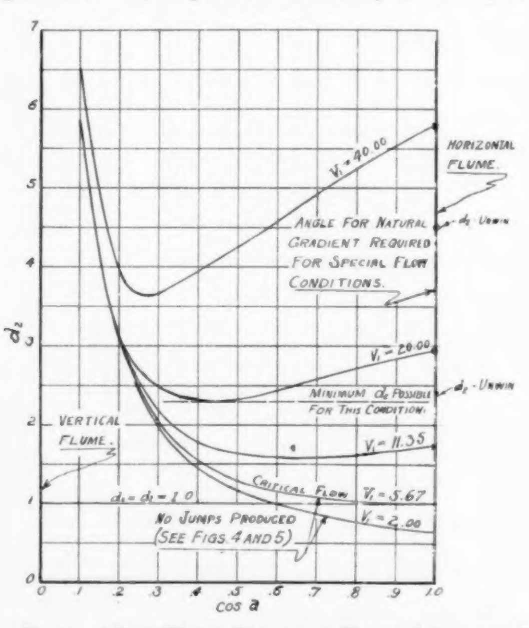

FIG. 7 GRAPH OF TAIL-WATER DEPTH AND FLUME ANGLE FOR $d_1 = 1.0$, EQUATION [19]

Fig. 7 illustrates the variation in the tail-water depth (d_2) for constant d_1 and V_1 conditions when only the angle of the flume is altered. Thus when $\cos a = 1.0$ the depth, d_2 is calculated by Unwin's formula. This calculation will hold true until the slope of the flume is increased just a little greater than the angle of natural gradient required to suit the special flow conditions in the flume. This position is represented by the vertical dotted line just to the left of $\cos a = 1.0$. As the angle of the flume increases, the depth d_2 falls off to some minimum value at which time $d_1/\cos a$ increases faster than d_2 was decreasing. This causes a rapid increase in d_2 for the smaller angles. At the condition $V_1 = 5.67$ for critical flow, no jump will occur, and d_2 only increases as the $d_1/\cos a$ causes it to increase. The curve for $V_1 = 2.00$ is only theoretically possible, and no jump will be produced.

Thus it may be seen that for $d_1 = 1.0$ and $V_1 = 20.00$, d_2 will equal 4.5 for a flume in the horizontal position. If the angle of the flume is tilted just a little steeper than the natural gradient required for the particular flow condition, d_2 will drop to 2.94 ft. This position is also shown on Fig. 6 at $(H_1/d_1) = 6.23$ and $(d_2/d_1) = 2.94$. If the angle of the flume is increased, d_2 will constantly drop to a minimum of 2.33, also shown on Fig. 6 at $(H_1/d_1) = 6.23$ and $(d_2/d_1) = 2.33$ on the dotted line. A further decrease of the flume angle will cause an increase in d_2 to infinity, where $a = 0.0$ for a flume in the vertical position. This is clearly shown on Fig. 7.

The physical reason for using the minimum positive value of Equation [5] for the tail-water depth (d_2) will now be discussed.

It is necessary to show purely from a physical standpoint why the jump produced in a sloping flume behaves according to the mathematics in this article. Referring to Fig. 2, it will be seen that it is impossible under the conditions shown for the depth of water d_1 above the jump to continue indefinitely on down the flume. It would be possible for this condition to occur in jumps produced in horizontal flumes. For the conditions of impact shown in Fig. 2, d_2 can be any value from $d_2 = (d_1/\cos a)$ to the depth stated by the momentum formula, Equation [4]. However, it cannot equal the latter depth, because there is an additional loss of energy due to the angular impact of the water. The rise in the surface of the water must therefore be a compromise between these two depths, and must necessarily be where the function of d_2 in Equation [5] is a minimum. The transition between the horizontal and sloping flume is therefore at the natural gradient for the particular flow condition. This angle is affected by flume friction, depth and velocity of water, shape of flume, and the like. No attempt has been made to correct any of the present formulas for the natural slope.

Some one might raise the question as to whether the water can be considered to flow horizontally immediately after impact. It is quite evident from an inspection of the turbulent impact taking place during the production of the jump that its flow is far from unidirectional. The only logic which may be applied here is that the momentum formula commonly used for jumps produced in a horizontal flume applies to that condition of turbulent flow as well as does Equation [19] now apply for jumps produced in sloping flumes. In either case the path of the center of mass of the moving water is very unsteady. Again, for both cases it cannot be said that the time of impact t is unity. It is quite evident from bubbles of entrained air in the turbulent part of the jump that internal impact and eddy losses occur a considerable distance down the flume.

A study of Fig. 6 or the data in Table 2 will show that the computed and measured values of d_2 do not agree exactly and that in general the runs made by the author are lower than their computed value, while the runs made by J. W. Ellms are higher than given by Equation [19]. It is very possible that different observers would read consistently high or consistently low tail-water depths. It is also possible that the flare of the flume and the effect of the floor of the flume (horizontal section) would cause these discrepancies. It is also quite likely that considerable velocity head was regained in the large expanding flume used by J. W. Ellms while the narrow flume with a steep descent used by the author caused a loss of velocity head.

CONCLUSIONS

The principal development in this paper is a comprehensive and rational mathematical solution of the jump for both sloping and horizontal flumes as expressed in Equation [5]. This formula states the relationship which exists between linear and angular impact. From it are derived the convenient forms [4] for horizontal flumes and [19] for sloping flumes.

The natural gradient determines the critical slope which indicates the correct form of Equation [5] to use.

Increasing the angle of the flume decreases the height of jump except for low flows and exceedingly steep flume slopes. This means that more energy is dissipated in jumps produced in sloping flumes than for those produced in horizontal flumes.

Essentially the same conditions of turbulent flow, time of impact, flume friction, and other related phenomena occur in jumps produced in either flumes. The factor of gained or lost velocity head after impact for jumps in sloping flumes has not been studied.

Data on jumps produced in sloping flumes materially substantiate the validity of Equation [5]. While these data do not prove the mathematical theories advanced in this paper, still both the mathematics and the physics of this phenomenon appear logical. The foregoing article is an attempt to stimulate constructive thinking about the jump so as to broaden its application and modify it to suit special flow conditions where impact occurs.

Discussion

R. W. Angus.[5] The author has given a brief review of certain formulas for the jump and has shown his reasons for concluding that in horizontal rectangular flumes Professor Unwin's is the most accurate. The writer has found it convenient to put Equation [3] in the form $\frac{d^2}{2} + \frac{Q^2}{gd} = \text{const.}$, on both sides of the jump, and then to draw the curve corresponding to this equation for a given Q, plotting against d. This method is illustrated by Bakhmeteff in his "Hydraulics of Open Channels" and is helpful in studying this problem.

Referring to the author's Table 2, the last two columns lead one to think that greater accuracy has been obtained by formula [19] than is actually the case, for the relatively large values of Z mask the value of d. The formula is used to calculate d_2, and the writer has selected at random every fifth run so as to shorten his discussion. With these values, the results to two decimal places are:

Run No.	5	10	15	20	25	30	35	40	45
$\frac{d_2 \text{ computed}}{d_2 \text{ observed}} =$	1.17	1.46	1.20	1.18	0.89	0.89	0.90	0.91	0.79

The minimum difference is 9 per cent, but the errors vary from this value to 46 per cent and are both plus and minus, so that there is some uncertainty as to the true value. The points plotted in Fig. 6 also suggest the same uncertainty in the result, and it would be impossible to draw any one curve corresponding, even roughly, to the great variety of points shown. The points on Fig. 6 show that the curve, if such is possible for the 8° 30′ slope, is much steeper than the one for the 17° 20′ slope, and that the one for the 12° 30′ slope lies between them; in fact, there are evidently three distinct experimental curves, while the paper shows that for the theory presented the three computed curves nearly coincide.

The writer is not altogether clear about some parts of Table 2. The columns headed d_1 and v_1 give information for finding Q, since $Q = v_1 d_1$, but this does not agree with the discharges given in column 2, and further, the three lower values of Q appear to be in error.

The author is to be commended for his table of experimental results and his constructive attack on a very troublesome problem.

Carroll F. Merriam.[6] The basis for the Unwin formula can perhaps best be visualized by the analogy illustrated in Fig. 8. Suppose that a stream of water at high velocity is deflected into a tank mounted on wheels as shown; the impulse of the striking water would cause a definite thrust against the car. Suppose at the same time an equal quantity of water were allowed to discharge horizontally from the tank at low velocity in the same direction as the entering stream; it is evident that there would be a reaction against the tank in a direction opposing the thrust of the impulse of the entering stream. Furthermore, since the quantities are the same in both cases, the net thrust would be determined by the flow and the difference in velocity in and out of the tank.

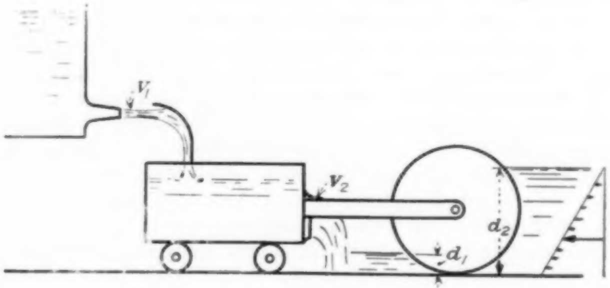

Fig. 8

Now assume that the car on which the tank is mounted is connected to a roller dam which is free to move on a horizontal plane, and that the force exerted would just balance the hydraulic thrust when the water is dammed to a height equal to that of the backwater of the hydraulic jump.

It has been demonstrated that although the action in the jump is exceedingly complex and consists of the pelting of a myriad of particles against a wall of water with a considerable absorption of kinetic energy, nevertheless this phenomenon is mathematically equivalent to this example.

The author deserves credit for demonstrating wherein several investigators have tried to fit theory to erroneous observations, and that finally when observations were carefully made by Gibson, the Unwin equation was found to satisfy the conditions exactly.

It is not clear, however, that the author has satisfactorily explained the marked lack of continuity in Fig. 7, where passage through the critical slope at a cosine slightly less than unity produces an abrupt change in d_2. Is it not possible that the jump, since the location where the author assumes the reaction to take place is not definitely located with respect to the actual phenomenon, may take place as though at some other point farther down the slope where the corresponding values of d_1, d_2, V_1, and V_2 would satisfy the momentum equation and be continuous with the solution for slopes less than the critical?

---

[6] With Pennsylvania Water and Power Company, Baltimore, Md.

Furthermore, the data represented on Fig. 6 indicate that there is considerable effect on the ratio d_2/d_1 caused by the angle of slope of the flume, whereas the author's Equation [19] shows so little effect that the curves for three different angles are drawn as one. This suggests that these differences may be accounted for by lack of definiteness as to the point where the jump can be considered to be concentrated, and that inconsistencies in the results may arise from the fact that d_2 is measured by reference to the height above the bottom of the flume at this point.

AUTHOR'S CLOSURE

The author wishes to thank those who have contributed to the discussion of this paper and hopes to clear up some phases of this research which may have been misleading. Recent mathematical investigations of the hydraulic jump have thrown new light on this problem, and their results will explain apparent discrepancies.

Before giving direct answer to the points mentioned in the foregoing discussions it will be best to briefly summarize what the author believes is one of the most important published papers on the hydraulic jump when it is produced in sloping flumes. The work referred to is a paper entitled "Supporting Force and Its Application to the Computation of Backwater Curves," by Dr. Ing. Th. Musterle, of Karlsruhe. This paper was approved by the structural engineering department of the Technische Hochschule at Karlsruhe as a dissertation, and has recently been translated by Herbert N. Eaton, Acting Director of the Bureau of Standards, Washington, D. C.

To summarize, Musterle explains that an independent method has now been developed for the computation of backwater curves on the basis of the law of supporting force as stated in the principle of the conservation of linear momentum. According to Newton, the applied force is equal to mass times the acceleration, or

$$F = m\frac{dv}{dt} \qquad \text{[A]}$$

To apply this principle to a moving stream, Musterle shows that this law can be expressed in the form:

$$P_1\Delta F_1 - P_2\Delta F_2 + \Delta G \sin a = m\frac{dv}{dt} \qquad \text{[B]}$$

where $P_1\Delta F_1$ and $P_2\Delta F_2$ represent the normal fluid pressures at any two given stations denoted respectively by the subscripts 1 and 2, *and "$\Delta G \sin a$" represents the resultant of the force of gravity in the direction of flow as given by the flume angle "a."* He shows in his paper that Equation [B] can be expressed in the form:

$$S_1 - S_2 + G \tan a - W = 0 \qquad \text{[C]}$$

in which

$S = b\Phi\left[\frac{d^2}{2} + \frac{dv^2}{g\cos^2 a}\right]$, which is an expression for the hydrostatic force and impulsive force at any vertical section of the stream. Here b = flume width, Φ = fluid density, d = depth of stream (vertical section), v = velocity of water, a = flume angle, and g = acceleration due to gravity. $G \tan a = b \times \left[\frac{d_1 + d_2}{2} l.\Phi \tan a\right]$ where l is the length of reach between the vertical sections 1 and 2.

W represents the frictional force opposing the flow and is therefore negative in this expression. Musterle states, "The actual magnitude of the frictional forces can only be determined in Nature. We have a measure of the influence of friction and slope in the well-known Chézy formula:"

$$v = c\sqrt{RI} \qquad \text{[D]}$$

in which v = mean velocity over the cross-section
c = velocity coefficient
R = area of stream cross-section divided by the hydraulic radius, and
I = flume slope.

Through several substitutions it was shown that the frictional force could be stated as:

$$W = \frac{d^2v^2(b + d_1 + d_2)l \cdot \Phi}{c^2\left[\frac{d_1 + d_2}{2}\right]^2} \qquad \text{[E]}$$

With the density of water, Φ, equal to unity, Musterle's final equation took the form:

$$b\left[\frac{d_1^2}{2} + \frac{d_1v_1^2}{g\cos^2 a}\right] - b\left[\frac{d_2^2}{2} + \frac{d_2v_2^2}{g\cos^2 a}\right] + b\left[\frac{d_1 + d_2}{2} l \cdot \tan a\right] - \frac{(d_1v_1)^2(b + d_1 + d_2)l}{c^2\left[\frac{d_1 + d_2}{2}\right]^2} = 0 \qquad \text{[F]}$$

According to Musterle, "The solution of this equation for d_1 or d_2, when the other quantities are known, is very difficult. It is best accomplished by cut-and-try methods." A study of this equation will reveal that the values of d_1 or d_2 are dependent upon the values of c. For smooth channels, c is large, and when this value is squared the last term of this equation has relatively very little value. Equation [F] is developed on the basis that the frictional forces on the side walls and floor of the flume, throughout the length of reach l, are sufficient, or insufficient, to produce a jump.

The author wishes to make clear that Equation [F] can only be used when the value of the velocity coefficient c can be determined. To attempt to solve any of the data given in this paper by the use of Equation [F] will show that these hydraulic jumps were produced on the flume slopes by the *artificial interposition of a baffle* downstream from where the jump was made to take place, and that they were not produced by flume side-wall and floor friction for which his equation was developed. As a result there is no way to predict the value of c which should be used in Equation [F] to give the proper tail-water depths. Equation [19], however, will give the correct tail-water depth for the type of jumps discussed in this paper. For the flume used by A. G. Levy and J. W. Ellms, as well as the one used by the author, the water was backed up on the slope so as to cause a jump to form there. The position of the jump on the slope was regulated by the height of weir downstream from the jump. For filtration-plant work it was necessary to regulate the tail-water level between certain elevations in order to insure the occurrence of the jump within the range of the slope. No jump would have occurred naturally in these steep flumes from only the frictional forces in the length of reach the jump was made to take place. This is why baffles were employed.

It will now be of interest to show how the author's Equation [19] can be derived from Musterle's Equation [F] after the latter is corrected for angular impact, and thus to emphasize the definite mathematical relationship between these two equations.

Since it has been shown by Musterle's equation that the values of d_1 or d_2 are dependent upon the value of c, it will be of interest to learn what effect the limiting values of friction produce on the backwater levels. To increase c to infinite proportions will decrease the frictional resistance W and cause the height of jump, d_2, to approach the value stated by Professor Unwin for horizontal flumes, corrected only by the flume slope. To decrease the value of c will increase the resistance to the flow. The limiting value of c is zero, for which case W will be infinite. Here we may consider that the length of reach l is infinite, which means that the *total* resistance to the flow of the water after impact must necessarily be infinite. For the type of jumps described in this paper the water before the jump plunged into a pool of slowly receding tail water, the rate of discharge being controlled by submerged baffles. This condition approximated an infinite resistance to the flow for which l could be considered infinite, or the tail water considered to have infinite mass. If $l = \infty$, then the third term, as well as the fourth term, in Musterle's equation equals infinity, while d_2 approaches an infinite depth, and v_2 approaches zero. This makes Equation [F] indeterminate. This indeterminate flow condition proved a stumbling block to an orderly study of this phenomenon many times before. For $c = 0$ and $b = 1$, Equation [F] can now be written as

$$\frac{d_1^2}{2} + \frac{d_1 v_1^2}{g\cos^2 a} - \frac{d_2^2}{2} - \frac{d_2 v_2^2}{g\cos^2 a} + \infty - \infty = f(d_2)\ldots \text{[G]}$$

In this equation, and for the type of jump under investigation, it would seem natural that the proper value of d_2 would be such a one as to make the change of momentum have a minimum value, a conclusion previously reached. To put Equation [G] into the same terms used in developing Equation [19], it is necessary to have

$$\begin{aligned} d_1 \text{ (Musterle)} &= \frac{d_1}{\cos a} \text{ (Equation [19])} \\ d_2 \text{ (Musterle)} &= d_2 \text{ (Equation [19])} \\ v_1 \text{ (Musterle)} &= V_1 \cos a \text{ (Equation [19])} \\ v_2 \text{ (Musterle)} &= V_2 \cos a \text{ (Equation [19])} \end{aligned}$$

Then

$$\frac{d_1^2}{2\cos^2 a} + \frac{d_1 V_1^2}{g\cos a} - \frac{d_2^2}{2} - \frac{d_2 V_2^2}{g} = f(d_2)\ldots\ldots\ldots \text{[H]}$$

Since Musterle's equations are developed on the basis of collinear velocities throughout the length of reach considered, and since it has previously been pointed out that this is not the case for the type of jumps studied by the author, it is necessary to correct V_1 again for angular impact. Thus in Equation [H], V_1 should be multiplied by $\cos a$, which indicates that the V_1 and V_2 velocity vectors are not in the same straight line, or even parallel, but differ by the amount of the flume angle a. Correcting V_1 in this manner yields

$$\frac{d_1^2}{2\cos^2 a} + \frac{d_1 V_1^2 (\cos a)}{g} - \frac{d_2^2}{2} - \frac{d_2 V_2^2}{g} = f(d_2)\ldots\ldots \text{[I]}$$

The first derivative of this function with respect to d_2, set equal to zero and solved for d_2, gives

$$d_2 = \pm\sqrt{\frac{2d_1 V_1^2(\cos a)}{3g} + \frac{d_1^2}{3\cos^2 a}}$$

which is the author's Equation [19] and which expresses in the positive value the height of jump d_2 necessary to produce a minimum change of momentum.

It must be borne in mind that frictional disturbances in the vicinity of the jump will influence the height of water directly after impact, and also that Equation [19] is developed on the theory that the length of slope is infinite. For all practical purposes this condition can nearly be realized by the use of baffles, which should be placed as far down the slope as possible, or even better on the horizontal floor of the discharge flume. Equation [19] is only strictly true for jumps produced in flumes of constant width. For flumes with flaring sides, d_2 is slightly reduced by the value $\sqrt{(b_1/b_2)}$, in which case a small finite length of reach must be used. Care should be used in applying this correction factor since no correction for flare has been introduced in the velocity vectors used in the development of Equation [19].

The author is indebted to Dr. Musterle for having developed the laws governing the type of jump produced by flume friction for sloping flumes. Heretofore a great deal of misunderstanding existed so that it was confusing even for those men who were thoroughly familiar with the action of the hydraulic jump and who perhaps felt that different flow conditions could be imposed on a moving stream to produce a jump.

It is important at this time to distinguish between the two types of jumps because it will answer the question raised by Mr. Merriam as to the "lack of continuity in Fig. 7, where passage through the critical slope at a cosine slightly less than unity produces an abrupt change in d_2." The explanation is that when the value of c in Equation [F] is such that it overcomes the effect of the slope, the jump will be produced according to Musterle's discussion and Equation [19] is invalid. In Fig. 7, therefore, for flumes of slight slope or high flume friction, d_2 should not be read from this graph but calculated by Equation [F].

In answer to Professor Angus' observation as to the accuracy of the data in Table 2, it will suffice to mention that measurements on turbulent waters are very difficult, especially when small laboratory experimental models are used. For this reason data taken on the large experimental flume used by Levy and Ellms were considered to have more weight than those taken by the author.

As for the values of Q stated in Table 2, the author only inserted them to give the reader some idea of the magnitude of the tests. Since flumes with flaring sides were used the value of the flume width was different for each of the 45 runs. The first four values of Q are for a small flume whose slope could be changed. The last three values of Q are for a large experimental flume which had a fixed slope. This large flume had a throat width of approximately five feet and a width at the downstream end of approximately 10 feet. The maximum flow which this flume could carry was a little over 40 cfs. The flume used by the author could only carry 1.5 cfs, and had a throat width of 0.25 ft and a downstream width of 0.67 ft.

From a consideration of the variation in flume sizes, the data are in good agreement. The author is positive that local frictional effect and the difficulty of making accurate water measurements on the small flume are the causes for observed discrepancies. It might also be mentioned that in Professor Angus' table of the ratio between computed and observed d_2, Run No. 10, which is off 46 per cent, will be noted as a starred run, for which the footnote of Table 2 explains as being in measured error. Aside from this run, the error in the data from Professor Angus' table is a plus 20 per cent and a minus 9 per cent.

Naturally many more data will have to be taken to confirm this work. It would be best to establish standard methods of measuring the jump so that results can be easily compared. With the help of Equation [19], and Musterle's Equation [F], much can be learned about the jump. The author believes that the theories advanced in these two papers can be further applied to other types of hydraulic flow.

Hydraulic Practice in Europe

By ROBERT W. ANGUS,[1] TORONTO, ONT., CANADA

The title describes in general the nature of this paper, but the author has confined the discussion to such features of European practice as are different from those in America. Various types of reaction turbines and draft tubes are illustrated, and also some two-nozzle Pelton wheels and one vertical four-nozzle machine. Types of valves, gates, and weirs peculiar to the Continent are discussed, and also some features of pumped-storage plants, with the special design of pump that is peculiar to them.

AS WOULD be expected, hydraulic practice in Europe is in many respects very much the same as in America, the interchange of engineers between the continents providing a means of unifying the methods of treatment of the various problems. But certain features have always been retained in Europe, and the author will endeavor to bring these to the attention of engineers in America. Reference will first be made to hydraulic power plants and their accessories; the large number of plants recently built in France, Germany, Italy, Austria, Switzerland, Scandinavia, etc., indicates that there has been great activity in Europe along this line. The power generated is used for operating the railroads, many miles of which have been electrified in Central Europe, and a great amount of power has been distributed to the municipalities and to industries.

REACTION TURBINES

Water powers, with both low heads and high heads, are very common; a discussion of the former will first be given. The low-head plants invariably contain reaction turbines, either of the Francis, propeller, or Kaplan type, of which the latter has until very recently been a purely European development. From the time of its invention by Viktor Kaplan, of Brünn, Czechoslovakia, the Kaplan turbine was put into usable shape by Swiss and German firms, and a number of machines were installed. One of the earlier plants was at Donaustetten, on the Danube near Ulm, Germany, and the latest, or at least the most prominent new one, is at Ryburg-Schworstadt, the first unit of this plant having been put into service in 1930, but the complete plant was not available till 1931. In the earlier developments the servomotor for the runner blades was on top of the machine and was stationary, with a piston revolving inside it. In some of the older units also the runner blades were moved by a forked lever, which engaged with lugs projecting from an inside rod through the hollow mainshaft. The turbines are now built entirely with the servomotor contained in the shaft just above the runner.

It is almost general practice in Europe to machine the runner blades of Kaplan and propeller turbines, this being accomplished by means of a vertical boring machine with the tool guided by a small-sized model. The machines are well worked out and produce a good copy of the model, and after the blades have been finished in this way they are ground. This method not only produces a very accurate blade giving a high efficiency, but as the blades are all alike, the runner is well balanced.

A section of the Donaustetten Power House is shown in Fig. 1, and there are four Kaplan units, two by Escher, Wyss & Co. and the others by Voith. The head is 25 ft, and each turbine produces 1740 hp at a speed of 214 rpm, the specific speed being 161. As the runner diameter is 6.85 ft, this corresponds to a rim speed 1.91 times the theoretical water velocity. The form of draft tube used is clearly shown and is quite typical of those with this kind of turbine, being made with a quarter-turn and a horizontal dividing wall down the center of the elbow and a vertical dividing wall under the outer end. The leading dimensions for the Voith unit are marked on the figure and show that the outlet of the draft tube is 39.4 ft from the turbine axis, which makes a long tube. One of the units showed efficiencies, as reported by Professor Braun, of Stuttgart, above 90 per cent for outputs between 760 and 1600 hp, while the maximum was 93 per cent at 1100 hp; the head during the test was below normal.

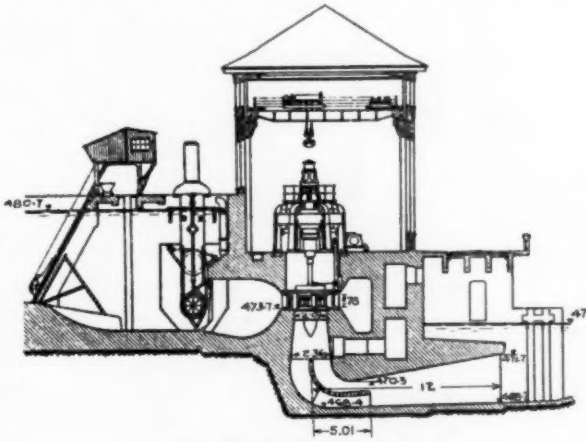

FIG. 1 DONAUSTETTEN POWER HOUSE
(Dimensions are in meters.)

A section through the Ryburg-Schworstadt Power House and turbine is shown in Fig. 2, taken from an Escher-Wyss publication. This plant, as is well known, is on the Rhine River, near the Swiss town of Ryburg (and Möhlin), and the works extend across the river from the Swiss to the German side, the spillway being in Switzerland and the power house in Germany. There are four Kaplan turbines, all exactly alike, and the designs are the results

---

[1] Professor of Mechanical Engineering, University of Toronto. Mem. A.S.M.E. Professor Angus was born in St. Thomas, Canada, on January 24, 1873. His public- and secondary-school education was received in London, Canada, and in 1897 he was graduated from the University of Toronto with the degree of Bachelor of Applied Science in Mechanical and Electrical Engineering. His first practical engineering experience was obtained from E. Leonard & Sons in London and in the drafting room of the Standard Oil Company in Cleveland, Ohio. After his graduation he returned to Cleveland to work on a special gas-engine design, and later he had valuable experience with the Shoenberger Steel Company (the U. S. Steel and Wire Company), Pittsburgh. When the separate department of mechanical engineering was established at the University of Toronto, Professor Angus was appointed its first head. He was made Professor in 1906, which position he still holds.

Contributed by the Hydraulic Division and presented at the Semi-Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of conferences between the engineers of the firms of J. M. Voith, Escher, Wyss & Co., and Ateliers des Charmilles. The first firm built two of the turbines, and each of the others built one. Each turbine has five runner blades and is built for a normal output of 35,000 hp at 36 ft head and 75 rpm, corresponding to a specific speed of 159, which is extremely high on such a large unit. The runner diameter is 23 ft, for which φ is 1.875, and some of the leading dimensions are marked. The figure shows the same type of draft tube as before, with both horizontal and vertical division walls, and a length of 115 ft from the axis of the turbine to the discharge end of the draft tube. The position of the runner-blade servomotor is shown in the mainshaft and also the general disposition of the parts is indicated. The first unit was put in service on November 3, 1930.

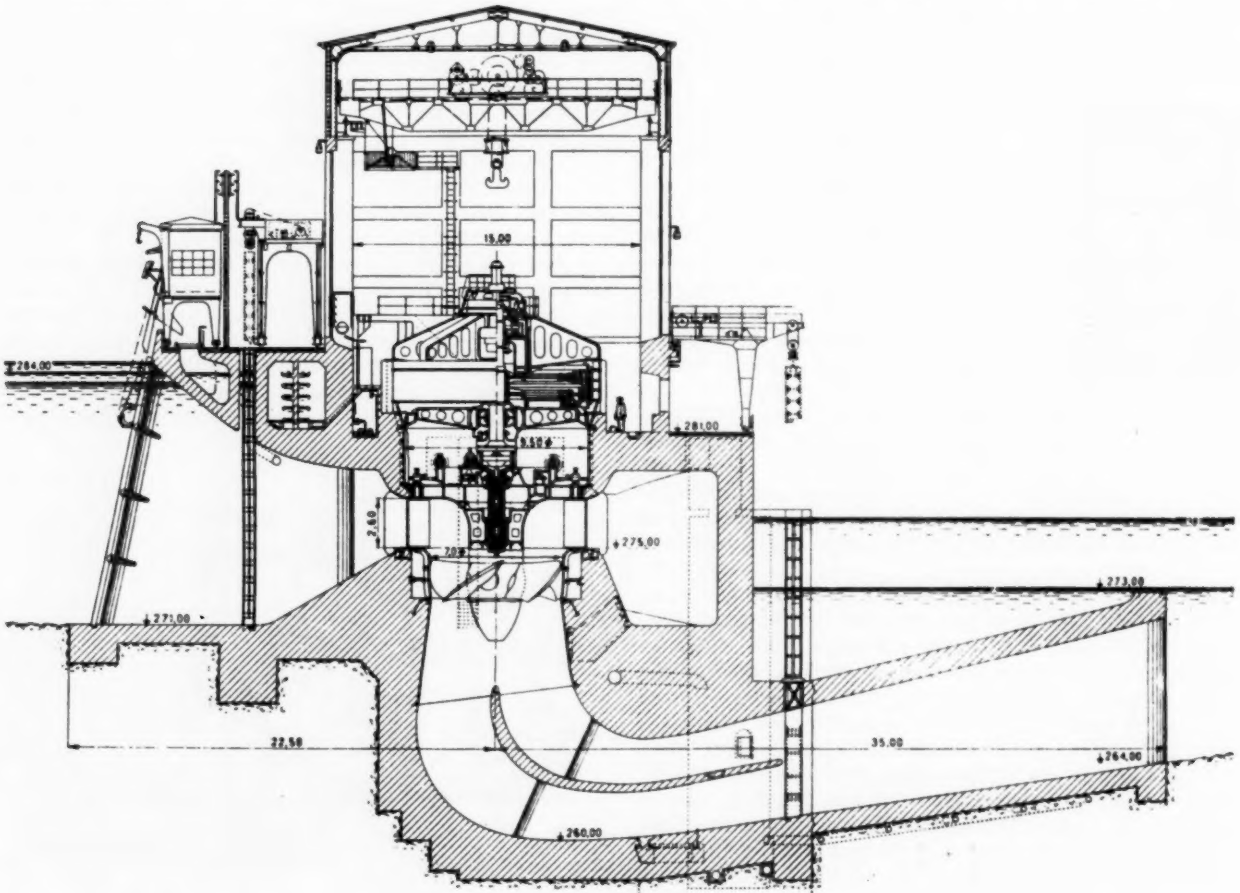

FIG. 2 RYBURG-SCHWORSTADT POWER PLANT
(Dimensions are in meters.)

By agreement, all units were to be accepted on the basis of test results on the first unit operated, which was the Escher-Wyss one, and therefore unusual care was exercised in making the test. Water measurements were made with a set of 15 current meters, and a timber-work guide was built in front to direct the water in straight lines. The results of the tests were given in *Power*, January 19, 1932, and indicate a maximum efficiency of 92.7 per cent at an output of 23,750 hp and about 83 per cent at 40,000 hp, while the efficiency exceeded 90 per cent between 10,000 and 35,000 hp. As the hub has a maximum diameter of 9.84 ft, the velocity head of the water after leaving the runner is close to 50 per cent of the entire head, so that the draft tube has an important service to perform. Very careful model tests were made on a wheel about 27.6 in. in diameter, with the object of finding out how to lessen cavitation, and it will be noted that the normal tail-water level is approximately at the center of the runner, the unit being set very low.

The type of draft tube shown in these two plants is also often used with Francis turbines, but instances of higher head installations are the developments at Eglisau, Mühleberg, and Chancy-Pougny in Switzerland. The first plant is on that part of the Rhine which is entirely in Swiss territory and is nearly north of Zurich, the power house being about 2 miles west of the Swiss town of Eglisau. The works cross the entire river, and they raise the water so much at the town that a new bridge had to be built as part of the project. There are seven vertical turbines, four having been built by Escher, Wyss & Co., Zurich, and three by Theodore Bell & Co., Lucerne, each guaranteed to deliver 6000 hp at 36 ft head and 83.4 rpm, these figures corresponding to a specific speed of 73, which would be a suitable speed for an ordinary high-speed Francis turbine.

An examination of Fig. 3 shows, however, a somewhat unusual shape of a runner, having a diameter of 6.56 ft over the blades at the crown and an exit diameter of about 13 ft, the distributor height being 3.3 ft. A photograph of this type of runner is given in Fig. 4*a* and shows the very large exit diameter relative to that at inlet. The draft tube is also of interesting design, being quarter-turn and curved throughout its length. Its top diameter is 14.1 ft, and the outlet end is rectangular, 16.4 ft by 25 ft, with well-rounded corners. Under a head of 32.8 ft, tests showed an output of 6210 hp with 79.6 per cent efficiency, and the latter rose to 85.9 per cent at 4676 hp, in both cases exceeding the expected results based on model tests.

A similar type of runner was used at a recent plant of the Bernischen Kraftwerke A.-G. located at Mühleberg on the River Aar, about 20 miles down from Berne. Here there are eight vertical machines, which may be run at either 133.3 rpm or 166.6 rpm, depending on the frequency desired, and at the former speed these produce 8100 hp each when the head is 65 ft, corresponding to a specific speed of 65. These turbines and draft tubes are almost identical with the Eglisau units and gave similar efficiencies.

Probably the most interesting examples of these unusual units are in the station at Chancy-Pougny, which stretches across the Rhone River a few miles below Geneva, the generating station being located on the Swiss side, while most of the overflow dam and transformer station are in France. Discussion will be confined to the five vertical generating units, three built by Ateliers des Charmilles and two by Escher, Wyss & Co.; there is also a 350-hp auxiliary unit. The main units were guaranteed for 8700 hp at a head of 29.1 ft and speed of 83.3 rpm, giving a specific speed of 115, so that the ordinary high-speed Francis unit would not be satisfactory. Both builders designed runners similar to those just described, the Escher-Wyss units being almost exactly the same as at Eglisau, while the Ateliers des Charmilles units have a slightly different form, as shown in Fig. 4*b*. A section of the plant is given in Fig. 5, and some figures of the elevations, etc., are marked on; the drawing shows a section through the draft tube and turbine. The Escher-Wyss units are spaced 46 ft on centers, while the others are 49.3 ft on centers.

Considerable interest centered in the turbines used on this plant because of the high specific speed, and careful tests were

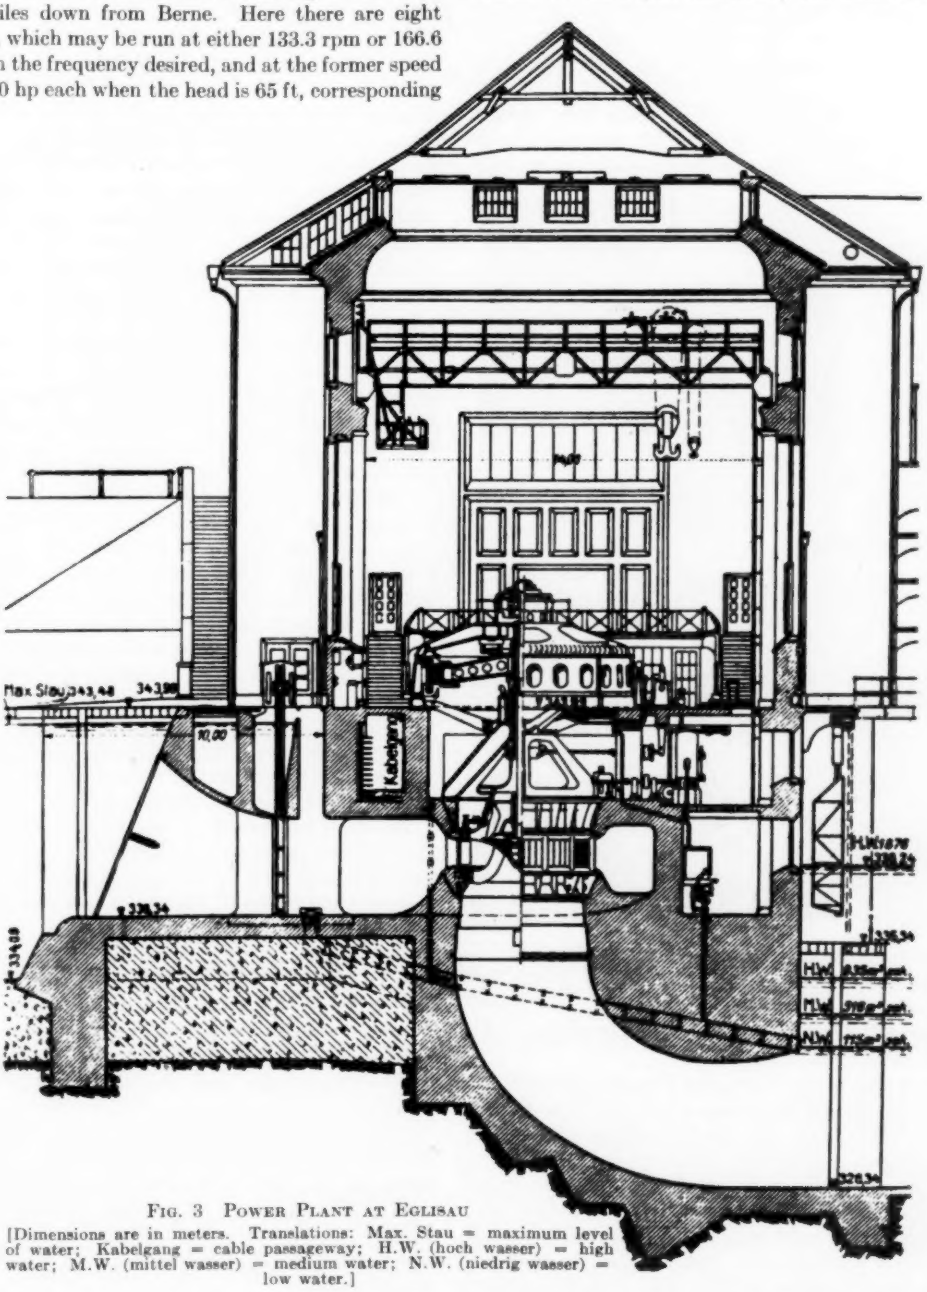

Fig. 3 Power Plant at Eglisau

[Dimensions are in meters. Translations: Max. Stau = maximum level of water; Kabelgang = cable passageway; H.W. (hoch wasser) = high water; M.W. (mittel wasser) = medium water; N.W. (niedrig wasser) = low water.]

carried out on one unit from each builder, the piers at the front of the power house being extended by timbers to give parallel flow toward the screens, as shown in Fig. 6. A set of nine current meters was mounted on a frame, as shown, and these were used to measure the water supplied, while the head and power produced were determined in the usual manner. One of the units gave a maximum efficiency of 88.9 per cent with an output of 9150 hp and a maximum output of 9450 hp with 85 per cent efficiency, while the other builder's unit gave its maximum efficiency of 78.7 per cent at its maximum output of 10,300 hp, all tests being at 29.1 ft head.

At the maximum output of power these units have specific speeds of 120 and 125, respectively, which is high for this type of wheel. Naturally, it is difficult to cast such a runner on account of shrinkage stresses, and they are often made in sections with the outside band shrunk on.

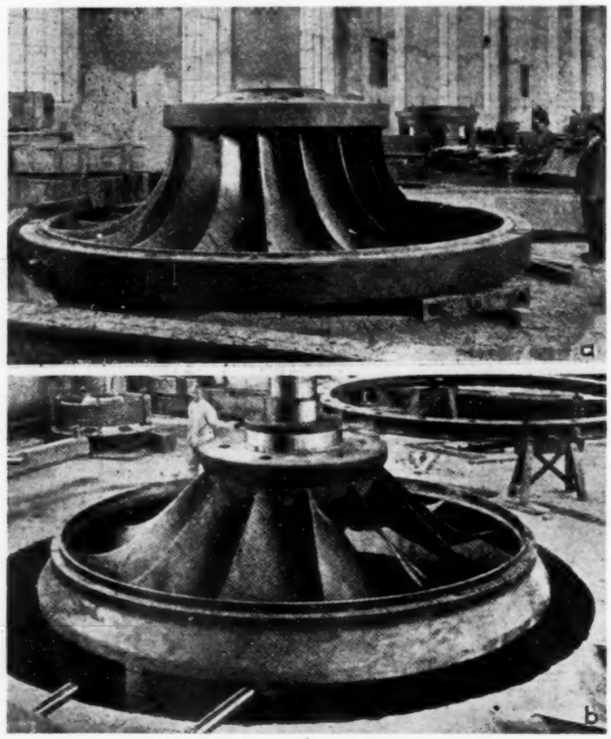

FIG. 4 TURBINE RUNNERS USED AT CHANCY-POUGNY
(*a*, Escher-Wyss runner; *b*, Ateliers des Charmilles runner. Picture from *Schweizer Bauzeitung*.)

Another unusual type is that built with a conical distributor, a design which enables the maximum capacity to be installed on an old setting without changing the center-to-center distances of the unit; in other words, the diameter of the unit for a given power is relatively small. One of the most interesting stations equipped with these units is that at Chevres, near Geneva, where they were placed by Ateliers des Charmilles. There are several types of turbines in this power house, which is quite old, but the units now under discussion displaced some vertical units with four runners on one shaft and which developed 1200 hp at 122 rpm and at 23 ft head.

These old turbines did not produce enough power and were replaced by new units with conical distributors, as shown in the photograph, Fig. 7, and the sectional drawing, Fig. 8, both from the builders' circular. The new units, placed in the same space as the older ones, gave 1850 hp at 21.3 ft head and 130 rpm, but the space was so cramped that the efficiency at this output was only 81.8 per cent. Results exceeding 90 per cent have been obtained with this design in other plants with more favorable settings. The distributor guides are moved either by a large bevel gear or else by the ordinary link mechanism with ball-and-socket joints. The turbines have been used with heads as low as 6.3 ft, with propeller and high-speed Francis runners, and they are made by several turbine builders.

The Lawaczeck turbine is best known through its adoption for a unit at the Lilla Edet Plant in Sweden. Careful tests were made to compare its merits with those of the Kaplan turbine in the same plant. The Lawaczeck turbine is not unlike the Chancy-Pougny turbines of Ateliers des Charmilles, but has not the outer band, and the machine at Lilla Edet has a runner diameter of 17.7 ft. In the comparative tests this turbine showed efficiency characteristics similar to propeller runners. It has a specific speed of 136 based on a head of 21.3 ft and an output of 10,000 hp at 62.5 rpm; these figures may be compared with those of the Kaplan wheel in the same plant, and which is 19 ft in diameter, 11,200 hp, and runs at 62.4 rpm, which corresponds to a specific speed of 140.

The very interesting two-bladed runner developed by Theodore Bell & Co. is known in America, being also investigated by the S. Morgan Smith Company, York, Pa. The runner has all the appearance of an auger and is the result of earlier research in the Bell laboratory and a careful investigation made by Dr. F. Prasil of Zurich. One of its most prominent early applications was in the Matte Hydraulic Power Station of the City of Berne.

The head on this plant is only 9.84 ft, and the plant had been equipped with three vertical Jonval turbines of 130 hp each at 28 rpm, which gave a specific speed of 18.3. As the demands for power increased it was desired to increase the output by the installation of new turbines, but as the space was limited, the power company desired the new turbines to be placed on the same foundations as the old ones, and the old draft tubes were to be used as far as possible. For this purpose Bell & Co. installed three of their new type of turbine, but had to reconstruct the draft tubes to a large extent. The new turbines developed 320 hp each at 9.84 ft head and 214 rpm, these figures corresponding to the very high specific speed of 218, and the units gave an efficiency of 85 per cent; these results are extremely good.

The draft tubes used are quarter-turn without division plate, the diameter at the top end being 5.57 ft, and at outlet the tubes vary a little in size, but all are oval, and one of them is 17.4 ft wide and 6.22 ft high. The tube slopes upward on the discharge part.

HIGH-HEAD TURBINES AND PELTON WHEELS

In impulse wheels the difference between the European and American designs is much more striking than with the reaction turbines. While the usual practice in America is to make single-nozzle runners and to obtain large powers by using two overhung wheels with the generator between them, it has been very common practice in Europe to use two nozzles per runner, and frequently two or three of the latter are mounted on the same shaft, but they are always placed close together and on the same side of the generator. A number of vertical turbines of the Pelton type have also been constructed, some with four nozzles, and as many as five have been used. It is possible to give only a few illustrations.

The machine shown in Fig. 9 was built by Costruzioni Meccaniche Riva, Milan, Italy, for the Mese Power Plant. This unit is of very large size, having an output of 35,000 hp under a head of 2430 ft and at a speed of either 500 rpm or 420 rpm, for frequencies of 50 and 42 cycles, respectively. There is but one runner with two jets, each having a maximum diameter of 6.30 in., the outside diameter of the runner being 8.81 ft. The positions of the jet deflectors and the mechanism for operat-

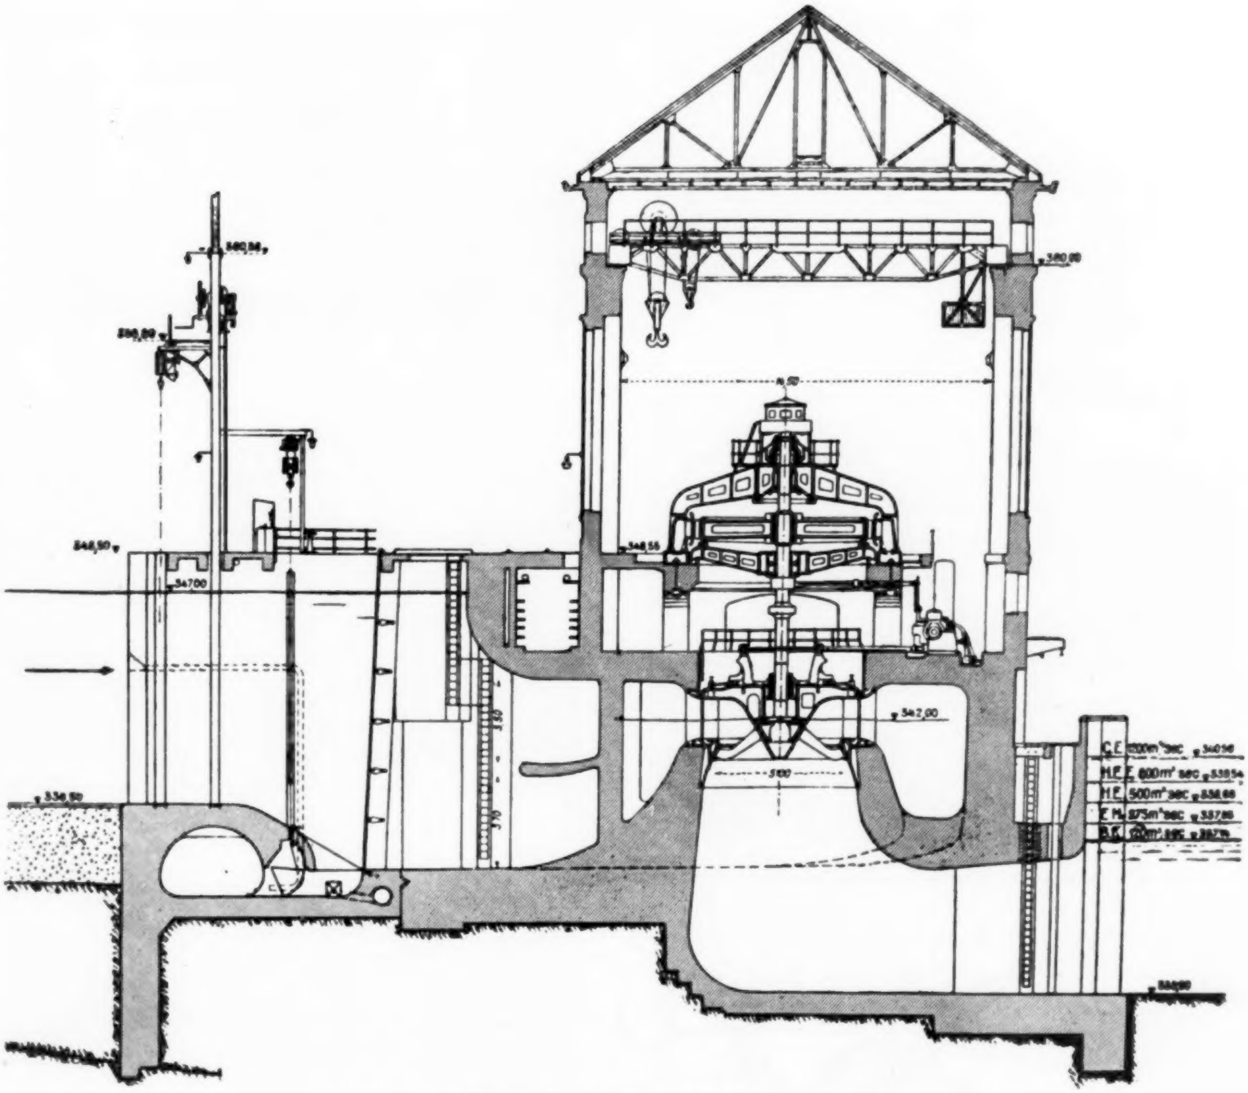

FIG. 5 CHANCY-POUGNY PLANT

[Dimensions are in meters. Translations: C.E. (élévation culminare) = highest possible elevation; H.E.E. (haut élévation extrême) = extreme high elevation; H.E. (haut élévation) = high elevation; E.M. (élévation moyenne) = medium elevation; B.E. (basse élévation) = low elevation. Picture from *Schweizer Bauzeitung.*]

ing them are clearly shown. There are 20 buckets, each of axial width 18.7 in. inside and each secured to the disk by two bolts. The center distance between the main bearings is 9.9 ft, the center of the runner being 4.84 ft from the center of the nearest one, and the shaft is 20.5 in. in diameter at the runner and 15.8 in. and 17.7 in. in the bearings.

Another turbine of large size is that at Schwarzenbach, a pumped-storage scheme belonging to the Badische Landes-Elektrizitäts-Versorgungs A.-G., of Baden, Germany. This plant contains both Francis and Pelton turbines, and those of the latter have an output of 27,500 hp at 500 rpm under a head of 1170 ft, which corresponds to a specific speed of 12.1 for the unit. One of the turbines in the plant, as made by J. M. Voith, Heidenheim, is shown in Fig. 10, and the shaft with the three runners mounted on it in Fig. 11, the buckets being made in pairs and each pair being held to the main disk by three bolts. Fig. 10 shows the arrangement of the distribution piping, also the mounting of the six nozzles, two per runner, and the mechanism for operating the needles. The pitch diameter of the wheel is 53.2 in., and the construction used requires the main bearings to be quite far apart.

Another large unit, built for a plant in Korea, with a head of 2180 ft, has an output of 45,300 hp at 360 rpm. In this case a single runner is used, and it is supplied by two jets about 90 deg apart, each being arranged with a deflector and moving needle.

The power plant at Jenbach, near Innsbruck, Austria, uses the Aachensee as a storage basin, and the head available for the turbines is 1250 ft, so that Pelton wheels have been used. There are eight units, these being of varying size, but the newest and largest one is for 31,000 hp at 500 rpm, and this machine uses 249 cfs. In this case there are two runners mounted on the same side of the generator, each with two jets, or four jets for the unit, and the specific speed of the unit is 11.83, or 5.91 per nozzle. In these units, as in many others, braking is effected by a small jet which may be made to strike on the backs of the buckets.

Many examples could be given if space permitted, for European practice has quite frequently adopted the two-nozzle runner and in some unusual proportions. In one instance, that of the

(Dimensions are in millimeters.)

Burglauenen Power Plant of the Jungfrau Railway, Switzerland, where the water used is sandy and unsuitable for a Francis unit, although the head is only 525 ft, an impulse turbine of 2900 hp was built by Escher, Wyss & Co., its speed being 500 rpm, so that the specific speed is 10.7. Just one runner with two jets was employed, giving the unusually high specific speed of 7.55 per nozzle, and since the maximum jet diameter is 5.57 in. and the pitch diameter of the runner is 37.4 in., the ratio is 1 to 6.7, a large value, which results of course from the high specific speed. This machine has a flywheel 7.2 ft in diameter and 11.25 in. face, the main bearings are 5.56 ft on centers, and the shaft is 8.65 in. in diameter at the bearings and 11 in. at the runner. This turbine gave a maximum efficiency of approximately 90 per cent at 800 hp, and the efficiency gradually fell as the load increased, being 85.5 per cent at 2000 hp and 76.5 per cent at 2900 hp.

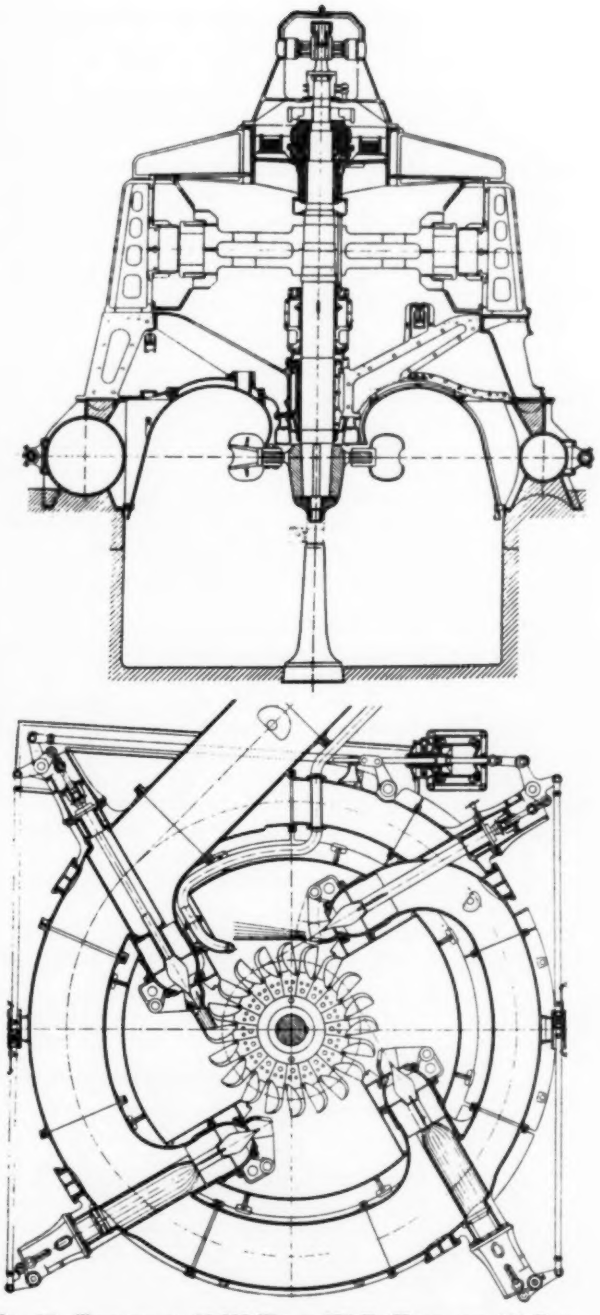

FIG. 12 TURBINE OF 18,600 HP AT 670-FT HEAD AND 250 RPM

But one further instance of Pelton units will be given, this referring to the vertical-shaft type more or less frequently made. These usually have four or more nozzles per runner, one built by Franco Tosi in Legnano in 1928 having five jets. The disposition of the parts in such a construction is shown in Fig. 12, which gives two sections of an 18,600-hp unit, running at 250 rpm under a head of 670 ft, the specific speed being 10, but as four nozzles are used the specific speed of each is only 5. The wheel was built by Escher, Wyss & Co. for the Whitehall Securities Corporation, London, which installed it in Chile. There is a spiral distributor pipe somewhat similar to the Francis turbine, and each nozzle has a needle, as well as a deflector, both of which are made of steel, the construction permitting of easy removal of the runner. This unit probably cost more than a Francis turbine would have done, and of course the Francis unit would have been at higher speed, but the water is gritty and it was thought that this type of wheel would have relatively little wear. The rotating parts were tested at 100 per cent overspeed.

The horizontal section through the distributor shows how the needles are connected and gives some idea of the large external diameter of the casing necessary with such a set-up.

Control Gates

In America control gates are largely of the Stoney type, and these have been used to a limited extent in Europe. A gate that finds very common application there is also a lift gate, but it is divided into two parts, and its construction is such that it may be adapted to very large openings. For example, the weir or spillway at the Ryburg-Schworstadt Plant has four openings each 78.5 ft clear width, there being a pier 16.4 ft wide between each pair of openings, and each of the latter is controlled by a lift gate of the type mentioned. The upper part of one pair is shown in Fig. 13.

The drawing, Fig. 14, gives in detail the construction of one of the gates for the Austrian plant at Pernegg on the Mur River, not far from Graz. This plant has three vertical Francis turbines of 9100 hp each, at 59.5-ft head and 150 rpm, and the water for these turbines is diverted from the river and carried to the power house by a trapezoidal canal over a mile long. The dam extends across the River Mur and has in it three openings each 49.2 ft clear width, with piers 13.95 ft wide between the openings. The normal depth of the river at the dam is 38 ft, and the gates are made in two sections so that the upper one may be raised or lowered, the lower one may be raised, or if desired, both sections may be lifted up clear of the water.

The drawing was made from plans supplied by the Maschinenfabrik Augsburg-Nürnberg, in Gustavsburg, Germany, and shows the sections arranged for the maximum height of water, the dotted position above showing the whole structure lifted out. The motor-operated lifting gear above serves to draw up the sections, which have a weight of 114 tons for each double gate, and the total maximum lift is 40.7 ft. The upper section is 10.8 ft and the lower one 27.6 ft high, the former being mounted on four wheels 19.7 in. in diameter, while the lower section has eight wheels 29.5 in. in diameter and 10 in. wide, both sets of wheels traveling on very heavy rails. The detail drawings of Fig. 14*a* show at (*a*) the method of sealing the sides of the upper section and at (*b*) that used on the lower section, while (*c*) shows the method of sealing the bottom and top of the lower section. Leakage is prevented by contact of a block of wood with the

(Dimensions are in feet and inches.)

wall in the pier, this wood being fastened to the gate by a piece of steel 0.236 in. thick and 22 in. wide on the upper section and 0.315 in. thick on the lower section.

An interesting apparatus is the roller weir, one form of which is shown in Figs. 15 and 16. (Fig. 15 is from "Der Bauingenieur," and Fig. 16 was supplied by M.A.N., Germany.) The basis of the device is a stiff steel-plate cylinder, to which is attached eccentrically a circular sector, the face of which acts as a dam. Attached to the ends of the roller there are spur gears which engage with racks on the piers, and the hoisting apparatus at the top, acting through the heavy chain, causes the gear to roll up the racks, carrying the cylinder with it, and this allows water to flow underneath, or if desired the roller may be lifted clear of the water, in a nearly horizontal position.

These roller weirs (Walzenwehre) are made in various shapes, with the sector placed in several positions on the roller, sometimes extending only downward, so that water passes over the upper surface of the roller. Water-tightness at the bottom is obtained by a wooden block connected to the weir by a steel plate. The rollers are often made without the sectors at all, and they have been used up to about 100 ft in length; that is, the clear width between the piers is about 100 ft. A few of these weirs are in use in America.

While this type of weir is largely used in dams, it is also applied to the control of the water entering turbines, as in the case of the Donaustetten (see Fig. 1) and other plants. The lifting chain is usually replaced by a cylinder and piston acting directly on the

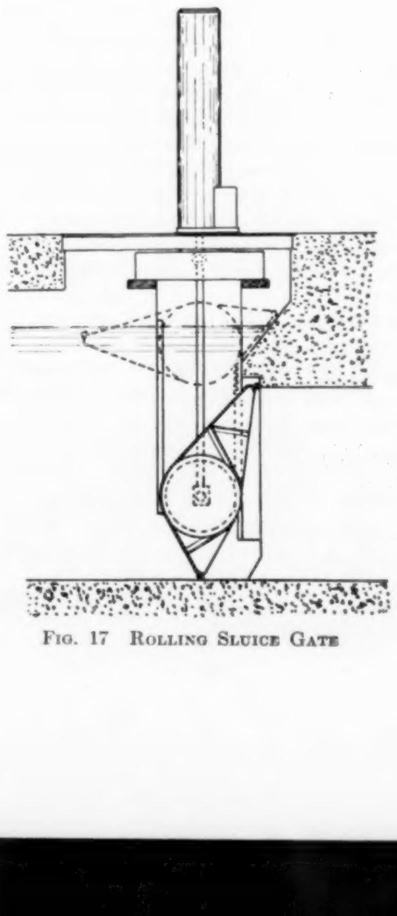

FIG. 17 ROLLING SLUICE GATE

axis of the roller. A diagram of such a roller gate is shown in Fig. 17, in closed and open position. The chains, racks, etc., are let into recesses in the piers so that the moving water does not come in contact with them. These gates are frequently subjected to severe ice conditions.

VALVES

Various types of valves of large and small size are in use in European practice, and of course the ordinary gate valves and disk valves are in quite common use, and some firms build the Johnson valve. For pumped-water-storage plants the design of the valves is of much importance, because the pressures are high and the lines fairly long.

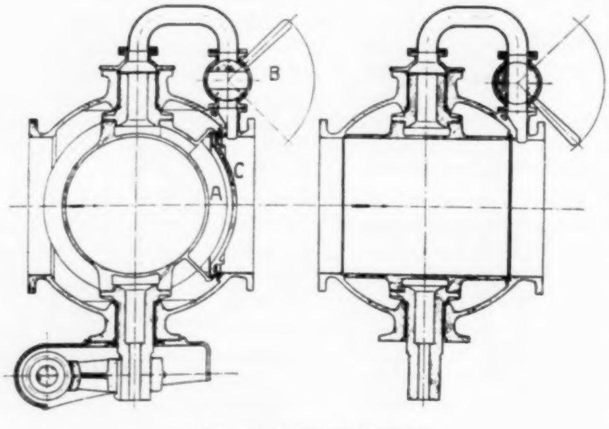

FIG. 18 ROTARY VALVE

The greatest attention is paid to the form of check valve to prevent undue water hammer in case the source of power should fail when the pump is delivering water to the upper reservoir. The ordinary check valve is not effective in this connection, on account of the suddenness of its closing.

One form of valve has had fairly broad application and has been developed by a number of the larger builders on the Continent, so that it should be mentioned. This is the rotary valve, the one shown (see Fig. 18) being made by Escher, Wyss & Co. and differing very little in its hydraulic features from those of Theodore Bell and others. In principle this valve is similar to the plug cock, but the turning piece is cylindrical instead of conical, and when it is wide open it offers as clear a passage for the water as the same length of smooth pipe. Fig. 18 shows a valve operated by worm and wheel, but in the larger sizes the central piece is often rotated by a servomotor, either directly or through a rack and pinion.

The left-hand figure shows the valve shut and the right-hand one gives the open position, the construction being evident from the drawings. The body of the valve is spherical, with a seat at the right side, and there is a corresponding seat on the side of the rotating piece, these seats coming in contact only after the rotating piece has come to its closed position. This is accomplished by closing the cock *B*, when water gradually leaks into the space *A*, pushing the disk *C*, with its finished seat, up against the seat on the valve body and ensuring perfect tightness. To open the valve, cock *B* is opened, balancing the pressure on the disk and allowing the valve to be easily moved.

Other makes of valves have a somewhat different method of accomplishing the same result.

PUMPED-STORAGE PLANTS

A very interesting hydraulic feature, occurring particularly in Germany and Switzerland, is the storage of power for the purpose of balancing out peak loads, the storage being in the form of potential water power. As the matter is already fairly familiar here, little need be said, except to discuss the plants in a general way. Such plants are not economical for low heads, 100 ft being perhaps the minimum, since the storage of any amount of power at very low head requires very large equipment and reservoirs.

TABLE 1 PUMPED-STORAGE PLANTS

Plant	Present power, kva	Ultimate power, kva	Reservoir capacity Upper, million cu ft	Reservoir capacity Lower, million cu ft	Mean head, ft	Present Turbine, hp	Present Pump, hp	Type of unit
Schwarzenbach.....	46,000	70,000	507.0	12.8	1148	62,500	25,100	Horiz.
Niederwartha......	107,500	215,000	71.4	71.4	469	120,000	100,000	Horiz.
Herdecke..........	140,000	140,000	57.0	56.0	508	194,000	102,600	Horiz.
Bringhausen.......	144,000	144,000	27.0	27.1	954	164,000	116,000	Horiz.

Among the largest of these plants are those given in Table 1, all having been put in operation since 1926. In addition to these there are a number of other very large ones, some with the power units having vertical shafts; but only brief reference will be made to these. The power plant in these installations usually has an electrical machine which may be run either as a motor or generator and is generally coupled to the water turbine, so that these always run together. The other side of the electrical machine is connected by friction, hydraulic, or magnetic coupling to the pumps, this coupling being so designed that the pump may be thrown on while the motor is up to full speed. Since the power required to drive some of the pumps is from 20,000 to 30,000 hp and it is desired to bring them up to speed in about 10 sec. the clutches themselves offer no small problems.

In some plants, as at Wäggital, Switzerland, the pumps are driven by an entirely separate motor, but this is not usual. Since the turbine is running all the time that the electrical machine is in operation, including the time when the pump is delivering water, some method must be devised for keeping the water from the runner when it is running idle. This is usually done by some special form of valve, such as the roller sluice, such a device being watertight, quick in action, and offering no resistance when wide open. The water is frequently driven from the turbine casing and draft tube by means of compressed air.

It is usual to employ the same pipe line for both power and pumping, and these lines are sometimes very long, as in the case of the Niederwartha scheme, in which there are now two pipes, each with a surge tank 55.7 ft in diameter, the pipe lines being 6200 ft long in each case. Later, there will be four pipe lines, these varying from 10.5 ft to 8.2 ft in diameter. In this plant all of the water used by the turbines is first pumped to the upper reservoir, but in some other plants only part of the water is pumped, the natural flow being appreciable.

The heads are generally fairly high, probably the largest being that at Tremorgio in the Alps, near the St. Gothard, where the nine-stage pump delivers 14.5 cfs against a head of 3020 ft, the speed being 1000 rpm.

PUMPS

The large pumped-storage schemes have given rise to some interesting pump designs. At Herdecke, near Essen, the designed head is 525 ft, at which the desired delivery is 468 cfs and the driving speed is 300 rpm, conditions that made it necessary to use a two-stage pump. The builders decided to divide the first stage between two single-entry impellers, placed back to back, these two delivering water to the second-stage double-entry impeller, this design largely eliminating end thrust on the shaft and pressure on the stuffing boxes. The first stage impellers are 8.18 ft in diameter, with an exit width of 0.558 ft, while the second-stage impeller diameter is 8.39 ft and its exit width is 1.116 ft. The guides in the ring on the second stage move with change of speed. Since the requirements were so unusual, it was thought desirable to investigate by the use of models, and two models were made with scales of 1 to 8.72 and of 1 to 4.8, the speed of the latter being 1440 rpm.

In the models, as in the full-size machines, the builders divided the vanes on the second stage into two parts, the outer of which is fixed and the inner movable, this arrangement being probably first used by Escher, Wyss & Co. The results of the tests on the models of the Herdecke pump are given by Dr. Hahn in the *Zeitschrift des Vereines deutscher Ingenieure* of June 21, 1930, and it is from this article that the curves of Figs. 19 and 20 have been prepared. The two sets of curves in Fig. 19 (*a* and *b*), were obtained from the small model running at 1495 rpm, while Fig. 20 is a comparison between the results on the large and small models when reduced to the same basis. In Fig. 19-*a* curves 1 and 5 give, respectively, the head and power on a discharge base for the two-stage pump, and these may be compared with curves 2, 4, and 6 for the single-stage pump with spiral casing, 4 being the efficiency, and with curves 3 and 7 for the single-stage pump with guide ring. To avoid complication the efficiency curve for the two-stage pump is omitted, but it is similar to curve 4, the efficiency reaching a maximum of about 82 per cent at about 1.10 cfs and having 75 per cent at 1.25 cfs. The effect of the guide ring is evident.

In Fig. 19-*b* sets of curves are given for the two-stage pumps, and these show the effect of moving the vanes in this ring, these guides being shown in Fig. 20 in the open, partly closed, and closed positions, only the inner section being turned about the center. The curves in Fig. 19-*b* are for different values of the opening *e* in Fig. 20, these curves being numbered, 1, 2, 3, 4, and 5 for values of *e* equal to 0.945 in., 0.606 in., 0.37 in., 0.244 in., and 0.126 in., respectively. The power curves were so close together that only three of them are shown at the bottom of the figure, the head curves being at the top and parts of the efficiency curves in the center. Clearly, the positions of the guides have a marked effect on the capacity of the pump and also on its efficiency, and in addition the power required at starting may be much reduced by their use.

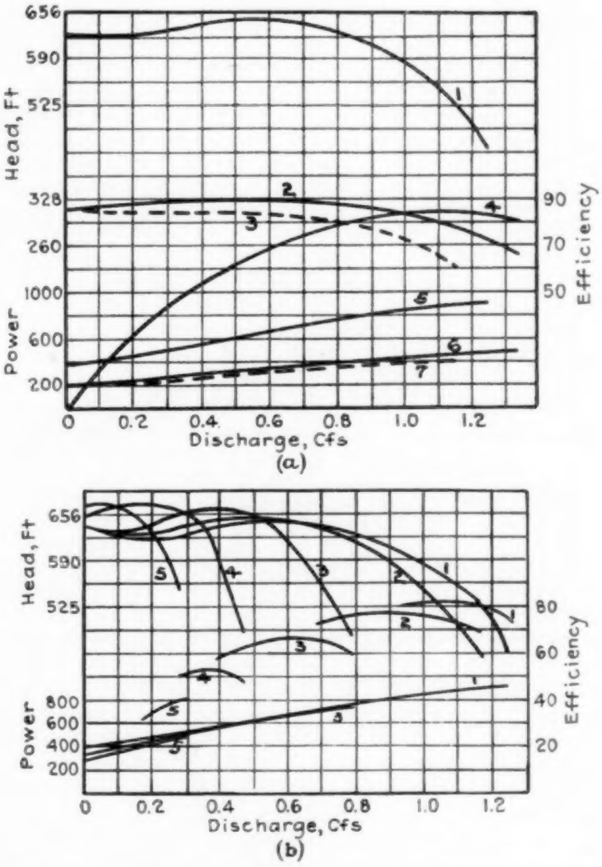

FIG. 19 TEST CURVES ON SMALL MODEL OF HERDECKE PUMP

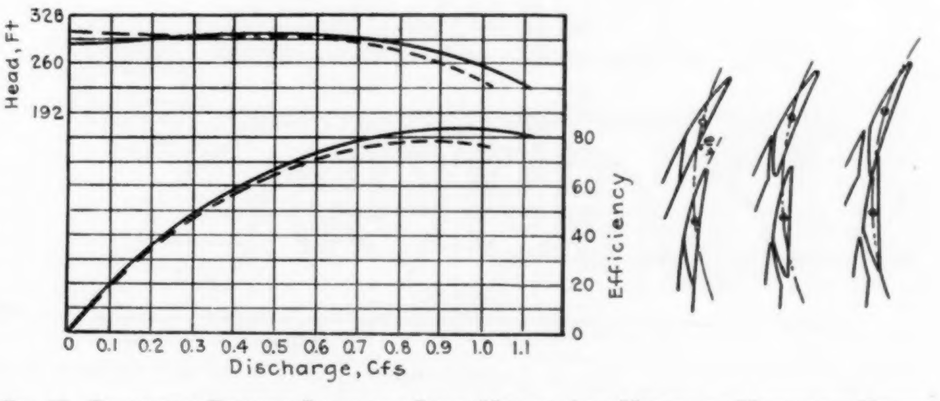

FIG. 20 COMPARISON BETWEEN LARGE AND SMALL MODELS, ALSO METHOD OF MOVING THE GUIDES
(Full lines show the large model; broken lines, the small one.)

The experimental pump and also the full-size machine were made by Gebrüder Sulzer, Winterthur, and J. M. Voith, Heidenheim. A diagram of the pump is shown in Fig. 21. There is a Föttinger coupling between the pump and motor, so that the pump may be started up when the motor is running at full speed. The governor for regulating the guides is similar to a turbine governor.

The Schluchsee Power Storage Station, built in 1929, is located at the plant at Hausern, Germany, a small town on the Rhine between Schluchsee and Waldshut and almost directly north of Zurich. In this case the unit is vertical, with the electrical machine on top, the Francis turbine below and rigidly coupled to it, and then the friction clutch with the pump below it. Much interest has been aroused also in regard to the Schwarzenbach plant of the Badische Landes-Electrizitäts Versorgungs A.-G. The turbine, shown in Figs. 10 and 11, is of 27,500 hp at 1170-ft head and 500 rpm, and is coupled to the electrical machine, the other side of which drives the pumps through gears which bring the pumps up to 1000 rpm. There are two pumps on the unit, with their shafts parallel, and driven from the same gear on the electric motor, the drive being through a magnetic clutch capable of bringing the pumps up to full speed in 10 sec if the motor is already up to speed. Each pump has an output of nearly 78 cfs at a head of 755 ft and requires 8320 hp. These pumps are similar to the Herdecke machines, being two-stage, with the first stage composed of two single-entry impellers discharging into one double-entry second-stage impeller. The cross-section of the Escher-Wyss pump is given in Fig. 22, where it is seen that the guide vanes from all three impellers are movable.

These pumps have characteristics similar to those already described.

The pumped-storage plant that has attracted most attention recently is the one completed within the last two years at Niederwartha, close to the city of Dresden, Germany. In this case there are four horizontal units, two by Escher, Wyss & Co. and two by Voith and Sulzer. Each unit consists of a 23,000-hp to 30,000-hp Francis turbine permanently coupled to an electrical machine delivering 21,500 to 26,875 kva as a generator and being capable of 29,200 hp as a motor. The electrical machine is connected to the pump by a friction coupling designed to be thrown in when the motor is up to speed. The pumps are for 330 to 415 cfs at heads from 506 to 453 ft, the speed being 375 rpm; the shaft horsepower required by the pumps is 23,800 to 27,000 hp.

The pumps are set as low as possible, the water in the lower pond varying in level from that of the pump shaft to 14.3 ft above it. The pump builders differed in their designs, Sulzer using a single-stage double-entry pump with adjustable guide vanes, while the firm of Escher-Wyss decided on two-stage pumps, the first stage being divided into two single-entry low-lift impellers which deliver water to a single double-entry second-stage impeller. A photograph of the station is shown in Fig. 23. Experience with the plant up to the present would indicate that the single-stage pumps are rather better suited to their work and have run with perfect satisfaction.

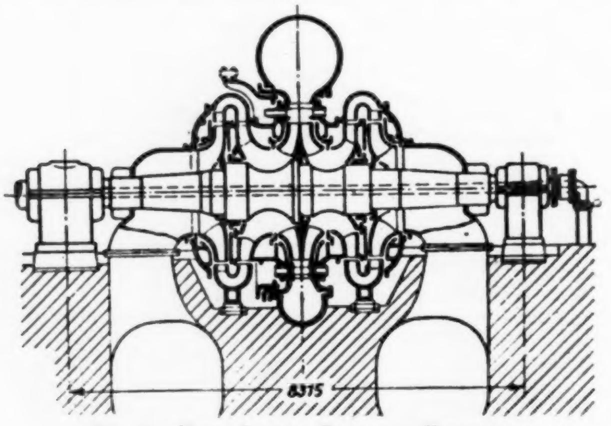

Fig. 21 Voith-Sulzer Pump at Herdecke

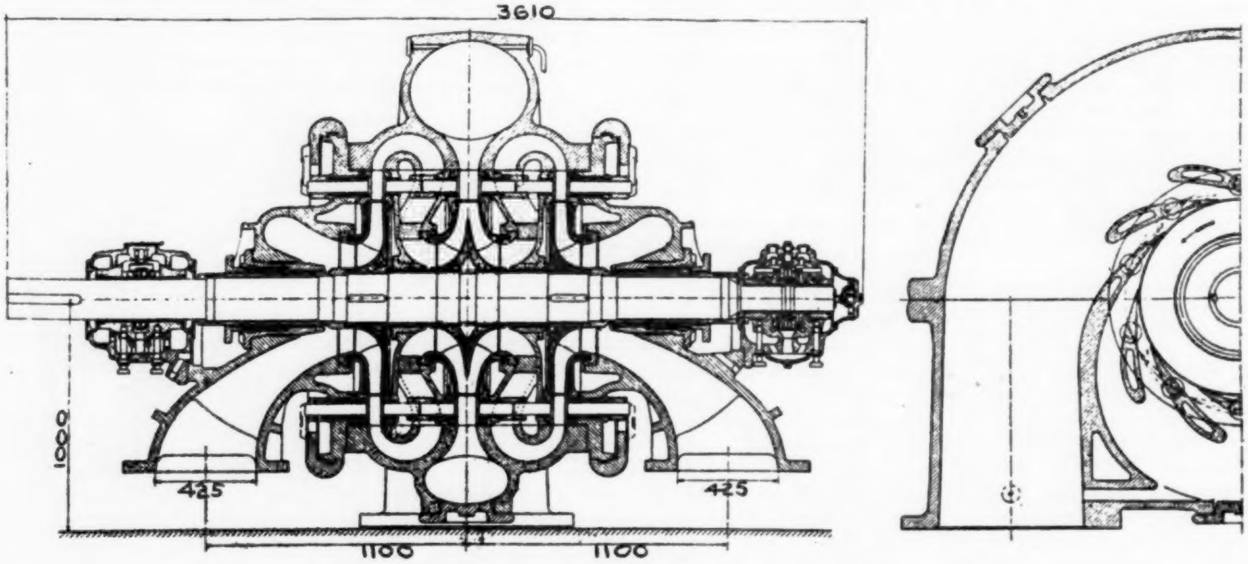

Fig. 22 Cross-Section of a Pump for the Schwarzenbach Works

Pumps for Ordinary Service

It is almost general custom on the Continent, and in England too, to use a solid casing on high-head pumps instead of the horizontally split American type, and while the practice in America is to omit the guide ring as far as possible, almost all pumps in Europe have the rings, particularly if they are more than one stage. In very high-lift pumps the cylindrical casing is cast in one piece, with ports of the water passages in it, and the guide rings and impellers are slipped in axially; in this way the maximum pressure causing leakage is only due to a single stage. Some companies make the pump up in sections, each of which is a unit of impeller with guide ring and casting with water passages, so that any number of stages may easily be built up by adding sections, these sections being held together by long bolts passing through the length of the machine.

End thrust is very largely balanced hydraulically, although very rarely the impellers are placed back to back, and some builders make two- and three-stage pumps with double-entry impellers which are largely in balance, but this arrangement has decided limitations. Considerable attention has been given to bore-hole pumps and to sinking pumps and the author has just seen a drawing for such a pump of five stages, for 212 cfm against a head of 1250 ft when running at 1480 rpm. Much ingenuity also has been shown in the design of low-head, high-speed pumps in which the flow is largely axial. Many larger boiler-feed and other high-pressure pumps also have been built, some of which are steam turbine driven at very high speeds.

The Escher-Wyss publication recently contained a description and section of a pump built by that firm for boiler feed, the drive being a direct-connected steam turbine. The pump is for a pressure of 1705 lb and delivers 4000 lb of water per minute at 3800 rpm. which requires 905 hp. The pump is 10-stage and the impellers are in two sets, the sets being placed back to back, the impellers being single entry. The passages are so arranged that the second stage is at the opposite end of the pump to the first stage and the third to the second, etc., so that the water travels back and forth along the pump and finally leaves at the center. This scheme provides nearly perfect end-thrust balance and avoids high pressures on the stuffing boxes, in addition to which it is relatively easy to draw off water between the sixth and seventh stages, send it through the heater, and back again to the seventh stage. The casing is cast steel, in one piece, and a thrust bearing is provided to take up the small unbalanced end thrust.

Some of the Sulzer bore-hole pumps are also very interesting in construction, as these have to deliver large volumes of water and the space they occupy is small. Sulzer Brothers estimate an average flow of 17,000 to 22,000 gal per hr from a 12-in. bore hole and 40,000 to 55,000 gal per hr from an 18-in. hole. Some of their pumps are arranged with two double-suction impellers in parallel in one case, working in series with other similar units; naturally the water passages are very restricted, but the efficiencies are by no means low.

Research Work

Hydraulic research is proceeding on a very large scale in Europe, and only very brief reference need be made to it. Excellent laboratories exist in the workshops of Theodore Bell & Co., Lucerne; J. M. Voith, Heidenheim, Germany; Escher, Wyss & Co., Zurich; Sulzer Brothers, Winterthur; Costruzioni Meccaniche, Milan; Verkstaden, Kristinehamn, Sweden, and other places, and these are responsible for the mechanical developments taking place, and they have supplied data for building the present turbines and pumps with their accessories.

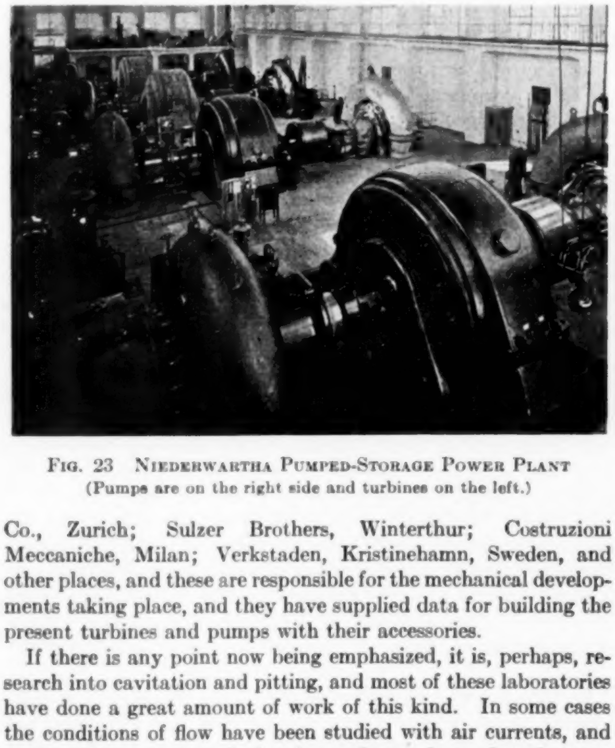

FIG. 23 NIEDERWARTHA PUMPED-STORAGE POWER PLANT
(Pumps are on the right side and turbines on the left.)

If there is any point now being emphasized, it is, perhaps, research into cavitation and pitting, and most of these laboratories have done a great amount of work of this kind. In some cases the conditions of flow have been studied with air currents, and most of them use glass draft tubes and some form of stroboscope in which the action may be studied. Many experiments also have been made on turbine nozzles, turbines, pumps (some of which have been outlined), etc.

The engineering colleges have shown a marked interest in hydraulic research, as is evidenced by the additions to the buildings in Brunswick, Hanover, Dresden, Zurich, Milan, etc., stress being laid on stream flow and open-channel experiments, although investigations on turbines, pumps, and other machinery are under way. There is great research activity among all of the European colleges, and much useful work is being published, one case being that of the important work done by Dr. Thoma, Munich, on the flow in centrifugal pumps.

Only passing reference may be made to the Forschungsinstitut fur Wasserbau und Wasserkraft, near Munich, as this has already been described in various journals. It is a most commendable laboratory, mostly outdoors. It has a possibe flow of 280 cfs from the Obernach River, and it fortunately enters the experimental flume without any great amount of agitation. The experimental field is nearly 2000 ft long and is equipped with measuring reservoirs, weirs, open channel about 8 ft wide and 7 ft deep, and there is a large area available for constructing river models. This institute publishes papers of its researches, which may be had on application.

It will be interesting to members of the Hydraulic Division to know that the reports of many of the researches conducted in Germany are frequently available in printed form and may be had by communicating with the particular person under whom the work has been done. This is at least true of the laboratories under the control of Dr. Thoma at Munich, Professors Rehbock and Spannhake at Karlsruhe, and Professor Oesterlin at Hanover, and some of the other laboratories as well.

Translations of some of these reports are now being undertaken and will be available to the members of the Society very soon. These are a further evidence of the debt that hydraulic engineers owe to Mr. John R. Freeman, through whose generous assistance, in cooperation with the Society, the work is being done.

Discussion

A. J. R. Houston.[2] The paper covers the field so thoroughly that only the following other features of European water-power practice occur to the writer:

(1) Cleaning racks by reversing flow. In some low-head plants where the turbine racks are divided into two or more parts by vertical walls, the racks may be cleaned by reversing the flow in one set at a time. This of course involves reducing the output of the unit during the cleaning operation. The system is not in general use, and rack-cleaning machines are perhaps as common there as here.

(2) In connection with low-head plants, the vertical-shaft geared units are interesting. The generator shaft is vertical as well as that of the turbine, and destroyer-type herringbone gears are used. The unit becomes very much more complicated mechanically, as in addition to the gearing there must be two thrust bearings. However, the speed of the generator is very high, and it becomes correspondingly small in size. Several such plants have been built.

(3) Sand-extraction schemes. In some plants an attempt is made to eliminate some of the material carried in suspension in the water. These devices are more frequently used in connection with high-head than with low-head plants. They are mostly of the settling-basin nature, usually with provision for continuous cleaning. One of the best known is the Dufour.

(4) Roller gates. It might be mentioned that with roller weirs which would call for a shield, the roller is sometimes replaced by trusses. The gate is raised by rolling the gear wheels up racks exactly as with the original roller type. The pure roller gates are often made sinkable so as to pass ice or other rubbish with a minimum loss of storage. The writer does not share the extreme enthusiasm for the roller weir of some American river-flow engineers, who seem to feel that it sometimes offers the only possible solution. While the roller dam is a highly satisfactory device, there are many other good forms of gate available, and it should in general be subjected to competition with other types.

(5) Automatic gates. Mention might also be made of the various gates for automatically maintaining the storage level. These are made in a wide variety of designs. Some are equipped with counterweights; others not. Often they are of the floating-leaf type, and also many are similar to the bear-trap gate so well known in this country.

---

[2] Harza Engineering Company, Chicago, Ill. Jun. A.S.M.E.

(6) Hydraulic clutches. In connection with pumped-storage plants it would probably be fair to say that the hydraulic clutch is now being favored over the friction and magnetic devices for coupling the pump to the electrical machine. The hydraulic device seems to take hold more smoothly.

S. Logan Kerr.[3] Several years ago the writer visited most of the plants described, and had the opportunity as well to visit the shops and laboratories of many of the European water-wheel builders. The hydraulic design of many of these plants has been the subject of exhaustive test and research work conducted in laboratories, in advance of construction. In many instances, considerable savings have been effected, but in many others it appears that the turbine installation has been studied in so far as the runner and guide vanes are concerned, and many of the vital portions of the plant, such as the intake and draft tube, have not been the subject of as much research as would be desirable.

This tendency, however, is now disappearing, and the entire structure is considered as a unit, and the principle that has been employed in American research work for a number of years is being more fully appreciated—namely, the interdependence of the various elements of any hydraulic-turbine installation.

The development work on impulse wheels for high-head applications in Europe has been most interesting, and is still considerably at variance with many elements of American practice. The multi-jet wheel appears to be in satisfactory use in many plants in Europe, and when conservative velocities are used with jets free from turbulence, good results should be obtained.

The question of efficiency in European turbine plants, as compared with American performance, has always been a moot question, as the test methods for water measurement have differed so radically. With the wide-spread use of current-meter testing in European plants, there has undoubtedly developed a high order of skill in the use of these meters, in many instances equaling the accuracy obtainable with the Gibson and Allen methods in America. The performance of the high-speed propeller and Kaplan-type units, in both Europe and America, has been virtually the same with respect to the values of efficiency attained. There have been many installations in America where accurate tests have demonstrated that the performance is in excess of 93 per cent, comparing very favorably with European practice.

With the impulse units, however, some reasonable doubt may be in order in certain of the installations, particularly where a single current meter has been used, located in the conduit, and its calibration assumed from laboratory testing. It would be of great interest if one of these impulse-wheel installations could be tested with the Allen salt velocity method and compared with the current-meter or other form of measurement used in most of the European efficiency tests. Performance of many American installations of impulse wheels has undergone considerable revision when the flow has been measured precisely by the Allen method instead of by pitot tubes or current meters. The difference between the actual performance and the estimated performance is so great as to result in a complete revision in design methods.

It would have been of great interest if the author could have described the type of power-plant auxiliaries, such as governors, oil-pressure systems, etc., utilized in the various European hydroelectric plants. It was the writer's impression, gained from visits to most of the plants described, that the turbine equipment itself compared favorably with American practice. There were many details of design of the operating mechanism, bearings, etc. that could be profitably employed by American designers. On the other hand, the ruggedness of the average American turbine was lacking in most of the European installations, and great stress was laid on savings effected in weight and materials, as compared with American practice, which is directed principally at savings in labor.

With regard to the governors and the oil-pressure systems, it was a distinct disappointment to see the complicated mechanisms used in even the most modern installations in Europe. The ease and convenience of control available with any of the modern American governors seem to be sadly lacking with the European designs. The use of a load limit and other simple adjustments, including the automatic change-over from hand control to governor control, were lacking in most cases, and the starting up and shutting down of units appeared to be a tremendous task, as compared with the simplicity of operation in most American installations.

The governor drives were almost invariably gear or a combination of gear and belt, driven from the main shaft of the turbine, and not a single installation of motor-driven flyballs could be found, even though they had become accepted standard practice in American installations.

In this respect the writer feels that the turbine manufacturers in United States and Canada have progressed much farther than the European designers. In the last few years considerable work has been done in Europe on the use of inertia-type governors for hydroelectric plants, but for ordinary turbine regulation it does not seem, at present, to be of sufficient advantage to warrant the expenditures necessary for development and engineering work of this type of governor.

The continued interchange of information and experience between European engineers and the engineers in this country and Canada cannot help but benefit both parties, as each has developed distinct advantages in many different features of their equipment. It is hoped that this international form of cooperation in engineering will continue to the benefit of all concerned.

Eric C. Molke.[4] The paper, especially the chapter on control gates, was most interesting, as the writer has just returned from Europe, where he saw several of the plants described. The spans on European hydraulic gates are generally much longer than those used on this continent, and the time will come when, on certain large rivers on this side, even under more serious climatic conditions, large-span control gates will be installed with advantage. The details showing how to take care of the big reactions at the gate guides are of great interest to engineers. The roller weir is especially very suitable for such spans, and from what was observed in Europe, has stood up well, even under very unfavorable conditions. The writer had an article on "Types of Gates Used on Dams in Europe," in *Power*, June 7, 1932.

W. Spannhake.[5] The design of turbines, especially the fast-running types for low heads, neither here nor elsewhere, has reached satisfactory development with respect to the danger of cavitation. In the future possibly some details in the general layout will be slightly altered in order to reduce cavitation. In my laboratory at the technical university a great many cavitation tests on models of turbines for the power station at Ryburg-Schworstadt have been made for the Atéliers des Charmilles. In addition to these, the writer has tested a new draft-tube device intended to give improvement, as compared with the usual construction, in the direction of less depth and length without decrease of efficiency, in spite of the existence of a whirl in the draft tube in the positive sense of the rotation of the runner, this whirl allowing the runner blades to be designed for lower relative velocities and in consequence for reduced possibility of cavitation.

[4] Montreal, Quebec, Canada.

[5] Professor, Technische Hochschule, Karlsruhe, Germany.

Paul E. Gisiger.[6] There is a striking difference in layout and arrangement of spillway equipment of European and American plants. While in the United States and Canada 50 ft is about the maximum so far used for the width of a gate opening, and as a rule gates are operated with one or (for a large number of gates) two traveling gantry cranes, in Europe widths of 80 ft for vertical-lift gates and still wider openings for roller-type gates have been used, and almost always individual hoists and operating mechanisms are provided for each gate. At first sight it would appear that European engineers are unduly conservative in duplicating hoisting facilities, but this feature, as well as very wide gates, is a result of geological and hydraulic conditions. Most European rivers, and especially those originating in the Alps, run through valleys covered with heavy glacial and alluvial deposits, and foundations usually have to be carried down to rock by the pneumatic-caisson method. Gate sills are usually not much higher than the original river bottom, so that the piers, and especially their foundations, are the major items of cost of the spillway. It is economical, therefore, to have wide openings and as few piers as possible. On the other hand, Alpine rivers have much more regular characteristics of flow than most American rivers, with the maximum flows amounting to only from four to six times the 180-day flow. Therefore, a very much smaller spillway capacity is usually required on a European river than on an American river having a comparable average or 180-day flow. For instance, while the Ryburg-Schworstadt development has only four gates at a site with a 180-day flow of about 35,000 cfs, the Safe Harbor development has 32 gates at a site with a 26,000-cfs 180-day flow. The number of gates is of course no measure of total discharge for the reasons stated, but it illustrates the wide difference of conditions that influence the choice of hoisting equipment. The number of gates usually required on a large low-head development in America puts separate hoisting equipment for each gate out of question, but with the four-gate to 10-gate installation most frequently met with in Europe the economics are largely in favor of individual hoists.

Carroll F. Merriam.[7] Much can be said on the subject of difference in engineering practices between Europe and the United States and Canada, and in many cases European designs are open to the criticism, when viewed by our engineers, that their construction is light, complicated, and involves considerable expenditure of labor, and that efficiency may be overemphasized. Consideration must be given in the first place to the fact that whereas we live in a land of plenty where materials are cheap, they have been forced by lack of natural resources to conserve materials and resources most carefully, while conversely, through overcrowded population, labor is correspondingly cheap. We have only to look at the illustrations in the author's paper to realize the force of this statement and appreciate that although our construction may be more rugged and generous in materials, it would be as equally unsuited to their conditions as their designs would be to ours.

Nevertheless, there are many lessons that we may profitably learn from European practice, and the author is to be congratulated for his continued interest in bringing to this country the results of his experience and contact with European engineers.

In recent American construction we have profited greatly by European contacts and have installed the most powerful Kaplan turbines in the world. Many ideas have been incorporated in the design of the dam and power house that have been taken from European practice.

In this connection there should be mentioned the double-leaf gates, very similar to those shown in Fig. 14, except that the upper leaf is practically equal in size to the lower and is controlled by an independent hoist remotely operated from the power-plant control room. These gates have proved very successful in assisting to maintain the desired constant pond elevation.

The design of Kaplan units of such large size has brought about many problems, particularly that of cavitation, and we have instituted important studies in conjunction with foreign authorities for the purpose of investigating this problem and advancing our knowledge of its control.

The plants for pumped storage common in Europe bring some most interesting economical problems, and although it may at first seem doubtful that steam-generated energy can profitably be turned into stored water and again reconverted to electricity with an overall efficiency of only slightly over 60 per cent, nevertheless careful analysis has shown that many factors that are not immediately apparent must be taken into consideration.

In regard to current-meter testing, the method illustrated in Fig. 6 is simply a forerunner to subsequent tests in which the corps of observers is replaced by a chronograph. This method is being used for important tests in this country, but with several modifications. The fundamental idea has been taken from foreign practice and applied to American conditions, with improvements. This may be considered as simply one example of what should result as we become more familiar with European ideas and come to a better understanding with engineers from abroad.

T. H. Hogg.[8] The paper brings together a great amount of information regarding modern European hydraulic practice, which is greatly amplified by the illustrations selected to accompany the text. The writer will comment only on five items in connection with plants and equipment described.

Changes in draft-tube design in Europe during the past 15 years have proceeded in general along the same lines as those followed in America. The quarter-turn of the draft tube is given a smaller radius of curvature than formerly, but the most striking change is seen in the great increase in the horizontal section beyond the quarter-turn. This is seen in the cross-sections of the Donaustetten, Ryburg-Schworstadt, and to a lesser degree in the Chancy-Pougny plants. The same feature is noticeable in many recently built plants in this country, for example, those at Chats Falls on the Ottawa River and Alexander on the Nipigon River.

One feature of draft-tube design in which European and American practice differ materially is the addition, in European draft tubes, of horizontal and vertical division walls. Such division walls were used formerly in a few plants in America, but with unsatisfactory results in some instances, as for example in the St. Timothee plant on the St. Lawrence River. High efficiency is evidently obtained with these in the European examples described by the author.

The concentric type of draft tube has never been favorably received in Europe. In our experience it has effected an improvement in efficiency and steadiness of operation at part gate in many instances. In some cases it has been found necessary to reduce the height of the central cone, in order to obtain the best results as to capacity and high-load efficiency.

It is interesting to note the simplification in the matter of water control in such large plants as that at Ryburg-Schworstadt, where steel gates of the stop-log type are substituted for headgates at entrance to the turbine settings.

The very considerable problem that is presented in the design of couplings between motors and pumps in pumped-storage plants suggests that the pump runner be permanently connected to the motor and that valves be provided to keep water out of the pump casing at times when the turbine is operating. This would seem to be reasonable, as a similar arrangement is used with respect to the turbine runner.

[6] Safe Harbor Water Power Corporation, Baltimore, Md.

[7] Pennsylvania Water and Power Company, Baltimore, Md. Mem. A.S.M.E.

[8] Chief Hydraulic Engineer, Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada.

It is interesting from the standpoint of economics to note that the Niederwartha plant near Dresden is in a locality where numerous steam-electric stations operate using brown coal for fuel, and off-peak power from these steam plants is utilized to drive the pumps in this station. The pumping head is the same as the head used on the turbines, so that the energy returned to the system from the pumped-storage plant is less than that used to run the pumps by the hydraulic and mechanical losses in pumps, penstocks, and turbines. Conditions are materially different from some cases investigated by the writer in which the pumping head was 10 to 15 per cent of the head on the turbines, and the output from the pumped-storage plant therefore much greater than the input. In one such instance the energy made available from the pumped-storage plant was only slightly less expensive than energy from other available sources. This is due to the seasonal variation in load demand, causing the output from the pumped-storage plant to have only surplus-power value during certain months of the year.

It is noticeable that there is less uniformity in design of control gates in Europe than is seen in American plants. The stony sluice has been superseded here in many cases by gates with fixed rollers. The rugged design of the gates at Ryburg-Schworstadt is worthy of note, and the division of the gate into upper and lower sections with its quite evident advantages is commendable. Roller gates of large size similar to those at Raanaasfos are in use in America, one installation recently completed having a span of 110 ft.

In Europe as in America there has been progress in the application of propeller and Kaplan-type runners to higher and higher heads. The installations at La Gabelle on the St. Maurice River, where a head of 60 ft is used, and at the Seven Sisters Development on the Winnipeg River, where the designed head is 66 ft, show a great increase in the head used for propeller units as compared with that used 10 years ago. The writer understands that heads approaching 100 ft are in use on turbines of the Kaplan type in Europe.

Albert J. Luchinger.[9] The author has given a complete description of the special types of hydraulic machinery peculiar to Europe. The paper shows that hydraulic machinery on the European Continent does not differ fundamentally from American practice. Having worked both in America and Europe, one fundamental difference in hydraulic practice, however, has occurred to the writer, and that is the difference in relations between the mechanical and the construction part of the developments. The chief engineer on hydro developments in America is normally more a mechanical one; in Europe, he is more a civil engineer.

The American developments are built around the turbines and gates; the mechanical part is the one that is first ordered and normally governs the design. In Europe the construction part dictates to a certain extent the machinery. Both methods have their advantages and drawbacks, and both methods given their special note to the developments. The difference is not a difference in technical quality, but in predominance of certain otherwise similar features. An interchange of engineers and ideas between the two continents can only help both of them, but need not level off their characteristic viewpoints.

It might be of interest to give a brief description of some unusual power-plant details now in construction in Europe.

The Wettingen plant, on the Limmat, in Switzerland, is one of the rare medium-head plants of that country. The main feature of the design was the selection of a spillway structure that would result in minimum scour to the river bed. A public contest was opened for the best design. The peculiar feature of this structure is the use of two types of discharge openings and three types of gates in the same cross-section.

The total spillway length is divided into four discharge sections, each 33 ft wide. The four crest gates are automatic tilting gates and take care of the flow up to normal high water. The four sluiceways are opened in times of high flood; they serve further for slicing out the accumulated gravel or exceptionally lowering the pond level. Each sluice opening has two gates—a tainter gate for easy and quick operation and a sliding gate in front of it. This second gate serves as a tight closure in time of low stream flow and during repairs on the tainter gate.

The maximum possible combined discharge of crest and sluice openings is 450 sec-ft per 1 ft of spillway length. Extended model tests in the hydraulic laboratory in Zurich have shown the great advantage of operating both crest and sluice gate together in times of flood. The depth of scour below the dam for separate part discharge over the crest or separate part discharge through the sluiceway was just as great as for combined total flow through both discharge openings. The impact of the two flows of different directions destroys a big amount of their energy.

The Kembs power house, on the Canal d'Alsace, near the Rhine, just below the city of Basel, now under construction, is the first of a number of power stations that are projected on a large power and ship canal parallel to the Rhine between Basel and Strasbourg. The interesting feature of this development is the spillway openings in the power house between the turbines and the generators. These openings are provided with automatic gates, which allow the water to pass the power station in case the turbine gates are closed. This provision also guarantees a continuous flow in the canal below the station in case of any shutdown of its turbines. This spillway within the power house saves the cost of separate spillway structures and also allows an easy discharge of the surface ice from the pond. There are six Kaplan turbines of 33,000 hp at 40 ft head.

As a most interesting hydraulic feature, the author discusses a number of the most recent pumped-storage plants. In the last few years there has been great activity in Europe along this line. These storage plants are particularly valuable in connection with large low-head plants like those on the Rhine. The power station at Kembs will be connected to a large pumped-storage plant in the Vosges mountains, the development of Lac Blanc and Lac Noir.

Two natural lakes of about 350 ft difference in elevation and 2500 ft horizontal distance are connected by a gallery and penstocks. Practically all the water used by the turbines is first pumped to the upper lake, the natural flow being very small. The pump, turbine, and electrical generator of each of the four units are mounted on one vertical shaft with fixed couplings. Both turbine and pump are running all the time the electrical machine is in operation; the one running idle is kept free from water by means of compressed air. Each of the four Francis turbines rates 28,000 hp, with 330 ft head; each of the four pumps has an output of 460 cfs and requires 24,000 hp, with 330 ft head and 272 rpm.

These three developments have been carried out by the Swiss firm of Locher & Co., Zurich, which firm is also consulting on the construction of the dam at Kembs and the development of Lac Blanc and Lac Noir. The turbines and pumps of this last development are built by Escher, Wyss & Co., Zurich.

Author's Closure

The author is grateful to those who have so kindly discussed and amplified his paper. The discussion has been constructive throughout and little need be said in regard to it.

---

[9] Engineer, Locher & Co., Zurich, Switzerland.

Referring to the point raised by Mr. Houston, the author was struck with the very general use of rack-cleaning machines, and these seemed to have a real duty to perform, judging by the amount of material they removed; some of the machines are illustrated in the paper.

Mr. Kerr points out the discrepancies that may arise in comparing the efficiencies of American and European plants due to the differences in the methods of water measurement. Undoubtedly there is need of more uniformity in test methods, but an effort has recently been made by German engineers to compare several methods of discharge measurement, and this comparison is still in progress. For many of the low-head European plants the current-meter method is almost essential, and the results of tests being made on a very large American plant in this way are being eagerly awaited.

The author did not gain the same impression that Mr. Kerr did with regard to the lightness of the parts of European turbines, and the complication of governor mechanisms. Europeans are more economical, in general, than Americans, but the proportions of their machines are usually so good that one ordinarily does not notice a suggestion of weakness. The inertia governor seems to be in favor in Europe, but it need not be a complicated device, for if the flyballs are displaced from the plane passing through the axis of rotation of the spindle in such a way that they move in planes parallel to the spindle, then the governor shows the inertia effect.

The author agrees with Mr. Kerr in regard to the need of continual cooperation between engineers everywhere, and that is one of the reasons the paper was prepared.

Cavitation, as Professor Spannhake points out, is still a serious problem everywhere, and the author mentions the stress that is being laid upon its study in Europe. The work being done by Professor Spannhake on this subject at the Massachusetts Institute of Technology is particularly valuable, and will bring the best experience of two continents together.

The comments of Messrs. Gisiger and Merriam are important, in view of many points of similarity between the Safe Harbor plant and some of the latest European developments, particularly that at Ryburg-Schworstadt. The author has found comparisons most interesting. In a personal letter, Mr. Merriam has pointed out to the author that in the original report on the Ryburg-Schworstadt plant an error had been made in the generator efficiencies, which were taken from 0.8 to 1.3 per cent too high, and that the actual turbine efficiencies were about one per cent lower than the paper states.

The difficulty of designing couplings for pumped-storage plants is mentioned by Mr. Hogg, but the author was impressed with the remarkably ingenious and perfect devices used for this purpose, enabling starting and operation to be effected without shock of any kind.

The Wettingen plant mentioned by Mr. Luchinger contains three 10,000-hp Kaplan turbines running at 214 rpm under a head of 75.5 ft, the highest head yet used on this type of turbine, but the specific speed has the very low value of 97. The center of the spiral casing is at minimum tail-water level, and about 6 ft below maximum tail-water level, and the draft tube is of the general design shown in Figs. 1 and 2. The author appreciates the reference to the Kembs plant, which was omitted on account of lack of space. The rapid development of the Rhine water powers is of great interest to engineers everywhere.

Information has been received from Bell and Company of a rotary valve 7.55 ft in diameter for a pressure of 95.5 lb per sq in., and they have also sent a drawing of a turbine with a conical distributer where the guides are almost radial. This turbine has 117 hp at 8.53 ft head and 130 rpm, which corresponds to a specific speed of 96.

HYD-54-8

Investigation of the Flow Conditions in a Centrifugal Pump[1]

By K. FISCHER[2] and D. THOMA,[3] MUNICH, GERMANY

This paper gives an account of an investigation recently carried out in the laboratory of the Technical University of Munich, into the flow conditions in the impeller of a centrifugal pump, the results of which may be summarized briefly as follows: (1) Practically all flow conditions for an actual fluid are fundamentally different from those theoretically derived for an ideal frictionless fluid. (2) The dead-water zones which form on the low-pressure sides of the blades undoubtedly cause a reduction in the angle at which the fluid leaves the blades from the actual blade angle. (3) The actual velocity distribution along circles concentric with the axis of rotation of the impeller is not the same as the supposed distribution computed on the basis that the fluid passages are completely filled with active flow. (4) The relative velocity along the high-pressure side of the blade should theoretically approach zero for relatively small reductions in the discharge below normal and with the fluid passages completely filled with active flow. Actually this velocity is greater than the theoretical value, and reverse flow along the pressure side of the blade does not take place even at small discharges. (5) In addition to (4), it was definitely proved that the flow at very small discharges is no longer stable. (6) The entrance flow may be assumed to be radial for all practical operating conditions. (7) The increase in the meridional velocity over the ordinary computed value alters the shape of the exit triangle considerably, which is of special importance in designing the guide-vane entrance angle.

I—INTRODUCTION

THE power actually required by the impeller of a centrifugal pump is considerably less than the theoretical value computed for an impeller containing an infinite number of blades. This is due to the variations in pressure and velocity, along circles concentric with the axis of the pump, created by the relative vortex in the fluid passages. The present methods of computation consider both these eddies and the accompanying reduction of the angle of exit from the impeller blades and give, by the use of correction factors, a result which is in sufficient agreement with the actual facts. It has been impossible, however, to definitely fix the value of the angle of exit for the actual delivery heads, and an exact knowledge of the flow conditions, particularly at exit from the impeller, is in many cases especially desirable. The assumptions which must be made when designing an impeller (e.g., that the fluid passages are always completely filled with actively flowing fluid) have often led to erroneous conceptions of the true flow conditions, especially in the case of small discharges. This is clearly shown by the research herein described. It is true that, since thorough investigation of the formation of "dead" zones on airplane wings, no further doubt has existed about the error in assuming the fluid passages to be completely filled with active flow. This phenomenon, however, was supposed to have but little influence on the power required by the impeller.

Theoretical investigation of the effect of the formation of dead zones was very difficult to conduct because no information was available concerning the extent of the zones and the conditions responsible for their formation. These phenomena have been clarified by the investigations described here in which an optical instrument called a "rotoscope" was employed which was designed by Dr. Thoma[4] several years ago for investigating the flow conditions in hydraulic turbines.

II—DESCRIPTION OF THE RESEARCH APPARATUS

The Pump

As shown by Fig. 1, the method of introducing water to the impeller differed but little from that employed in actual practice; however, the special purpose of the apparatus was given consideration in the design of the bearings and driving mechanism. The single impeller bearing was fitted to the outside of the stationary horizontal suction pipe so that the visibility would not be impaired by an outside bearing. The most essential fact is that the entire impeller and the guide vanes were clearly visible through a single plate-glass wall which took the place of the outside pump case and formed the front shroud of the impeller.

The Impeller

The impeller consisted of six blades cast integral with the

---

[1] On reviewing Dr. A. J. Stepanoff's excellent paper entitled "Leakage Loss and Axial Thrust in Centrifugal Pumps," Dr. Thoma feels that he has made a valuable contribution to our knowledge of the subject. Some recent tests made, under Dr. Thoma's direction, in the laboratory of the Hydraulic Institute of the Technical University of Munich have cleared up a number of the uncertain flow phenomena in pump impellers which Dr. Stepanoff has discussed. These tests and the accompanying report, made by Mr. Karl Fischer, will, it is hoped, throw new light on some of the hitherto highly speculative flow conditions. The English text of this report was prepared by Mr. C. P. Kittredge, B.S., Massachusetts Institute of Technology, and holder of one of the John R. Freeman Traveling Fellowships.

[2] Diploma Ingenieur and Doktor Ingenieur, Technische Hochschule, Munich, and Regierungs-Baumeister.

[3] Professor of Hydraulics and Director of the Hydraulic Institute of the Technical University of Munich. Mem. A.S.M.E. Dr. Thoma was graduated from the Technical University of Munich in 1906 as a Mechanical Engineer. From 1906 to 1908 he was employed as designer by the firm of Briegleb, Hansen & Co., of Gotha, manufacturers of water turbines, governors, etc. For the following two years he was associated with Prof. A. Föppl as assistant in technical mechanics. During this time he remained in touch with Briegleb, Hansen & Co., and in 1910 became head of its governor department. He was chief engineer of its turbine-testing stations, as well as head of the governor department, after 1913. A new testing laboratory was built according to his plans in 1913–1914. After 1915 he was also superintendent of all the offices of the firm for the designing of all kinds of water-power machinery and water-power plants. In 1920 he was appointed Professor of Technical Mechanics of the Technical University at Munich. In 1921 he assumed his present position.

Contributed by the Hydraulic Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27–July 1, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] D. Thoma, "Die Versuchsanstalt für Wasserturbinen in Gotha," published by Engelhardt-Reyher, Gotha, 1918.

back shroud. The front shroud was a detachable circular glass plate. The blades were designed according to standard practice. Both the blades and the back shroud had painted surfaces in contact with the water. The impeller was designed to deliver 8.3 liters per sec (132 gpm) against a head of 1.65 m (5.41 ft) at 400 rpm, and 9.40 liters per sec (149 gpm) against a head of 1.885 m (6.18 ft) at 450 rpm.

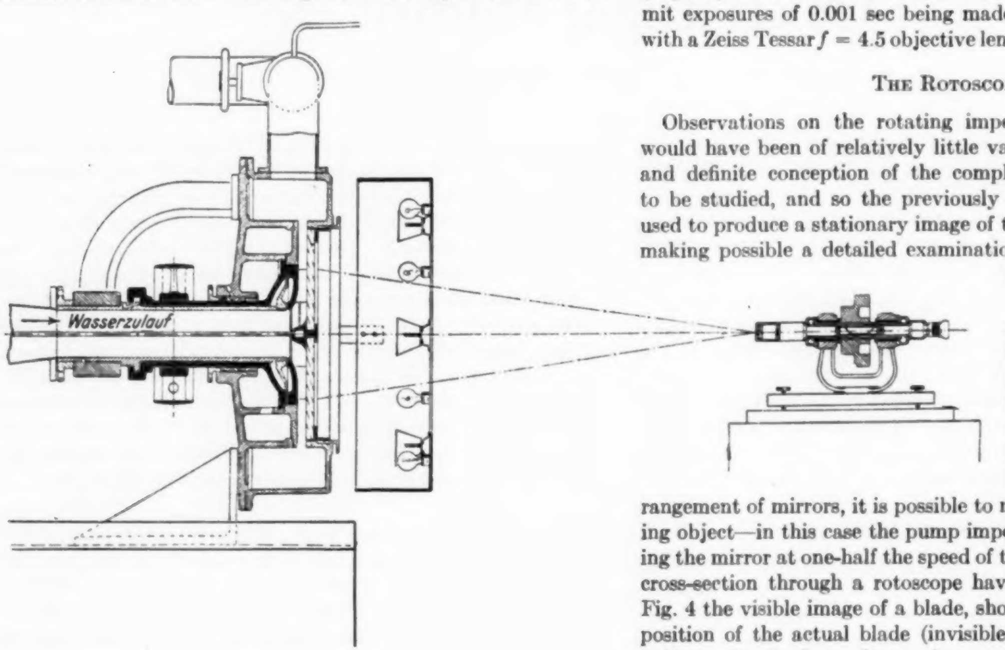

Fig. 1

Impeller Data

Clear distance between blades at entrance b_1 = 22.5 mm (0.886 in.)
Clear distance between blades at exit b_2 = 20.0 mm (0.787 in.)
Entrance diameter d_1 = 140 mm (5.51 in.)
Exit diameter d_2 = 280 mm (11.02 in.)
Suction-pipe diameter d_s = 100 mm (3.94 in.)
Number of blades z = 6
Blade angle at entrance β_1 = 17°
Blade angle at exit β_2 = 28°

As shown in Figs. 1 and 2, the illumination consisted of six concentrically arranged 100-watt lamps for ordinary use and six additional 1000-cp carbon arc lights for use when photographing the flow. The total illumination was sufficient to permit exposures of 0.001 sec being made with a camera equipped with a Zeiss Tessar f = 4.5 objective lens.

The Rotoscope

Observations on the rotating impeller with the naked eye would have been of relatively little value in obtaining a correct and definite conception of the complicated conditions of flow to be studied, and so the previously mentioned rotoscope was used to produce a stationary image of the rotating parts, thereby making possible a detailed examination of the flow phenomena with respect to the blades.

The principle of the rotoscope is that the image of a stationary object when viewed in a rotating inclined mirror revolves at half the speed of the mirror. Therefore, by means of a suitable arrangement of mirrors, it is possible to make the image of a rotating object—in this case the pump impeller—stationary by rotating the mirror at one-half the speed of the object. Fig. 3 shows a cross-section through a rotoscope having three mirrors, and in Fig. 4 the visible image of a blade, shown by solid lines, and the position of the actual blade (invisible), shown by dotted lines, indicate clearly how the stationary image is produced. The illustrations, *a*, *b*, *c*, and *d* show the displacement of the image relative to the blade when the blade is stationary and the mirror system revolves, and *a'*, *b'*, *c'*, and *d'* the displacement of the blade relative to its image when the impeller is revolving at twice the speed of the rotoscope. In each case the diameter of the circle shown dotted represents the apparent plane of reflection. It will be seen that in the latter case the image remains stationary. In actual practice the rotoscope is constructed as shown in Fig. 5 with an inverting prism replacing the three mirrors and a lens system provided to increase the field of view of the instrument.

General Arrangement of Apparatus

The water was supplied to the pump under a positive head of

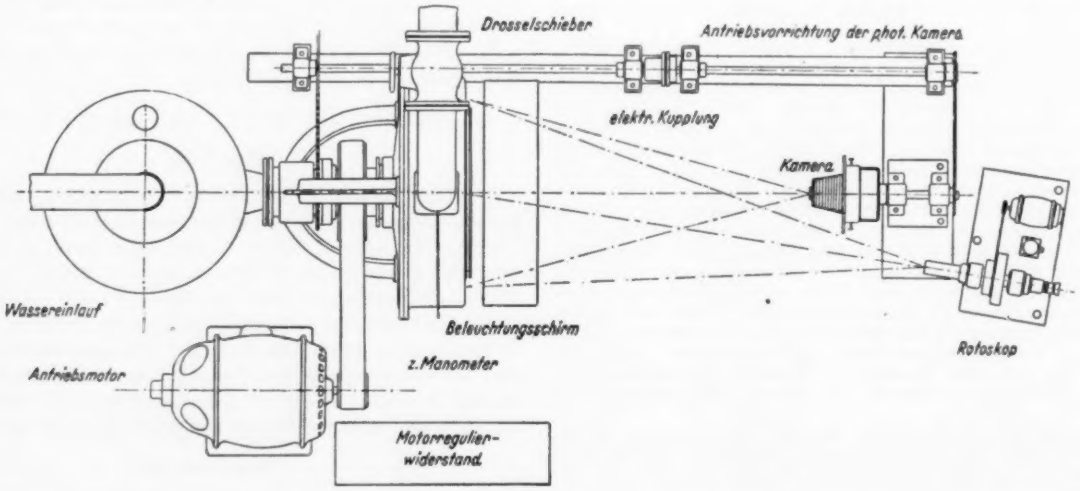

Fig. 2

(*Wassereinlauf* = water inlet; *Antriebsmotor* = driving motor; *Motorregulier-widerstand* = motor regulating resistance; *z Manometer* = to manometer; *Beleuchtungsschirm* = illuminating arrangement; *Drosselschieber* = throttle valve; *elektr. Kupplung* = electromagnetic coupling; *Antriebsvorrichtung* = driving arrangement.)

about 1.2 ft from a small constant-head tank, which was in turn fed by the laboratory supply system. Figs. 1, 2, 6, and 7 show the arrangement of all parts of the equipment. The discharge water was throttled through a gate valve to vary the head and discharge, and then piped to a weighing tank on the floor below where it was accurately measured. The pump was belt-driven by an electric motor the speed of which was regulated by means of a variable-resistance unit. The total static head was measured by a mercury manometer.

In order to keep the effect of viscosity, which owing to the relatively small dimensions of the pump became more important than under most practical conditions, from influencing the final results, the rotating speed was made as high as the strength of the plate-glass wall would permit (about 450 rpm). The Reynolds numbers, based on the hydraulic radii at entrance to and exit from the water passages of the impeller were 164,000 and 108,000, respectively. These are frequently exceeded in practice, but they are already so high that no fundamentally different flow conditions are to be expected in a larger impeller.

METHOD OF OBSERVATION

As already stated, the rotoscope was used for making a continuous observation of the flow conditions to be investigated. It was placed at a distance of from four to five feet from the pump impeller, and, as shown in Fig. 8, was driven by a small belt-connected electric motor equipped with a variable resistance for coarse speed adjustment. Fine speed adjustment was obtained by braking the flywheel of the rotoscope gently with the finger tips, so that an absolutely stationary image of the blade could be easily produced. In order to secure a permanent record of the flow conditions a camera, rotatable about its optical axis, was used in place of the rotoscope and driven by a two-piece countershaft from the pump driving mechanism as shown in Figs. 6 and 7. The two parts of the countershaft could be connected at will by the electromagnetic coupling shown in Fig. 9. A chain drive was used to avoid any speed difference between the pump and camera.

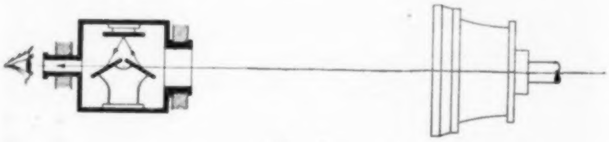

FIG. 3

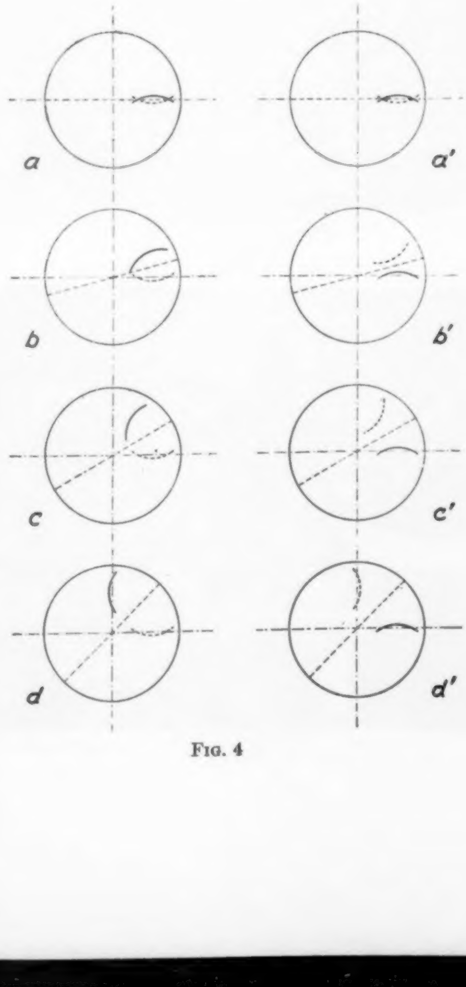

FIG. 4

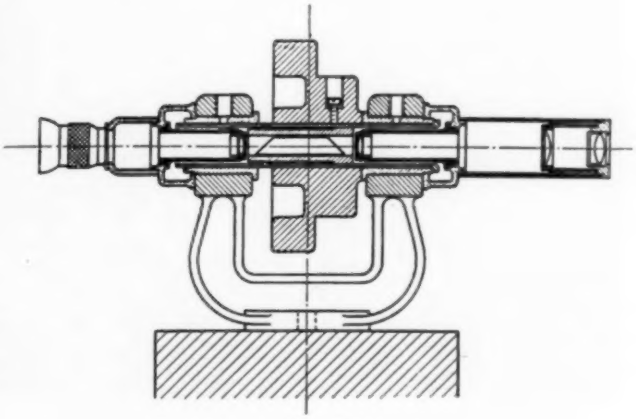

FIG. 5

Theoretically both the camera and the rotoscope should have their optical axes coincide with the prolonged axis of rotation of the impeller, but, when necessary, the position of the rotoscope may be altered slightly, as shown in Fig. 7, without excessive blurring of the image taking place. In this way the impeller could be observed through the rotoscope while the pump discharge was being adjusted. When the proper flow conditions were obtained the camera was set in motion and the shutter tripped at the critical instant to record the particular phenomenon under observation.

The flow conditions in the impeller were made visible by injecting a special dark-colored dye into the water at several points. The dye was brought into the impeller through a brass pipe, 5 mm in diameter, as far as the glass plate. From there two branch pipes, each 2 mm in diameter, carried the dye in one case to the inner nose of one of the blades, as shown at *B* in Fig. 10, and in the other case to about the middle of the high-pressure side of another blade, as shown at *C* in Fig. 18. In order to make sure that these branch pipes did not cause unexpected disturbances in the flow, the inner nose of one of the blades was equipped with three 0.5-mm (0.02-in.) holes, shown at *A* in Fig. 10, which were connected to the nearest attachment bolt for the glass shroud by a canal cut in the interior of the blade. This particular attachment bolt was made hollow and the dye brought to it through a rubber tube from the central supply pipe, outside the glass shroud. A further precaution was taken while injecting the coloring material to apply only enough pressure to get the dye into the water so that disturbances in the flow conditions would not be caused by too high an injection velocity.

III—RESULTS OF THE EXPERIMENTS

According to the researches made by Oertli,[5] the flow in a centrifugal impeller is not exactly two-dimensional, but the flow along the blades at mid-depth will be sufficiently characteristic of the total flow as long as the operating conditions do not vary

---

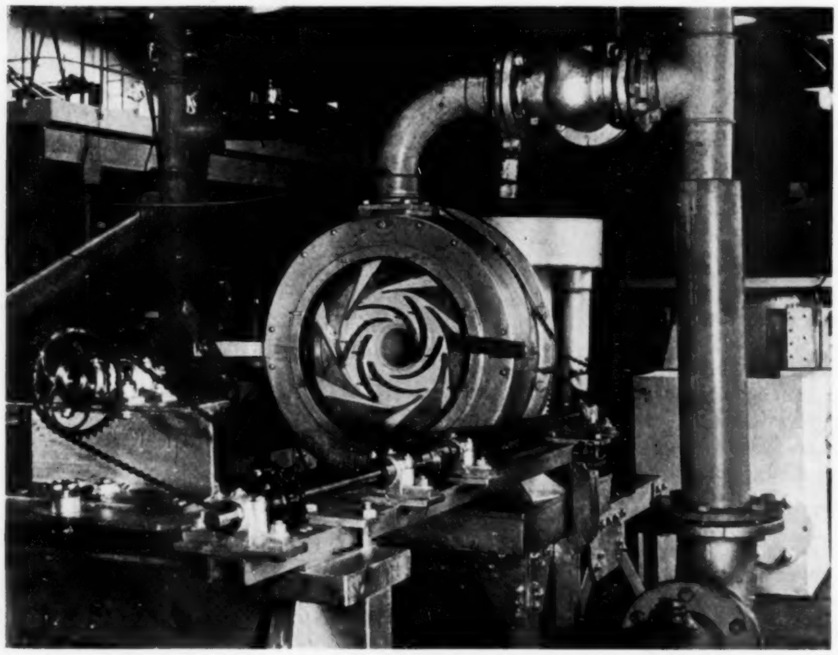

Fig. 6

too widely from their normal value. Accordingly, the points of injection of the coloring material were located at the mid-depth of the respective blades.

Flow Conditions at Entrance to Impeller

It was necessary in this case to consider the absolute flow conditions in order to determine the error in assuming radial entrance flow in impeller design. Neither the rotoscope nor the rotating camera was necessary for this purpose, and direct observation was more desirable. Figs. 11–15 show five different entrance-flow conditions, the data for which are listed in Table 1. It was impossible to detect any difference in the flow phenomena above a speed of 350 rpm.

It will be seen in these photographs that the variations from radial entrance flow are confined within narrow limits. Prerotation of the water is noticeable only at very small discharges (Figs. 14 and 15). The chief cause of this is the reverse flow from the water passages of the impeller, and to a lesser extent the increase in the relative frictional effects at small discharges. It will be shown later that below a certain critical discharge a definite reverse flow takes place in the water passages of the im-

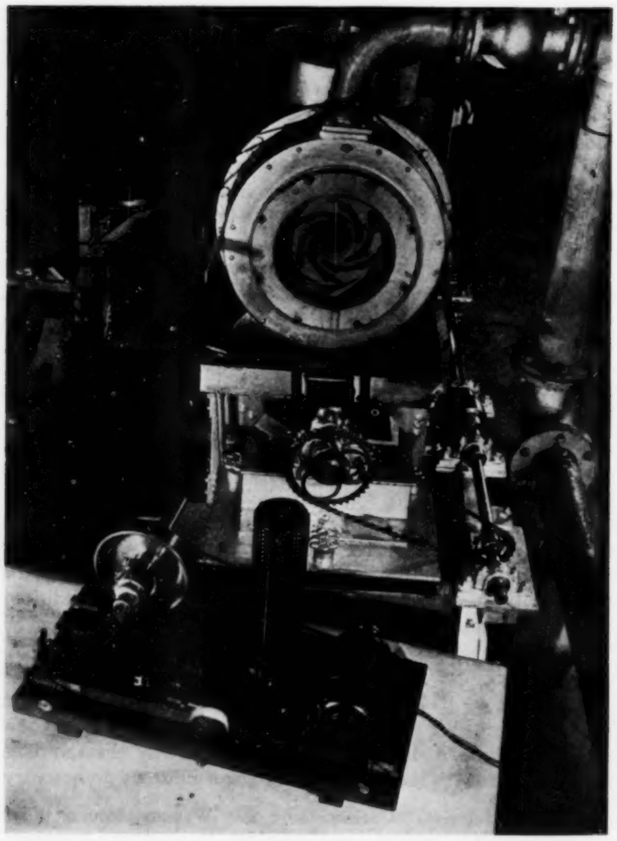

Fig. 7

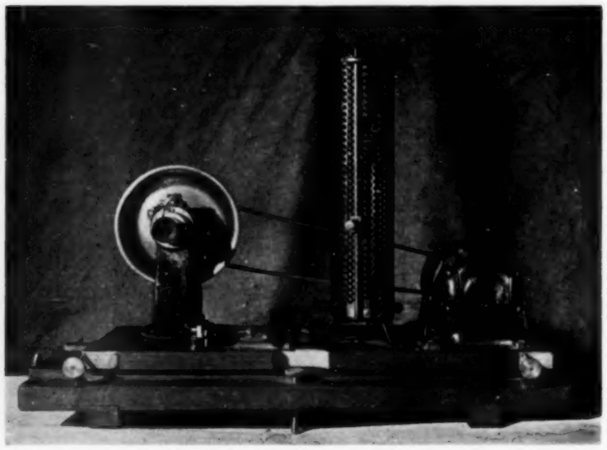

Fig. 8

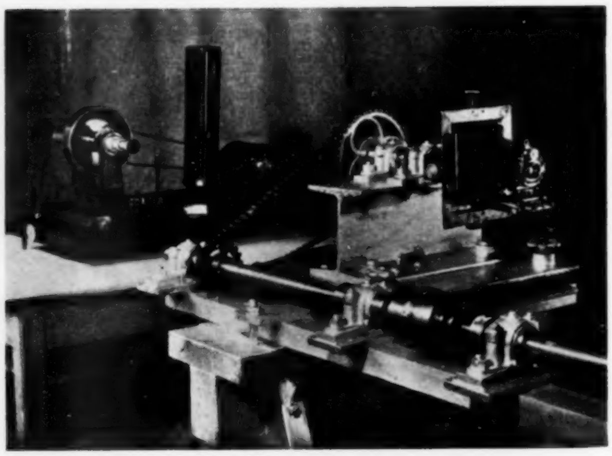

Fig. 9

peller (Fig. 21). It is sufficient here to state that below a critical discharge, reverse flow in some of the water passages takes place, that this flow is not stationary with respect to the impeller blades, and that its location in the impeller changes periodically. The water which flows inward from the impeller also has considerable energy of rotation, and as it mixes with the incoming water from the suction pipe, part of this rotation energy is given up, causing prerotation of the latter to take place. This mixing phenomenon, together with the variations in the reverse flow, causes a very uneven velocity distribution, as is clearly shown by the broken and complicated form of the dye streams in Figs. 14 and 15.

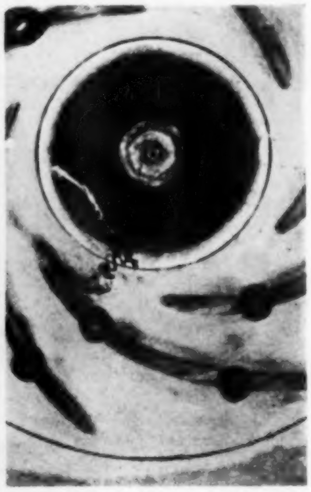

Fig. 15

Flow Conditions in the Water Passages of the Impeller

A great many theoretical investigations have been made in an attempt to solve the problem of the relative-flow conditions in rotating fluid passages. In analyzing the problem, the relative flow has generally been divided into two components, one a nonrotational component representing the flow through a stationary canal, and the other a constant rotational flow having the same angular velocity as the impeller. The resultant of the two components is supposed to give the actual flow. The advantage of this method is that the flow conditions may be easily computed for every speed and discharge. Kucharski[6] has made a strict mathematical derivation of the flow conditions in a rotating impeller having a finite number of straight blades which extend a finite distance radially outward from the axis of rotation, with the space between filled with an ideal fluid and neglecting friction. The fluid passages, formed by curved blades of a finite length and cut off by entrance and exit circles, as found in actual practice,

Flow Conditions in the Water Passages of the Impeller

A great many theoretical investigations have been made in an attempt to solve the problem of the relative-flow conditions in rotating fluid passages. In analyzing the problem, the relative flow has generally been divided into two components, one a nonrotational component representing the flow through a stationary canal, and the other a constant rotational flow having the same angular velocity as the impeller. The resultant of the two components is supposed to give the actual flow. The advantage of this method is that the flow conditions may be easily computed for every speed and discharge. Kucharski[6] has made a strict mathematical derivation of the flow conditions in a rotating impeller having a finite number of straight blades which extend a finite distance radially outward from the axis of rotation, with the space between filled with an ideal fluid and neglecting friction. The fluid passages, formed by curved blades of a finite length and cut off by entrance and exit circles, as found in actual practice,

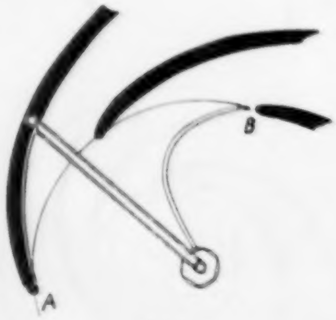

Fig. 10

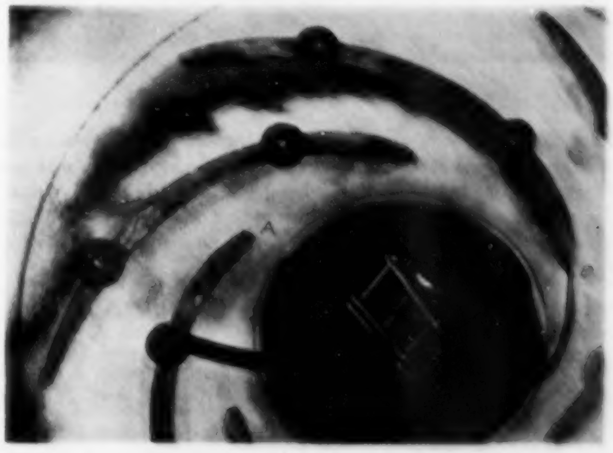

Fig. 16

---

[6] Kucharski, "Strömungen einer reibungsfreien Flüssigkeit bei Rotation fester Körper," Munich and Berlin, 1918.

present many difficulties to theoretical investigation.[7] Actually the flow conditions, especially at small discharges, are totally different from those theoretically deduced, due to the effects of friction and instability and the fact that the active flow breaks away from the faces of the blades. At no time in the research herein described were the water passages of the impeller completely filled with active flow.

Establishing the Border Between the Dead-Water Zones and the Active Flow

The flow conditions, as already described, were made visible by injecting a coloring material into the water at the points labeled *A*, *B*, and *C* in the accompanying illustrations, the injection point *A* giving the best results. At the beginning of a test the color was usually first injected from the tubes *B* and *C*, and Fig. 16 shows the location of one of the color streams along the inside of a blade shortly after the admission of the dye.

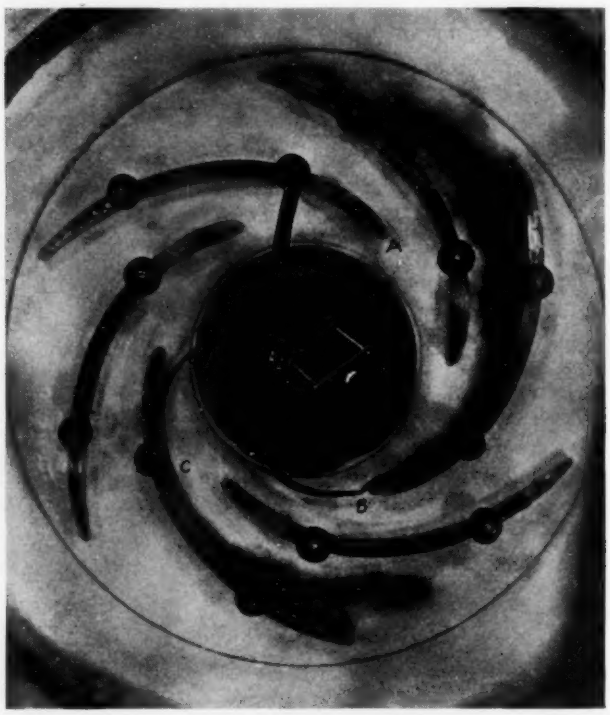

Fig. 18

The dye slowly collected in the dead-water zones as shown in Fig. 18. Except at small discharges there was a rather definite line of demarcation between the dead-water zones and the active flow. In any case, however, the water which may have been discharged through the dead zones was but an insignificant portion of the total flow.

Flow for Different Values of the Ratio Q/Q_{normal}

(*a*) ***Flow at Discharges Below Normal*** ($Q/Q_{\text{normal}} < 1$). If the value of the ratio (Q/Q_{normal}) was lowered below a certain limit the flow conditions were characterized by two different criteria:

1 The outward flow was no longer stable and varying conditions of reverse flow appeared

2 At any given time different flow conditions were to be found in the different water passages.

The following examples show how the change from stable flow to pulsating flow takes place:

Fig. 17 shows the absolute flow conditions in one of the water passages as determined by observations on the relative flow conditions with the rotoscope for

n = 252 rpm; Q = 2.46 liters per sec (39.0 gpm);
Q/Q_{normal} = 0.47; H = 0.75 m (2.46 ft)

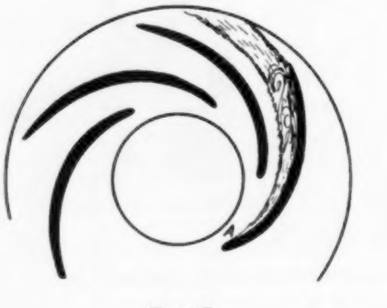

Fig. 17

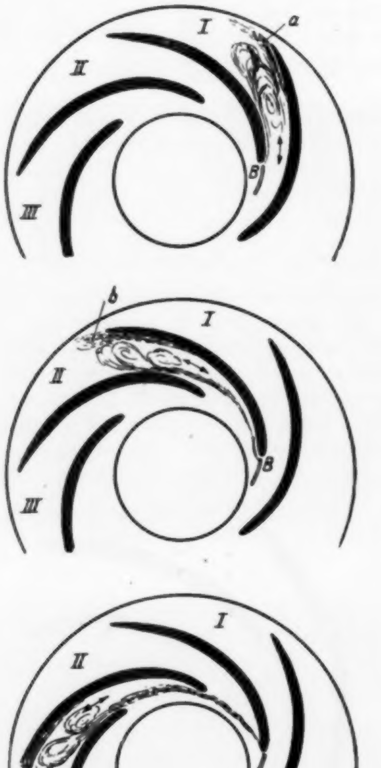

Fig. 19

No difference between the flow conditions in the various water passages could be determined for this speed and discharge. More than half the water passage is, however, taken up by the dead-water zones composed of whirls and eddies, while the active flow occupies only a narrow strip along the high-pressure side of the blade. For the photograph, Fig. 16, the operating conditions were:

---

[7] Spannhake, "Hydraulische Probleme," Mitteilungen des Instituts für Strömungsmaschinen der Technischen Hochschule Karlsruhe, Heft 1, 1930.

$n = 250$ rpm; $Q = 2.79$ liters per sec (44.2 gpm);
$Q/Q_{\text{normal}} = 0.53$; $H = 0.77$ m (2.52 ft)

which corresponds closely to the case just mentioned.

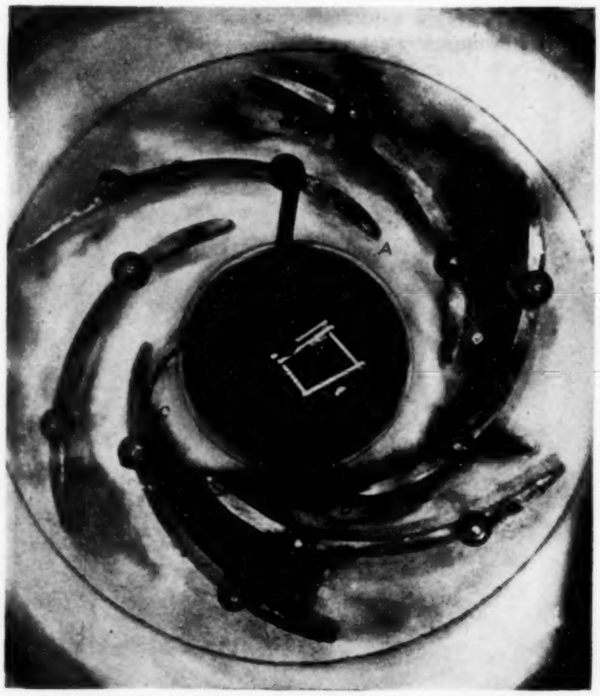

Fig. 20

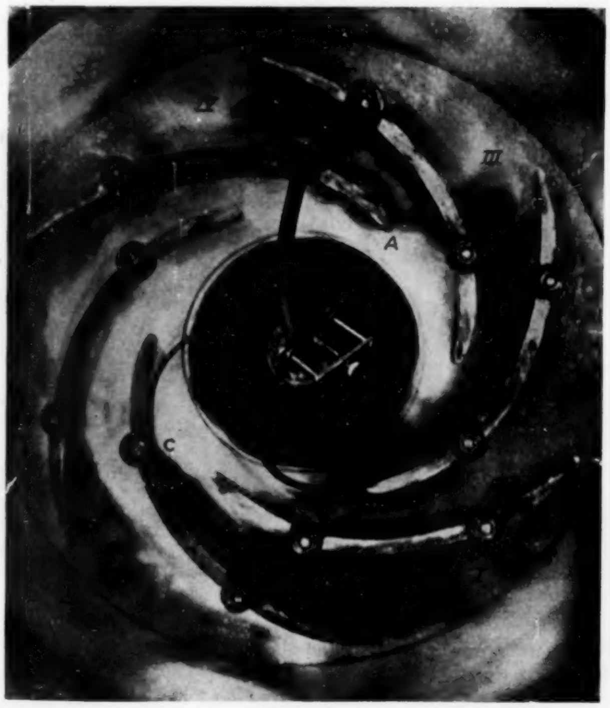

Fig. 21

If the discharge is now decreased considerably a rather uniform pulsating flow appears which has a definitely timed cycle, and the previous uniform flow conditions in the different water passages disappear. This phenomenon is undoubtedly brought about by the impeller blades themselves. The water passages are now almost entirely filled with dead water which surges back and forth parallel to the blades with a periodic motion. These conditions are always such that outward flow is taking place in some passages while there is inward flow in others. Some of the inward flow crosses the entrance circle, and instead of returning to the same passage it enters the second or third passage beyond. In all probability the water delivered by the impeller is forced out across the exit circle by this periodic swinging motion taking place in the space between the blades.

An example of the phenomena taking place during one period is illustrated in Fig. 19 for

$n = 240$ rpm; $Q = 1.038$ liters per sec (16.46 gpm);
$Q/Q_{\text{normal}} = 0.206$; $H = 0.79$ m (2.59 ft)

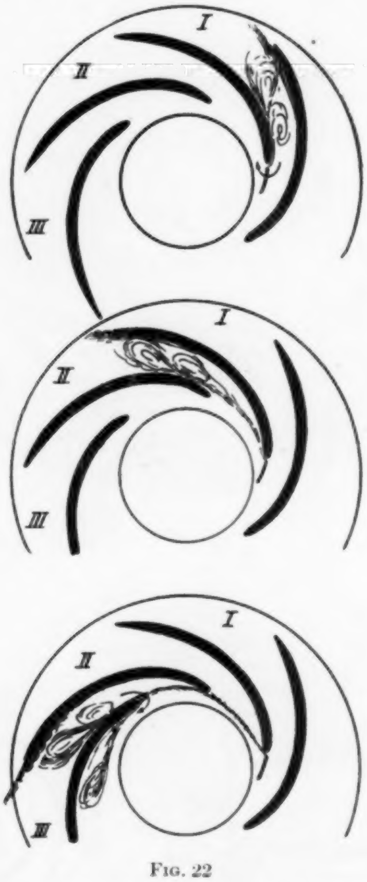

Fig. 22

At the beginning of a period the color was injected from the tube B and entered water passage I (Fig. 19, Condition 1). It flowed closely along the pressure side of the blade and then gradually broke away to form eddies which filled the entire breadth of the passage. This required only a small fraction of a second, but the eddies remained surging back and forth in the passage for a relatively long period of time, and at the point a it was noted that the color was always slowly breaking away from the blade. Meanwhile an outward flow took place in passage II about a third to a quarter of a second after the beginning of the period, and the dye stream entering this passage revealed eddies nearly filling the space between the blades as shown in Fig. 19, Condition 2. As before, the eddies surged back and forth, with the color leaving the blade at the point b. The end of the outward flow in passage II was indicated by the sudden entrance of the dye stream in III, where exactly the same phenomena as in passages I and II took place (Fig. 19, Cond. 3). This marked the end of one period, the duration of which was from 5 to 7 revolutions of the impeller or about 1.5 sec.

Figs. 20 and 21 require no further explanation. The reverse flow in passages I and IV and the outward flow in passage III are clearly visible. Fig. 22 was constructed for

$$n = 243 \text{ rpm};\ Q = 0.133 \text{ liter per sec } (2.12 \text{ gpm});$$
$$Q/Q_{\text{normal}} = 0.025;\ H = 0.812 \text{ m } (2.66 \text{ ft})$$

The irregularities in the flow became clearer as the violence of the back-and-forth surges of the eddies increased.

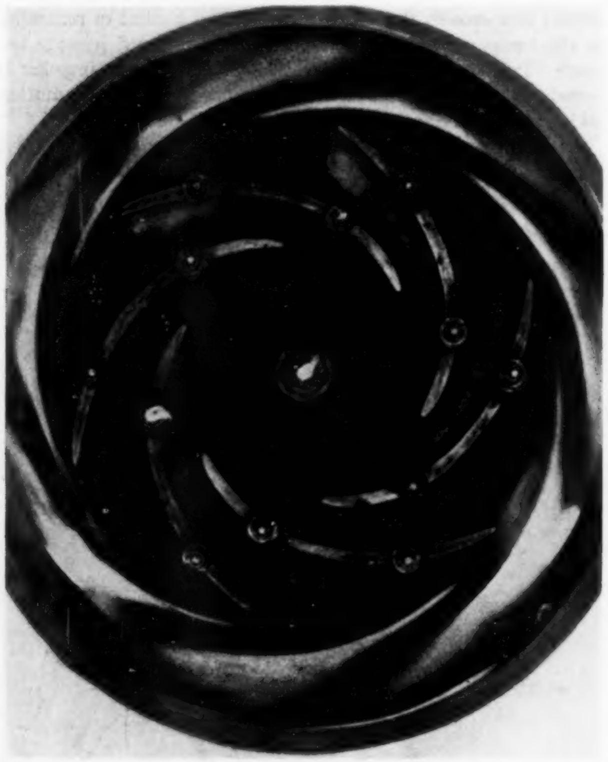

Fig. 23

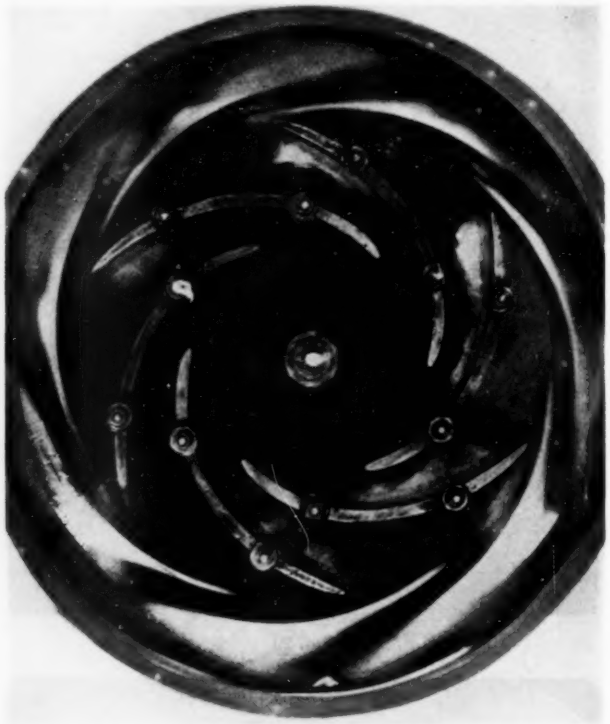

Fig. 24

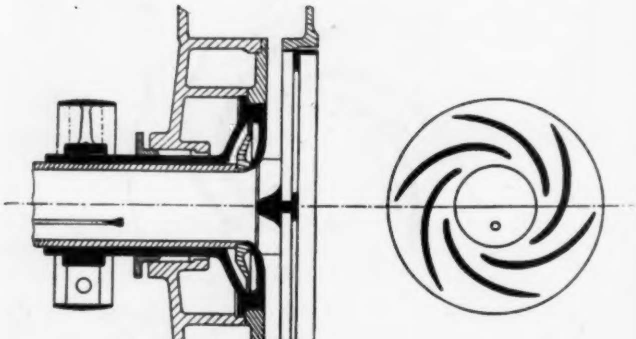

Fig. 25

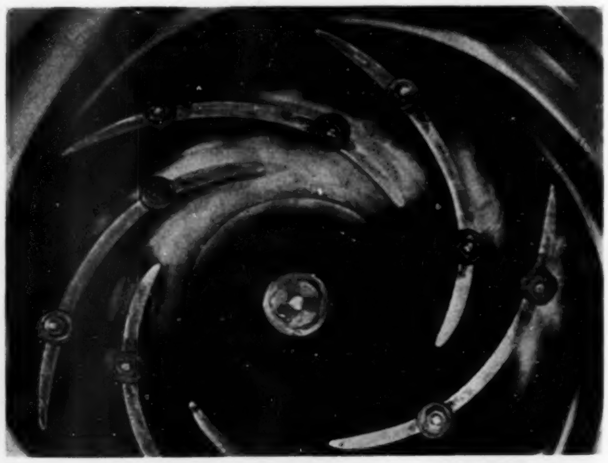

Fig. 26

In connection with the description of the flow conditions by different discharges below the normal value (9.40 liters per sec = 149 gpm), some additional photographs have been included for which a different coloring system was used to show the flow phenomena. To obtain these photographs the pump was started with clear water and then the dye was suddenly forced into the suction pipe through a quick-opening valve. In this way it was possible to completely color a slug of water in the suction pipe and photograph it as it flowed through the impeller. In Figs. 23 and 24 the active flow is shown by the black portion, while the dead-water zones on the low-pressure sides of the blades remain filled with clear water.

This method could not be used with discharges as large or larger than half the normal value because the color spread too rapidly due to increased turbulence in the flow. To prevent this a horizontal partition was placed in the suction pipe and the dye inlet located in the lower half as shown in Fig. 25. With this arrangement only half of the water was colored, so that the blades passed alternately from the colored to the clear water. The dye remained in the dead-water zones, which appear black in the upper half of Fig. 26 ($Q/Q_{\text{normal}} = 0.47$), and the active flow is shown by the white areas.

(*b*) ***Flow at Normal Discharge*** ($Q/Q_{\text{normal}} \cong 1$). Fig. 27 shows the flow conditions for

$$n = 400 \text{ rpm};\ Q = 8.86 \text{ liters per sec } (140.5 \text{ gpm});$$
$$Q/Q_{\text{normal}} = 1.06;\ H = 1.41 \text{ m } (4.63 \text{ ft})$$

Here, for the first time, a favorable flow condition with negligible entrance shock appears, as shown by the dye streams injected at points *A* and *B*. (The mouth of the tube *B* was in the center line of the blade produced.) At exit from the impeller the conditions are still somewhat unsatisfactory since the dead-water zones on the low-pressure side of the blades (shown black at *Z-Z*) fills about one-third of the width of the water passage and consequently causes almost a 50 per cent increase in the velocity of the active flow. These dead-water zones reduce the actual exit angle from 28 deg (blade angle) to about 20.5 deg. Scarcely any separation of the flow from the high-pressure faces of the blades could be detected under these conditions.

(*c*) ***Flow at Discharges Above Normal*** ($Q/Q_{\text{normal}} > 1$). In Fig. 28 the conditions are

$$n = 400 \text{ rpm};\ Q = 14.30 \text{ liters per sec. } (227 \text{ gpm});$$
$$Q/Q_{\text{normal}} = 1.71;\ H = 0.61 \text{ m } (2.00 \text{ ft})$$

The water enters the impeller at an angle greater than the blade entrance angle as shown by the path of the dye stream injected at *B*. The dead-water zone on the low-pressure side of the blade is somewhat smaller than under normal conditions (about $^1/_4$ the width of the passage at *Z-Z* as against $^1/_3$ for normal conditions), while on the high-pressure side of the blade a breaking away of the active flow and resultant dead-water formation are clearly visible.

RELATION BETWEEN THE DEAD-WATER ZONES ON THE LOW- AND HIGH-PRESSURE SIDES OF THE BLADES FOR DIFFERENT DISCHARGES

The results of the investigations show that dead-water zones form on the low-pressure sides of the blades for all discharge conditions. These zones increase in size as the discharge is decreased from above normal to very subnormal conditions, and at the same time the points at which the water leaves the blades move toward the entrance edges.

On the high-pressure sides of the blades the reverse phenomena take place, viz., the dead-water zones are larger and the points of separation of the water from the blades nearer the entrance edges under above normal than they are under normal, and below normal conditions when the dead-water zones (at normal speed) disappear entirely and the water follows the blades throughout their length.

In order to give a clearer idea of the relative extent of the dead-water zones and their location in the water passages, Fig. 29 has been constructed with data obtained from photographs of the flow conditions for different values of head, speed, and discharge. It should be borne in mind that it was very difficult to locate an absolutely definite boundary between the active and dead-water zones for most of the flow conditions investigated, the mixing between the two zones being much more noticeable at small discharges. Fig. 29 also shows that for the four pump speeds investigated the width of the zone of active flow (except at very small discharges) always remained practically constant from entrance to exit. When the dead-water zone disappeared from the pressure side of the blade, the opposite dead-water boundary remained almost parallel to the blade's curvature.

H = 0.6648 m = 2.18 ft

Q = 4.15 lps = 65.8 gpm
H = 1.071 m = 3.51 ft

Q = 4.06 lps = 64.4 gpm
H = 2.022 m = 6.63 ft

Q = 4.00 lps = 63.4 gpm
H = 2.440 m = 8.00 ft

FIG. 29 (lps = liters per second)

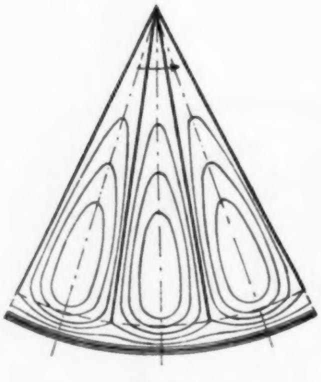

FIG. 30

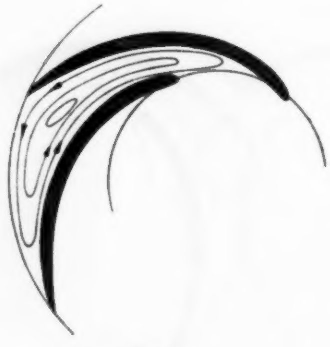

FIG. 31

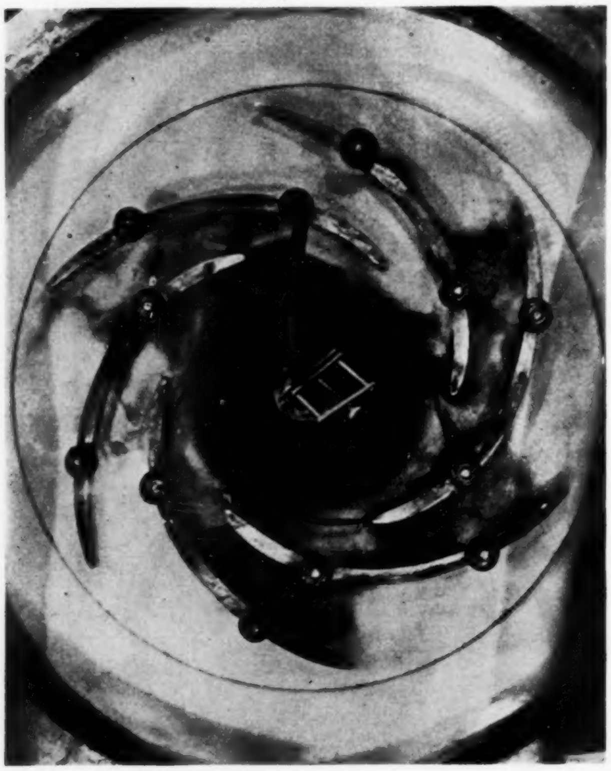

FIG. 32

flow through the fluid passages and (2) pure rotational flow with the angular velocity of the canal eddy = $-\omega$, the general character of the resultant flow will be governed at small discharges almost entirely by component (2), with component (1) gaining influence as the discharge is increased.

PURE ROTATIONAL FLOW ($Q \cong 0$)

For pure rotational flow ($Q = 0$) between straight blades of a finite length extending radially outward from the axis of rotation and neglecting friction, Kucharski derived theoretically the flow conditions shown in Fig. 30. If these conditions are applied to a curved passage the result is as shown in Fig. 31, wherein the fluid flows in a closed path around a stationary nucleus. A comparison of this condition with the actual phenomena where friction exists shows a fundamental change in the flow conditions. As seen in Fig. 32, the main negative eddy is broken up into a series of continually changing smaller eddies having no relation to the original. The results of these investigations show, as was expected, that the friction effects predominate if the pump discharge is zero, whereby the flow through the impeller is only enough to supply the leakage losses.

RADIAL-FLOW CONDITIONS AT SMALL DISCHARGES

By making the same assumptions as for pure rotational flow, Kucharski constructed the diagram shown in Fig. 34 which, transcribed for a curved passage, appears in Fig. 35. For small values of Q/Q_{normal} the rotational eddy overcomes the effect of radial flow to such an extent that reverse flow may be expected to take place along the high-pressure side of the blade. There is no apparent reason why the flow of a frictionless fluid should show continually changing conditions in the different fluid passages; it would more probably show the same constant flow conditions in all passages as long as the working conditions of the pump remained unchanged.

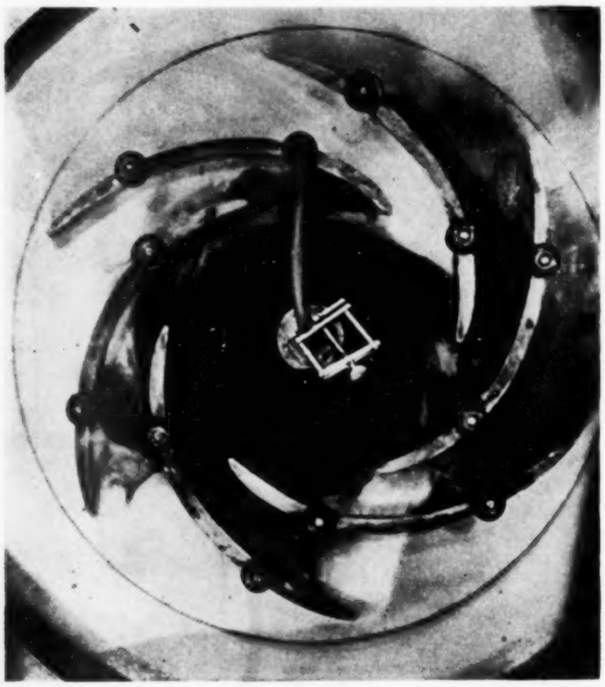

FIG. 33

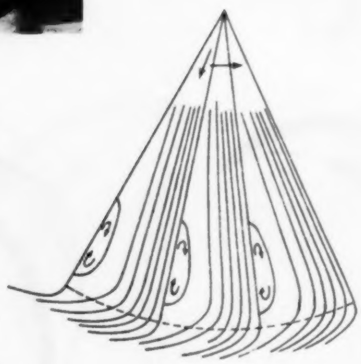

FIG. 34

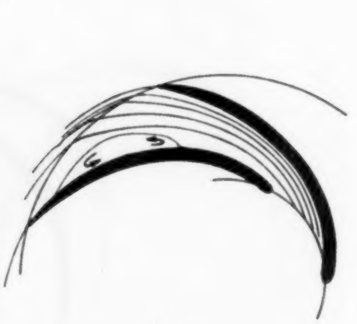

FIG. 35

The actual phenomenon is shown in Fig. 17; the discharge was reduced to a point where reverse flow would be expected with a frictionless fluid, but is still large enough to insure steady flow conditions in all passages. The figure shows that (1) no reverse flow exists, and (2) that a considerable dead-water zone builds up on the low-pressure side of the blade.

V—EFFECT OF THE DEAD-WATER ZONES ON THE ACTUAL TOTAL HEAD

The phenomena already described offer the following explanation for the reduction in the power required by the impeller.

The equation for the theoretical head delivered by an impeller having an infinite number of blades and radial flow at entrance [Fig. 36(*a*)] is

$$H_{\text{theoretical}} = (c_{2u} \times u_2)/g$$

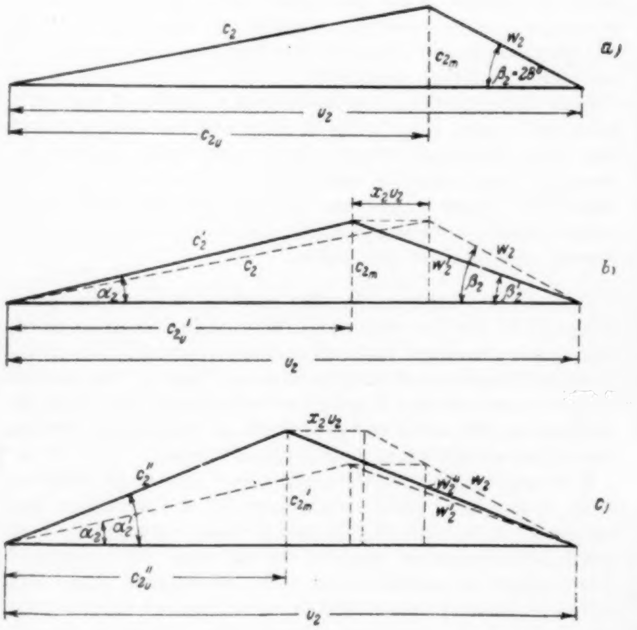

Fig. 36

Fig. 36(*b*) shows the average exit-velocity triangle for a finite number of blades and considering that the space between them is completely filled with active flow, as given by Pfleiderer.[3] The diagram is qualitatively correct as shown by the actual entrance- and exit-velocity distributions in Fig. 37, where the dye streams of passages *A* and *B* have been redrawn in passage *C*. In the same period of time the particles *P* and *Q* move the distances *P-P″* and *Q-Q″*, respectively. Since *P-P″* is much longer than *Q-Q″*, the higher velocity must be on the low-pressure side of the blade. Consequently the average relative velocity at exit is increased and the actual exit angle decreased, both of which cause a reduction in the power required by the impeller.

The fact that the water passages are almost never completely filled with active flow causes a still further increase in the average relative velocity at exit and consequent reduction of the actual total head as shown by Fig. 36 (*c*).

VI—INFLUENCE OF THE INCREASED MERIDIONAL VELOCITY c'_{2m} ON THE SIZE OF THE ENTRANCE ANGLE OF THE GUIDE VANES

The theoretical path of any water particle leaving the impeller is a logarithmic spiral, provided the width of the water passages remains constant. The difference between the angles α and α' is shown in Fig. 36; the tangent of α', which is the actual angle at which the water enters the guide vanes, is given by

$$\tan \alpha' = c'_{2m}/c_{2u}$$

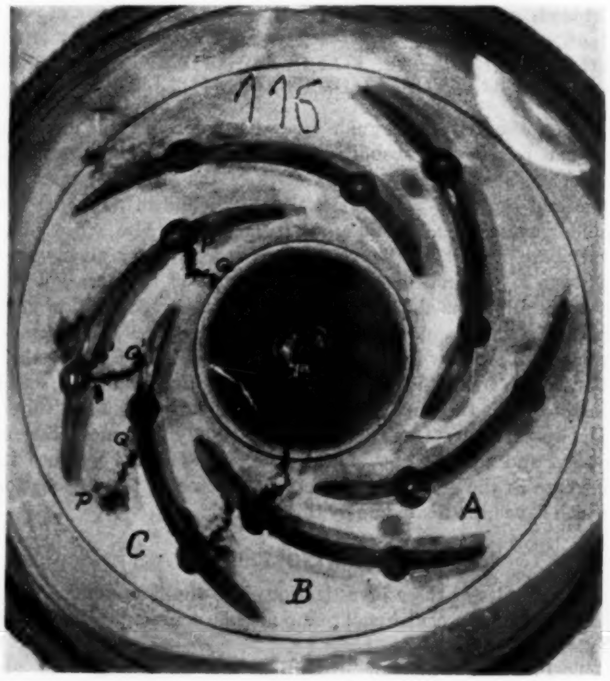

Fig. 37

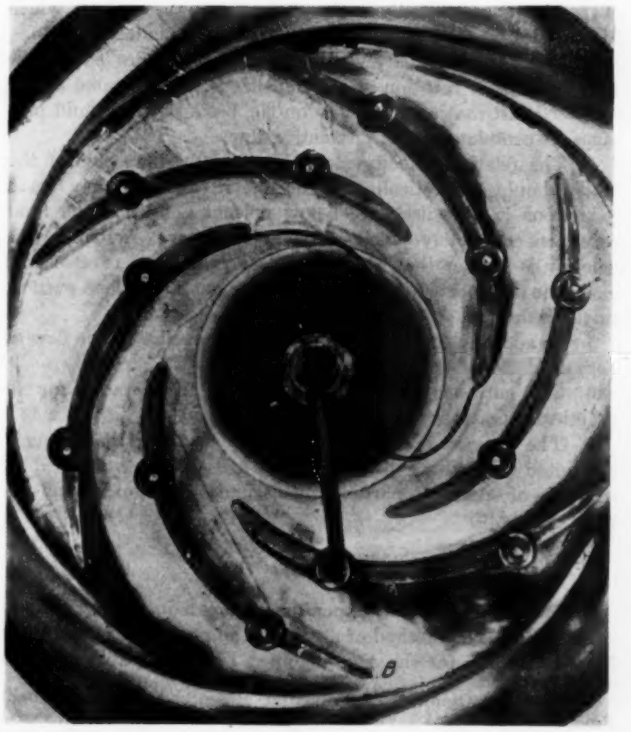

Fig. 38

---

[3] C. Pfleiderer, "Die Kreiselpumpen," Berlin, 1924, p. 89 et seq.

The presence of dead-water zones along the blades causes an increase of c'_{2m} over c_{2m}, and consequently an increase in α', so that if the vanes are constructed with the entrance angle equal to α there will be a shock loss in the active flow at entrance. A redistribution of the velocities must take place in the space between the impeller blades and the guide vanes if this loss is to be avoided.

VII—INFLUENCE OF FIXED GUIDE VANES ON THE RELATIVE FLOW IN THE IMPELLER

The presence of fixed guide vanes has a considerable influence on the relative-flow conditions in the impeller and causes a pulsating flow in the water passages of the latter. Neglecting this and the dead-water zones usually results in designing the guide vanes with too small an entrance angle. Also, when guide vanes are present, the flow conditions at exit from a given water passage in the impeller at a given instant of time are not the same at all points along the exit circle. In Fig. 38 the flow at *A* is restricted to a narrow passage, which produces shock losses, while at *B* the flow is practically unhindered. All the investigations made with guide vanes showed an entirely different set of conditions in the impeller from those made without the vanes. The research by Omori[9] showed that only the most careful design and construction of the guide vanes would produce an increase in the efficiency of the pump, some of the reasons for which have been cleared up by this research.

VIII—CONCLUSIONS

The results of these investigations into the flow conditions in the impeller of a centrifugal pump may be summarized briefly as follows:

1 Practically all flow conditions for an actual fluid are fundamentally different from those theoretically derived for an ideal frictionless fluid.

2 The dead-water zones which form on the low-pressure sides of the blades undoubtedly cause a reduction in the angle at which the fluid leaves the blades (β'_2) from the actual blade angle (β_2).

3 The actual velocity distribution along circles concentric with the axis of rotation of the impeller is not the same as the supposed distribution computed on the basis that the fluid passages are completely filled with active flow.

4 The relative velocity along the high-pressure side of the blade should theoretically approach zero for relatively small reductions in the discharge below normal and with the fluid passages completely filled with active flow. Actually this velocity is greater than the theoretical value, and reverse flow along the pressure side of the blade does not take place even at small discharges.

5 In addition to (4), it was definitely proved that the flow at very small discharges is no longer stable.

6 The entrance flow may be assumed to be radial for all practical operating conditions.

7 The increase in the meridional velocity over the ordinary computed value alters the shape of the exit triangle considerably, which is of special importance in designing the guide-vane entrance angle.

Discussion

R. W. Angus.[10] The paper describes an ingenious method of research. The method of studying the problem of pump flow is most helpful, for the experimenters have been able to make any experiments desired and then photograph the results by a relatively stationary camera just at the most desirable instant.

The experiments show that the impeller is rarely filled with water, and that as the discharge varies, the water area decreases instead of the relative velocity. There is also included the statement that the angle of flow of the water at exit is different from the blade angle, which has frequently been assumed in pump theory. The problem still left to be solved is how to find the exact depth of water in the impeller beforehand for given head and discharge. Is there any way of predicting what will happen before the pump is built?

The authors' experiments were made at several speeds, and taking those shown at Fig. 29, the pump would appear to have a rather unusual shape of head-discharge curve, and the maximum head was always low, the probable limitation in this respect being the strength of the glass-sided pump. Is it possible that in a larger pump, or even in a pump of this same size operating at higher speeds and pressures, the flow conditions would seriously differ from those described?

Some years ago the writer carried out a number of tests on a pump with radial guide vanes at entry and was unable to find that these had much effect, which agrees with the authors' conclusion that entry is radial under all ordinary operating conditions. There is, however, evidence that the water in the suction pipes of some pumps whirls, and this must be true at the impeller entry in these same pumps.

Carroll F. Merriam.[11] The authors' conclusions point distinctly to the fact that water does not behave as assumed, and we may conclude that pump designers should now be encouraged to make use of the facts as demonstrated. The question may be asked whether it would be advantageous to fill in the dead spaces with metal and thus break up the parasitic circulation of flow which tends to result in loss of efficiency.

It is unfortunate that the authors were limited to comparatively low speeds, since certain parts of the apparatus had necessarily to be made of glass, which would not stand the high speeds of a commercial pump of the size used. It is suggested that it might be possible to use such a commercial pump with bull's-eye windows which might be viewed through the rotoscope supplemented by some form of stroboscope. Such an investigation might throw light as to whether the conditions in a high-speed pump are correctly similated in the low-speed laboratory model used by the authors. It would certainly be desirable to know whether the dead spaces shown to exist in the laboratory are still present in pumps of commercial design.

Authors' Closure

The views advanced in the discussion must be appreciated as valuable contributions to the problem. No claim is made by the authors that the investigations described in the paper present a perfect and final knowledge of the flow in centrifugal pumps, which has been shown to be very complex.

As Professor Angus has pointed out, a problem still to be solved is that of finding the exact depth of the actual flow through the impeller, and of predicting, before the pump has been constructed, what is likely to occur. However, the authors hope that their experiments may be of service to designers in so far as they give a hint as to the changes that can be made in the shape of the runners to improve the efficiency of centrifugal pumps.

The change suggested by Mr. Merriam is one which deserves close consideration. The actual effect of such a change will of course have to be determined by tests in which the power input can be measured. The relatively large influence of bearing friction rendered this measurement impossible with the experimental pump.

[10] Professor of Mechanical Engineering, University of Toronto, Toronto, Ont., Canada. Mem. A.S.M.E.

[11] Pennsylvania Water and Power Company, Baltimore, Md. Mem. A.S.M.E.

The question as to whether the flow, in the case of a larger pump or one of the same size operating at higher speeds, or, again, of a commercial pump, would not seriously differ from that described, certainly deserves investigation by tests on a suitable pump, which could be designed in accordance with the suggestions made by Mr. Merriam. In the opinion of the authors it is probable that the flow, in these pumps also, has the peculiarities revealed by the small experimental pump, but of course only up to the limit of cavitation, which, as is well known, seriously affects the flow.

The interesting fact that, as observed by Professor Angus, the water in the suction pipes of certain pumps is liable to whirl, may be explained by the fact that the reverse flow, which takes place in some of the water passages of the impeller, mixes with the incoming stream in the suction pipe. This effect has been observed in the experimental pump and has been described on page 5 of the paper.—D. THOMA.

Lignum-Vitae Bearings for Roll Necks of Medium-Sized Rolling Mills

By K. W. Atwater,[1] Chicago, Ill.

The performance of metal roll-neck bearings is frequently unsatisfactory, particularly with regard to rapidity of wear and excessive power loss in friction. Roller bearings, although free from these disadvantages, are comparatively expensive, and are limited in applicability because of their space requirements. These circumstances provide a definite field of usefulness for bearings made of very hard wood. Tests of various species of lignum-vitae and of different methods of cutting bearings from the log have indicated specifications under which satisfactory lignum-vitae bearings can be produced. Bearings produced according to these specifications are used successfully in a great many rolling mills and can be lubricated adequately by means of water sprays. With such lubrication, the rate of wear and the power loss in friction are considerably lower than those of metal bearings lubricated with oil or grease. In some rolling mills the use of this type of bearing has effected power saving as high as 25 per cent in comparison with metal bearings. Tests have also shown that their life in certain cases is 15 times as long as that of metal bearings. Experience has indicated that the best results with such bearings can be obtained by polishing the roll necks before installation in the mill.

THE selection of suitable roll-neck bearings for small- and medium-sized rolling mills, such as rod, merchant, skelp, strip, hoop, and sheet-bar mills, has been a rather formidable problem. Difficulties have frequently been encountered in the use of metal roll-neck bearings, for the reason that such bearings are not easily lubricated. Lubricants which lack a natural affinity for metals are washed off the bearing surface by the water which is applied to cool the neck and bearing. The use of lubricants containing fatty acids, which have a natural affinity for metals, or of systems of forced or pressure lubrication, might be expected to lubricate metal bearings adequately, but the constant presence of foreign matter remains as an obstacle to efficient bearing operation. Under these circumstances it has become almost a tradition that the performance of metal roll-neck bearings is marked by rapid wear, short life, and excessive power losses in friction.

In some cases these difficulties can be overcome by the use of anti-friction bearings, which must always be adequately lubricated, and which are always so constructed as to retain the lubricant and to exclude water and foreign matter. Because of their space requirements, however, anti-friction bearings cannot easily be applied to small- and medium-sized rolling mills. Moreover, since the satisfactory performance of anti-friction bearings depends upon careful selection of materials, painstaking care in manufacture, and thorough inspection, such bearings are often rather expensive. These circumstances provided a definite field of usefulness for roll-neck bearings made of very hard wood.

Wooden roll-neck bearings were first introduced in Germany during the World War, as a result of the fact that wood, unlike metals, was not seized in transit as a contraband of war. Experiments with oak bearings indicated that oak was by no means hard enough for this purpose. Lignum-vitae bearings, because of the resin content, great density of grain, and extreme hardness of this wood, were found to be fairly satisfactory.

The successful use of lignum-vitae roll-neck bearings was not immediate, however. It has been found that the numerous species of lignum-vitae, which differ principally in density of grain, resin content, and specific gravity, are not all equally suitable for use in roll-neck bearings. Experience has also shown that the method of cutting bearings from lignum-vitae logs has a considerable effect upon bearing performance. By means of extensive investigation, the species of lignum-vitae having the greatest specific gravity and certain definite methods of cutting bearings from the log have been selected to provide the most satisfactory bearing performance. Lignum-vitae bearings which are constructed according to these specifications are called "millwright" bearings.

A characteristic feature of these bearings is the grain edge on each wearing surface. This feature is desirable in the respect that it provides the maximum resistance to wear and is secured by an oblique method of cutting. The surface which receives end thrust, as well as the principal bearing surface, is provided with edge grain. In some cases the lignum-vitae log is not large enough to permit the construction of a large bearing in a single piece. In such cases, the bearing is made up of small pieces. The separate parts are then doweled together to form the completed bearing.

Although the selected species of lignum-vitae approaches uniformity more nearly than other varieties of wood, it is nevertheless subject to variations in hardness, grain density, and specific gravity. For this reason, experiments are being made with a modified method of construction which is intended to produce bearings of uniform performance in spite of the non-uniformity of the material. The essential feature of this method is the construction of each bearing from several pieces of lignum-vitae, each of which has been cut from a different log, with edge grain running in a different direction. Although this modification is still in the experimental stage, it appears to hold considerable promise of success.

Roll-neck bearings of lignum-vitae are not subject to the disadvantages of metal bearings. They can be lubricated adequately by means of water sprays, which serve simultaneously to cool the bearing and the roll neck. With water lubrication, the rate of wear and the power losses in friction are considerably

[1] Mechanical Engineer, H. A. Brassert & Co. Mr. Atwater's early engineering experience was received with the Demag Corporation, Duisburg, Germany. From 1914 to 1916 he superintended erection of floating cranes on the Panama Canal. From 1916 to 1922 he was designing engineer, estimator, and division engineer of Heyl & Patterson, contracting engineers, Pittsburgh, Pa., and for the five years following was consulting engineer in Pittsburgh and resident engineer of the Demag Corporation. Since 1928 he has been employed by H. A. Brassert & Co., engineers, in general engineering work.

Contributed by the Iron and Steel Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

lower than those of metal bearings lubricated with oil or grease. The operating efficiency, including consideration of initial cost, life, tonnage rolled, cost of maintenance, and continuity of operation, is very much higher than that of metal bearings.

These statements are based upon the results which have been obtained through the use of such bearings in a great many rolling mills. The following specific data may be of interest in this connection.

The average life of metal roll-neck bearings on an 18-in. continuous-strip mill was about 80 hr. running time. Lignum-vitae bearings on the same mill, measured after 672 hr. running time, showed $^3/_8$ in. of wear on the bearing surface. On certain finishing stands of a mill in the Chicago district, where metal bearings had to be replaced every three or four weeks, lignum-vitae bearings served for 13 months without replacement. Power savings as high as 23 per cent, in comparison with metal bearings, are not infrequent. It has been reported that in the hot-strip mill of the Riverdale works of the Acme Steel Company the use of these bearings effected a power saving of 40 per cent in comparison with metal bearings. The operating efficiency, as previously described, exceeds that of metal bearings; frequently in the ratio of 10 to 1, and in one particular installation in the ratio of 17 to 1.

In the finishing stands of a continuous rod mill in the Pittsburgh district, it was observed that rather rapid wear of both the lignum-vitae bearings and the roll necks occurred immediately after installation, and continued until the roll necks had become highly polished, removing about $^1/_8$ in. of the material of the bearing. This condition having been attributed to the initial roughness of the roll-neck surface, the practice was adopted of buffing the roll necks before installation in the mill. The results of this practice were gratifying. The starting torque of the mill was reduced considerably, and the life of the bearings was lengthened by 50 per cent, which was 31 times the previous average life of metal bearings.

Present knowledge seems to indicate that the coefficient of friction and the accompanying power loss in friction approach closely to those of anti-friction bearings. It is certain that in many respects these bearings are more suitable than metal bearings for application to roll necks. It is therefore evident that they merit consideration in the selection of roll-neck bearings for small- and medium-sized rolling mills.

Discussion

C. G. Williams.[2] The author has made out a good account in savings for wood against metal bearings, but the writer would like to ask how he will rationalize his statements with experience derived from the actual use of lignum-vitae bearings in paper mills where an operating savings in power alone of 6 per cent has been shown by a change from lignum-vitae bearings to ball bearings and of 11 per cent by a change to tapered roller bearings, and a life of six years, with an apparent life of double that time. This is a business where, admittedly, machinery and bearings are on the whole a hundred years behind present practice and where pressures per square inch are but normal compared to pressures on rolling-mill machinery.

There is another item in the use of lignum-vitae bearings and that is lubrication or lack of lubrication. (The author states that lubrication is to be a spray of water.) Experiments with these bearings in woodworking machinery have shown that one can expect short life if the commonly used lubricants are put on these bearings. In a heavy-duty bandsaw (re-saw) lignum-vitae bearings lasted but three months, with oil as a lubricant. Babbitt bearings when substituted lasted nine months. Lignum-vitae bearings, again installed and lubricated with a stream of running water, lasted two years. The roller bearings have lasted eight years thus far.

In paper-mill machinery, lignum-vitae has been in the past a standard bearing. In one case where a bearing was renewed after a few months' wear, the firm stated that it used a common lubricating oil, which in this case was the cheapest that could be purchased. With this oil the bearing lasted but $2^1/_2$ months. The bearing was 26 in. long, and the shaft was 9 in. in diameter. The load was approximately 48,000 lb. The bearing had been designed for circulation of water inside the bearing and a flood of water over the entire surface of the bearing. The circulation holes had been plugged up and the bearing oil-lubricated. When refitted with lignum-vitae and the original plans of water lubrication carried out, the bearing lasted 18 months. Another lignum vitae bearing, 24 in. long, on an 8-in. shaft, water-lubricated, had a life of 27 months under a pressure of 37,000 lb., but the wear was about $^9/_{16}$ in. Can this amount of wear be tolerated in a bearing for a roll neck. The writer would consider it doubtful, from experience with this type of machinery. A substitution of roller bearings has lasted eight years, with a saving of 7 per cent in power.

There is another item of cost to the installation and use of lignum-vitae bearings that has been but slightly touched—that is, the cost of raw material and the waste that is encountered in cutting the log. Actual experience has shown that it costs double for material and four times for labor to install lignum-vitae over installing babbitt, and anti-friction bearings having the same load-carrying capacity can be installed in less space, though costing double to install, if length of service life is not considered.

While lignum-vitae bearings gave good service in cane crushers at a Louisiana sugar mill, their life was but two seasons. A rejuvenating of this machinery by using roller bearings gave a saving of 31 per cent in operating cost, and after 10 years there is promise of not less than 10 years' more wear.

There is a lowered cost in installation and in renewal of the lignum-vitae bearing, but what about the actual from day to day operating cost and life as against the life and operating cost of anti-friction bearings?

After years of experience in the use of lignum-vitae bearings in various types of machinery, these statements would seem to be too sanguine to convince operators.

Water-Lubricated Soft-Rubber Bearings

By W. F. BUSSE[1] and W. H. DENTON,[2] AKRON, OHIO

W. F. Busse

W. H. Denton

Rubber bearings lubricated with water are found to have remarkably low coefficients of friction and to give excellent service under many conditions. The softness of the rubber makes these bearings stand up in the presence of sand and grit, and it also makes the laws of lubrication governing these bearings differ from the classical laws worked out by Reynolds and others for cylindrical metal bearings.

This paper gives a comparison of the frictions of rubber and metal bearings lubricated with water at various loads and speeds. Metal bearings have the lower static coefficient of friction, but the coefficient of running friction is usually lower for rubber bearings. The difference in favor of rubber bearings increases as the load increases, provided the shaft is smooth and the load is applied after the shaft gets up to speed. Rubber bearings have been tested at loads up to 850 lb. per sq. in.

Rubber bearings are particularly suitable for use on shafts running at high speeds not only because the friction is very low but because the softness of the rubber allows the shaft to turn on its center of gyration even though this differs slightly from the geometrical center, thus reducing the dynamic load in the bearing and the vibration in the machine.

INTRODUCTION

Bearings of soft vulcanized rubber have been used for many years in marine service under conditions necessitating the use of water as the lubricant, where sand and grit are often present. The toughness, resiliency, and the low coefficient of running friction of rubber make it a superior material for this service, and it has been found to outwear harder materials such as metals and lignum vitae by as much as ten times their service life.

The softness and resilience of rubber which permit it to be deformed enough to allow sand grains to travel through the bearing without scoring it or the shaft, also have an important effect upon the performance of the bearings when lubricated with water free from grit. The resilient rubber can accommodate itself to slight irregularities present in a shaft, and hence a thinner film of lubricant will serve than would be required by a hard bearing.

A fundamental study of the friction of different types of soft-rubber and of metal bearings under various conditions has shown that the classical laws of bearing lubrication worked out by Towers, Reynolds, etc. for cylindrical metal bearings do not apply to the commercial type of fluted rubber bearings. Because of the difference in the fundamental laws underlying their performance, rubber bearings are superior to metal bearings under many conditions of industrial as well as marine service. This paper compares some of the relations which have been found between the coefficient of friction and the load, speed, shaft roughness, etc. of soft rubber and of metal bearings lubricated by water. It also gives data which should help engineers in using these bearings to greatest advantage. There seems to be no upper limit to the speeds at which water-lubricated rubber bearings can be used if sufficient lubrication is provided. Rubber bearings have yielded good service at shaft speeds of 12,000 r.p.m. or 4330 ft. per min. The upper limit of loads these bearings can carry depends very much on the operating conditions, but bearings have been run when loaded as high as 850 lb. per sq. in.

BEARING THEORY

A simple application of the theory of dimensions[3] shows that if the friction of a cylindrical bearing is a function of v, the bearing speed in r.p.m., the viscosity of the lubricant η, the unit load P, and certain dimensionless ratios such as diameter to length, clearance to length, etc. then the coefficient of friction f should be a function of the combination $(\eta v/P)$, or, for geometrically similar bearings, $f = \phi(\eta v/P)$, a form to which the more detailed equations of Reynolds, Harrison, etc. can be reduced.

The assumptions made in these derivations are not generally true, though they should not be very far wrong for smooth metal bearings of small clearance in the range of viscous-film lubrication. A large number of experiments have been made to see how accurately the formula fits observed facts, but in relatively few cases have the conditions necessary for a rigorous

test been satisfied. No journal or bearing is perfectly rigid, so it will vibrate at high speeds and be deflected by high loads, and changes in these factors will also vary the temperature and rate of shear of the lubricating film, thus changing the viscosity. Since it is almost impossible to measure the temperature of the lubricant in the film, the actual viscosity may be quite different from the value taken for the calculations.

From our physical picture of the action of a bearing, and also from Harrison's[4] mathematical analysis, we should expect that in the range where the eccentricity of the bearing is small, the coefficient of friction will be a linear function of the factor $(\eta v/P)$. Hersey[3] found experimentally that the function ϕ was of the form

$$f = \phi\left(\frac{\eta v}{P}\right) = a + b\left(\frac{\eta v}{P}\right)$$

where a and b were essentially constant over a considerable range of values of $(\eta v/P)$. In some cases it has been possible to express the results by a function of the form

$$f = K\left(\frac{\eta v}{P}\right)^b$$

where K is a constant and b is a constant somewhat less than unity. Illmer's summary[5] of bearing-friction research showed that very often the results were given by an equation of the type

$$f = K\frac{\eta^r v^m}{P^n}$$

where K is a bearing constant, and the exponents r, m, and n are determined by bearing conditions. The values of the exponents usually ranged from $^1/_3$ to $^3/_4$. Such variables as the character of oil, rate of oil feed, and journal clearance seemed to have a considerable effect on the values of the exponents of the equation. The difficulties mentioned above probably account for the fact that the values of r, m, and n are not identical as demanded by the theory.

It should be noted that actual friction measurements on bearings as well as the mathematical theory of Reynolds,[6] Harrison,[4] etc. all show that over a limited range the coefficient of friction decreases as the viscosity of the lubricant decreases. However, since these results apply only under conditions of perfect film lubrication, the viscosity cannot be reduced indefinitely to produce lower and lower frictions in the bearing. Under a given set of bearing conditions, as the viscosity of the lubricant is reduced the lubricating film will finally become thinner than the height of irregularities in the metal surfaces and the moving metal parts will come in contact, thus increasing the friction and rate of wear of the bearing.

Because rubber is flexible, it can accommodate itself to slight irregularities of a shaft. Consequently a thinner film of lubricant will suffice to keep a rubber and a metal surface separated than would be necessary to keep two similarly rough metal surfaces apart. This probably accounts for the fact that a low-viscosity liquid such as water is a suitable lubricant for rubber bearings run at moderate speeds under moderate loads, while water can be used satisfactorily with metal bearings only at high speeds with light loads.

Another factor may also help to account for the satisfactory service of rubber bearings. A detailed study of the hydrodynamics of bearing lubrication by Sommerfeld,[7] Mitchell,[8] etc. led to the introduction of the tilting bearing pad found in the present Mitchell and Kingsbury thrust bearings. By allowing the wedging angle to change with the speed and the load these bearings operate at a much higher efficiency, and can carry much greater pressures than the conventional thrust bearings. Fluted rubber bearings allow the shaft to rest on a series of longitudinal strips of rubber running the length of the bearing (see Fig. 1). These strips can be deformed slightly, and so the angle of approach between the bearing surface and the shaft will change as the load is changed, producing the same effect as the pivoted bearing pads do in a modern thrust bearing. This probably accounts for the fact that over a considerable range of pressures the coefficient of friction of a rubber bearing is unaffected by changes in load. The grooves also allow sufficient cooling water to flow through the bearing, to wash out sand and grit that might otherwise get into it. Smooth cylindrical rubber bearings do not give a coefficient of friction which is independent of load, though the change of friction with load is less than for cylindrical metal bearings.

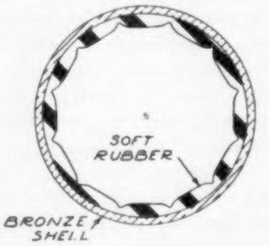

Fig. 1 Cross-Section of a Fluted Rubber Bearing

It should be understood that the statements about rubber bearings in this paper apply only to bearings of soft rubber. Hard-rubber bearings, even those containing graphite, give frictions about the same as are found with metal bearings.

EXPERIMENTS

Effect of Shaft Speed and Roughness

The static friction of soft rubber against dry metal varies from about 0.3 to 0.8, depending on the smoothness and cleanliness of the surfaces. The friction is even greater when the surfaces are wet. The static friction of a rubber bearing should therefore be high, but it should decrease with speed as a lubricating film is built up between the shaft and the bearing. The rate of decrease should depend very much on the smoothness of the metal surface. Preliminary experiments were carried out to show how the friction of wet rubber against metal depended on the speed and smoothness of the shaft.

By means of a lever acting through a roller bearing, a flat strip of rubber 3 in. wide and $^3/_{32}$ in. thick fastened to a metal backing was pressed against a cast-iron pulley 6 in. in diameter and having a 3-in. face, and the tangential force exerted on the rubber was measured for various pulley speeds and conditions of the pulley surface. Lubrication was obtained by allowing the bottom of the pulley to dip in a pan of water. To study the effect of surface roughness the face of the pulley was first knurled to a depth of 0.009 in. to give a surface which would make viscous-film lubrication almost impossible. After this surface was tested, the knurling was removed and right- and left-hand threads 0.002 in. deep and 48 to the inch were cut over the face of the pulley, to give a surface simulating a badly scored shaft. When tests of this surface were completed the face of the pulley was cut as smooth as possible in a lathe, and retested. Then the wheel was polished with crocus cloth to a smoother finish, and was finally given a light coating of wax and repolished to a glossy finish, the tests being repeated on each surface.

The effects of speed and surface roughness on the coefficient of friction are shown in Fig. 2. The friction of the rubber on the knurled surface remains at the high value of the static friction up to a surface speed of 1400 ft. per min. The friction on a badly scored surface decreases somewhat with speed, but remains much too high for a good bearing. Only the smoothest surfaces give a reasonably low coefficient of friction down to peripheral speeds of 100 to 200 ft. per min. It may be mentioned that roughness of the surface of the rubber is nearly, but not quite, as influential as roughness of the metal surface for increasing the friction.

[8] *Ibid.*, 1905.

In other tests the width and thickness of the rubber were varied; but, with a reasonably smooth pulley surface, these changes had relatively little effect on the friction over the range from 0.5 in. to 3 in. in width and $^3/_{16}$ in. to $^3/_8$ in. in thickness. Tests were run at several loads, but, except at the lower speeds, the load had only a small effect on the coefficient of friction over the range of pressures from 5 to 260 lb. per square inch of contact area. Raising the temperature of the water increased the friction, probably because of the lower viscosity of the water at the higher temperatures.

Comparison of Water-Lubricated Rubber and Metal Bearings

This work was done primarily to ascertain how the friction of rubber and metal bearings compared under conditions commonly encountered in marine service. However, water has some distinct advantage as a lubricant in studying bearing theory, for it gives a convenient way of investigating the effects of the factor $\eta v/P$ over the lower ranges which are usually ignored in fundamental studies of bearing lubrication. The results of the investigations showed that in the region of low values of $\eta v/P$, where most water-lubricated bearings operate, the fundamental laws governing the relation between friction, load, and speed are very different for soft-rubber and for metal bearings, and indicated that rubber bearings might find uses in industry under conditions where water-lubricated metal bearings could not be employed.

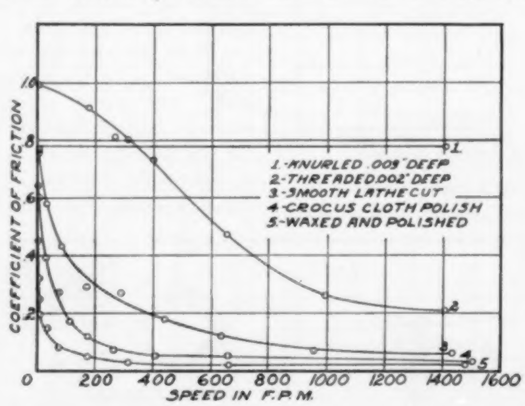

Fig. 2 Effect of Speed and Roughness of Metal Surface on the Coefficient of Friction Against Wet Rubber

The difference in the fundamental laws governing metal and fluted soft-rubber bearings is shown very strikingly by the friction-load-speed curves obtained with $^7/_8 \times 3^1/_2$-in. rubber and brass bearings lubricated with water. The apparatus for testing these bearings is shown in Fig. 3. The bearings B were run on a monel metal shaft S submerged in water. Above the rubber bearing was a 6-in. pulley P mounted on ball bearings, around which was a flexible steel wire W for transmitting the load to the bearing from the loading arm A. The load was applied directly to the bearing by a cradle C of two thin flexible steel straps. The connection between the wire and the cradle was made flexible so that the load would distribute itself equally between the two straps. The torque set up by the bearing was transmitted through the cradle and wire to the upper pulley, and the friction was measured by using a spring balance at the end of the torque arm on the upper pulley. The effect of vibration was reduced by dashpots D on the loading and torque arms.

Fig. 3 Machine for Measuring the Coefficient of Friction of Metal and Rubber Bearings

For the lowest friction values it was found essential to use a very flexible wire to transmit the load to the cradle. Several strands of fine piano wire twisted together were found to be most satisfactory, though for frictions below 0.002 the stiffness of even this wire had an appreciable effect on the readings. The sensitivity of the apparatus was increased in the lower friction range by snubbing a cord around the bearing and measuring the friction force directly instead of using the torque arm. Tests showed that, in most cases, the additional force applied to the bearing by the friction-measuring device was negligible compared with the total load; but where necessary, the proper corrections were made. The difficulties of finding a flexible material strong enough to carry large loads set the upper limits of loading and the lower limits of the frictions that can be tested by this method.

The change of friction with load for a water-lubricated brass bearing is shown in Fig. 4, and part of the data are shown on an enlarged scale in Fig. 5. The curves are what one would expect from the theory, the coefficient of friction at a given speed decreasing with load in the range of viscous lubrication, reaching a minimum, and then increasing asymptotically to the value for the static friction at high loads, where the metal surfaces are no longer separated by a lubricating film. Fig. 5 shows that the maximum loads which this brass bearing will carry under conditions of viscous-film lubrication are about 0.4, 1.0, 3.5, and 7.0 lb. per sq. in. for speeds of 66, 183, 366, and 733 ft. per min., respectively. These low loads explain why water is used as a lubricant for metal bearings only because of necessity.

If the torque is plotted against load, a rather interesting series of curves is obtained, as shown in Fig. 6. Although the points are rather scattered, it appears that at high loads—i.e., when there is metallic contact—the frictional force F in the bearing seems to follow the equation

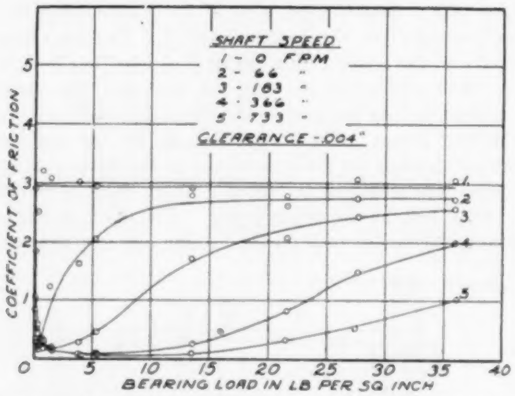

Fig. 4 Effect of Load on Coefficient of Friction of a Cylindrical Brass Bearing

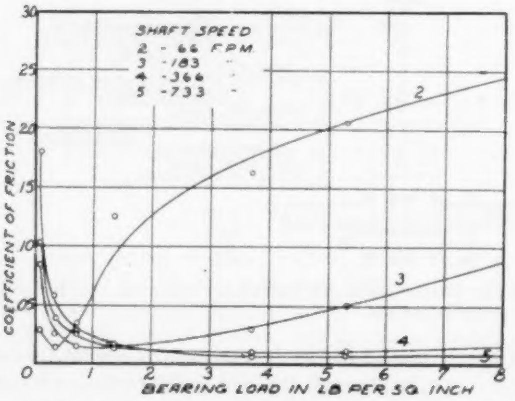

Fig. 5 Effect of Load on Coefficient of Friction of a Cylindrical Brass Bearing for Light Loads

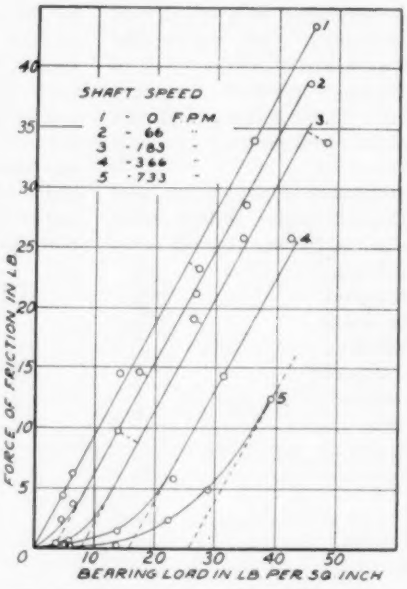

Fig. 6 Friction of a Brass Bearing

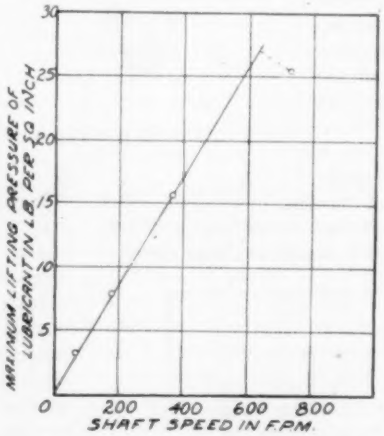

Fig. 7 Change of Lifting Pressure in Lubricant With Speed

$$F = C\,(L - x)$$

where L is the load applied, C is the static coefficient of friction, and x is the intercept of the extended straight portion of the curve on the load axis. x may be interpreted as being the supporting force exerted by the lubricant after there is full metallic contact in the bearing. The value of x in this test proves to be proportional to the speed of the shaft as shown in Fig. 7. The equation may therefore be written

$$F = C\,(L - kv)$$

where v is the speed of the shaft and k is a constant determined by the viscosity, clearance, etc. This equation applies of course only when the loads are great enough to make the film thickness small compared with the irregularities in the bearing surfaces. It is probably also necessary that the bearing projections be of approximately a uniform height, for when a badly scored bearing was tested, the friction-load curves did not become straight lines until very much higher loads were reached. The intermediate region of mixed viscous and solid friction was much larger under these conditions. Further tests on bearings of different sizes and clearances are required to determine if this law is generally valid. A bronze bearing (88-10-2) was tested in the same way, and gave about the same results as the brass bearing, except that it did not wear away so rapidly.

When a $^7/_8 \times 3^1/_2$-in. fluted rubber bearing was tested on the same shaft under the same conditions, very different results were obtained. To make sure that the conditions were the same in testing the two bearings, the rubber and brass bearings were tested alternately at each speed, and each bearing was tested at the same place on the shaft. Changes in shaft roughness or other experimental conditions, therefore, could not account for the differences which were found. The results are plotted in Fig. 8.

It is seen that when the rubber bearing is run at a given speed the coefficient of friction is almost independent of the load, over the range from 2 to 45 lb. per sq. in. bearing pressure. This implies that the frictional force is directly proportional to the load. This relationship does not resemble that of a plane bearing[9] where we should expect the coefficient of friction to be proportional to $\sqrt{1/P}$. Instead it more nearly resembles the change of static friction with load, though the running frictions are much lower than the static friction. It is probable that these results are due to the change with the load in the angle between the rubber and the shaft at each flute. This was confirmed by testing a smooth cylindrical rubber bearing without flutes, having a clearance of 0.008 in. and a $^1/_8$-in. rubber wall. The curves of coefficient of friction against load for this bearing, shown in Fig. 9, are similar to those of the metal bearing, but the fric-

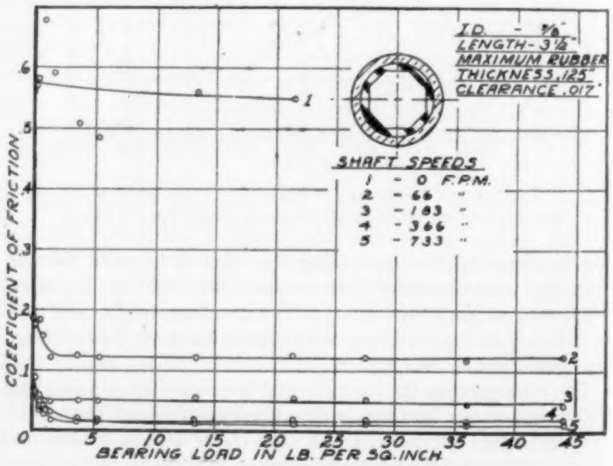

Fig. 8 Effect of Load on Coefficient of Friction of a Fluted Rubber Bearing

tions are lower. They are not far from the friction of the fluted rubber bearing. The coefficients of friction of the rubber bearings at the higher speeds ranged from about 0.01 to 0.005, which is the order of friction found in good ball bearings.

---

[9] Archbutt and Deeley, "Lubrication and Lubricants," London, 1927, p. 100.

Even in the cylindrical rubber bearing the rubber is flexible enough to allow some deformation and change in the angle of approach as the load changes. Hence the friction of the cylindrical rubber bearing does not increase as rapidly with load as it does in a metal bearing, in spite of the fact that a rubber bearing has a higher static friction than a metal bearing.

A comparison of Figs. 4 and 8 shows that at very slow speeds and light loads the metal bearing has a lower friction than the fluted rubber bearing, but at higher speeds, and especially at higher loads, the friction of a rubber bearing is much less than that of a metal bearing. Figs. 10 and 11 give a comparison of the coefficient of friction and the friction loss in the rubber and the metal bearing when run at a speed of 800 r.p.m. or a peripheral speed of 183 ft. per min.

The upper limit of the speed at which rubber bearings may be used has not yet been determined. However, the fact that Kay Don used a rubber bearing on *Miss England II* when he broke the world's record showed that the limit for this type of bearing is above a shaft speed of 12,000 r.p.m. or a peripheral speed of 4330 ft. per min. At these higher speeds the rubber bearings are particularly effective for they allow a shaft to turn on its center of gyration even if this does not correspond exactly to the geometrical center, thus reducing the dynamic stresses in the bearing and the vibration in the whole structure.

Tests of Rubber Bearings at High Loads

The use of rubber for severe service, as in the roll necks of steel mills, demands a knowledge of how these bearings will behave under high loads. The apparatus used for the tests already described could not be used to secure complete friction-load-speed curves of large bearings at high loads, but tests previously made by Mr. Annis of the B. F. Goodrich Company's engineering department showed that under certain conditions rubber bearings may be used at loads up to 850 lb. per sq. in.

Bearings 2 in. I.D. × 5 in. long were mounted on a shaft and loaded by a lever arm. The bearing was surrounded by a tank of $3^1/_2$ gal. capacity and water flowed through this tank at the rate of 1 gal. per min. It was found that friction at the packing glands through which the shaft passed caused negligible heating. The rise in temperature of the water on flowing through the tank therefore gave a measure of the energy consumed in the bearing, and this was used to calculate the coefficient of friction. This method leaves much to be desired from the standpoint of precision, but at least it gives the order of magnitude of the frictions at these loads.

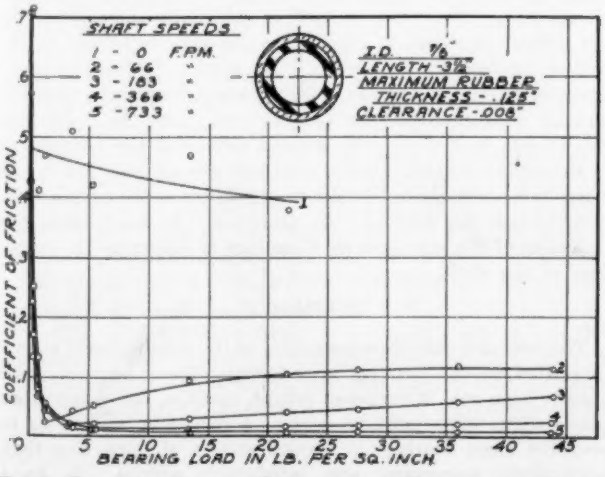

Fig. 9 Effect of Load on Coefficient of Friction of a Cylindrical Rubber Bearing

In making the tests a load was applied to the bearing and it was run for 20 min. to reach equilibrium conditions, after which the temperature of the water leaving the tank was taken. The load was then increased 50 lb. per sq. in., and the process repeated.

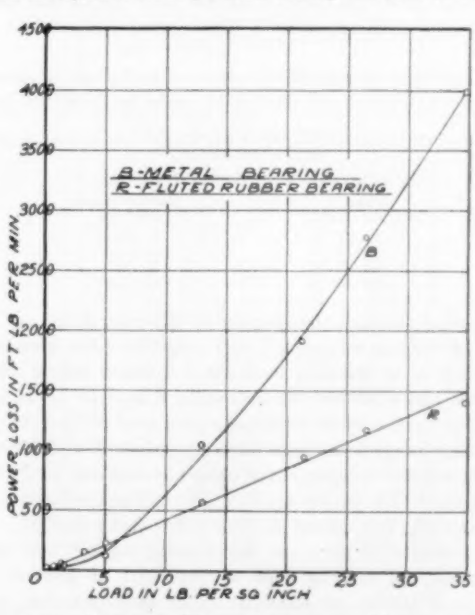

Fig. 11 Power Losses in Water-Lubricated Metal and Fluted Rubber Bearings

(Speed, 800 r.p.m. or 183 ft. per min.; bearing size, $^7/_8$ in. × $3^1/_2$ in.)

A typical test on a 2.025-in. I.D. × 3-in. O.D. × 5-in. long spiral-grooved rubber bearing is shown in Table 1. After this test the bearing was worn only slightly, with no evidence of scoring. The shaft was very smooth as it had been coated with a graphite soap before the test. The maximum temperature of the water was 42 deg. cent., a rise in temperature of 9 deg. The bearing temperature went up to 47 deg. cent. A plain cylindrical bearing of $2^1/_{16}$ in. I.D. was run on the 2-in. shaft

Load, lb. per sq. in.	Coefficient of friction
150	0.038
300	0.026
500	0.018
600	0.015
700	0.014
800	0.012
850	0.012

TABLE 2 COEFFICIENT OF FRICTION OF A 2.062 × 5-IN. PLAIN RUBBER BEARING

(Speed, 700 r.p.m., or 366 ft. per min.)

Load, lb. per sq. in.	Temperature rise, deg. fahr.	Coefficient of friction
55	1.8	0.0580
135	1.8	0.0236
184	2.7	0.0260
334	4.5	0.0240
384	4.5	0.0208
484	4.5	0.0164
590	5.4	0.0164
640	5.4	0.0148

in the same way, and the results shown in Table 2 were obtained. There was no sign of scoring on the bearing after this test.

Bearings up to 6 in. I.D. × 24 in. long were also tested by Mr. Annis, but they could be loaded only to 70 lb. per sq. in. The shaft on which the bearings ran was mounted in ball bearings, and the energy consumed in the rubber bearing was determined from the power used by the driving motor. Again this is not an entirely satisfactory experimental arrangement, but it should give the upper limits of the friction, and the data are consistent with the results which were obtained by other methods.

A typical test on a 5.933 × 24-in. fluted bearing similar to that shown in Fig. 1, but having 10 faces, is shown in Table 3.

TABLE 3 COEFFICIENTS OF FRICTION OF 10-FACE 5.933 × 24-IN. BEARING

(Speed, 420 r.p.m., or 660 ft. per min.)

Load, lb. per sq. in.	Coefficient of friction
34.77	0.0253
41.74	0.0236
56.61	0.0197
69.50	0.0158

Water flowed through the bearing at the rate of 0.3 cu. ft. per min. The bearing was coated with graphite when installed and it was broken in without load for 1.5 hours before the test. In another test a 20-face fluted bearing 6 in. I.D. × 24 in. long was run under the same conditions at a load of 72.5 lb. per sq. in. and was found to have a friction coefficient of 0.00844.

A 12-face fluted bearing of the same size was run for 70.5 hours with a load of 72.5 lb. per sq. in. The initial coefficient of friction was 0.0202, but during the test it dropped to 0.0037. There was no measurable wear on the bearing during this test. A plain cylindrical bearing had a coefficient of friction which ranged from 0.0021 to 0.00075. This indicates that a plain bearing yields the lowest friction values; but, as a matter of safety, it may be necessary to use flutes in the bearings to allow more cooling water to flow through.

While the foregoing figures are not as precise as might be desired, they at least show the upper limits of the frictions which may be expected from soft-rubber bearings. It must be emphasized that these results can be obtained only when the bearings are used on smooth shafts with the load applied after the shaft reaches its running speed, and with sufficient cooling water supplied to the bearing. As the temperature of the water entering the bearing is raised the amount of water must be increased or the maximum load capacity of the bearing will be markedly decreased. The reason for this is that nearly all the heat generated in the bearing must be removed by the water, and the temperature of the lubricating water in the thin film between the rubber and the shaft must be kept below the boiling point. Much higher loads can of course be carried by rubber bearings if the water is admitted to the bearing surface under pressure.

Deflections in Rubber Bearings

The deflections of a rubber bearing vary greatly with the hardness of the rubber, the design of the bearing, etc. The curves of Fig. 12 show the deflections of thin-wall-type fluted rubber bearings up to 5 in. in diameter, and of a thick-wall-type bearing 19.68 in. in diameter made for marine service. The dimensions of these bearings are given in Table 4.

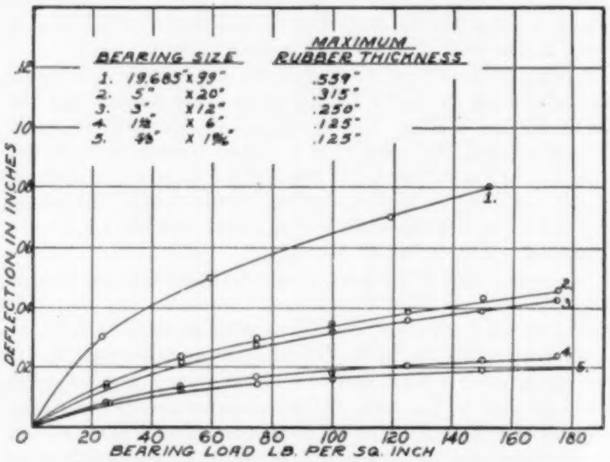

FIG. 12 LOAD-DEFLECTION CURVES FOR MARINE TYPE FLUTED RUBBER BEARINGS

TABLE 4 DIMENSIONS OF BEARINGS USED IN LOAD-DEFLECTION TESTS

Bearing no.	Internal diameter, in.	Outside diameter, in.	Length, in.	Maximum thickness of rubber, in.
1	19.68	21.65	99.0	0.559
2	5.0	6.125	20	0.315
3	3.0	3.75	12	0.250
4	1.5	2.0	6	0.125
5	0.625	1.0	$1^{9}/_{16}$	0.125

In every case but No. 1 the deflection tests were made on complete bearings. The results for this bearing were obtained by measuring the deflection of a single flute and calculating the deflection of the shaft in a complete bearing.

It is of course possible to make rubber bearings which give much smaller deflections than the standard marine bearings shown here. Since rubber itself is essentially incompressible, the deflections shown in Fig. 12 are due entirely to the distortion of the flutes in the bearing. By making the bearing cylindrical instead of fluted the deflections will be greatly reduced, and by using graphited hard-rubber end plates the deflections can be still further reduced without sacrificing the advantages of the rubber bearing. When sand and grit are plentiful in the water it is advisable to increase the thickness of the rubber wall, even though this increases the distortion. In many cases the deflection of the bearing is an advantage in taking up the vibration of the shaft.

SUMMARY

The foregoing data show something of the possibilities of water-lubricated rubber bearings in industry. These bearings have already been used in deep-well pumps, turbines, and many other places where water must be used as a lubricant, as well as in propeller shaft bearings in various classes of ships, and they have given economical and satisfactory service. In sand washers and other places where conditions are equally severe, they have yielded service many times that of metal bearings. Under proper conditions, the cofficient of friction of soft rubber bearings compares favorably with that of the best roller bearings.

Rubber bearings will carry loads of 600–800 lb. per sq. in., provided the shaft is very smooth and that the load is applied only after the shaft gets up to a peripheral speed of about 500 ft. per min. It is also necessary that sufficient cooling water flow through the bearing to keep the temperature of the lubricating film below the boiling point. Still higher loads can be carried if the water is forced into the lubricating film under pressure, or if the shaft revolves at higher speeds.

Soft-rubber bearings are particularly suitable for use on high-speed shafts, not only because a rubber bearing can withstand high loads at these speeds, but because the bearing acts as a cushion which reduces the vibration and decreases the magnitude of the dynamic loads set up by the revolving shaft.

Discussion

R. E. B. SHARP.[10] The statement is made in the paper: "The static friction of soft rubber against dry metal varies from about 0.3 to 0.8, depending on the smoothness and cleanliness of the surfaces. The friction is even greater when the surfaces are wet." From Fig. 2 the coefficient with the metal surface waxed and polished is 0.45. An examination of Figs. 8 and 9 indicates this static coefficient of friction to be 0.57 and 0.48, respectively, for the fluted type of bearing and the cylindrical type. It is assumed that these tests were made with the rubber and metal surfaces in a wet condition.

If it is true that static friction with wet surfaces is greater than with dry surfaces, it is difficult to understand why horizontal-shaft rubber bearings, wherein the shafts are started from rest under load with the surfaces wet, stand up against wear to the extent that they are known to. Actual tests showing the difference in static coefficient of friction for wet and dry surfaces would be of interest.

It is noted that the minimum coefficient of friction from Fig. 2 with the metal surface waxed and polished is about 0.02 from 400 f.p.m. upward, whereas in Fig. 9, which pertains to the cylindrical rubber bearing, the coefficient is about 0.01 for varying loads and for a speed of 733 f.p.m. It would be interesting to know whether the authors have any comments to offer on the reason for this difference in coefficient.

Referring to Fig. 12, the writer has just succeeded in obtaining readings of actual deflection for two different loads in the case of a fluted type of rubber bearing with an internal diameter of 16.5 in. and a length of 25 in. Fig. 13 shows the authors' curves 1, 2, 3, 4, and 5 reproduced to a larger scale, with the points obtained by the writer plotted thereon. For bearing load of 13.3 lb. per sq. in. (5000 lb.) the deflection was 0.005 in., and for a deflection of 26.6 lb. per sq. in. (11,000 lb.) the deflection was 0.0105 in.

Fig. 14 shows the set-up for these tests. The deflections were obtained with micrometers. The maximum rubber thickness was 0.435 in. The bearing contained a total of 24 separate rubber strips vulcanized to metal backs.

It will be noted that these points through which curve 6 passes show less than half the deflection indicated by the authors' curve 1, which is a calculated curve for a 19.68-in. bearing. In view of the fact that the 16.5-in. bearing was designed for use in a vertical hydraulic turbine, which condition requires that the oscillation of the shaft be kept to a minimum, it is gratifying to note that the comparatively heavy load against the bearing produces so small a deflection.

The rubber in this bearing is designated by the Goodrich Rubber Company as their stock No. 8230. The increasing use of rubber bearings for marine, industrial, and hydroelectric application makes it desirable to have a standard method of determining hardness of the rubber used. Such a gage would correspond with the Brinell method of determining the hardness of metal.

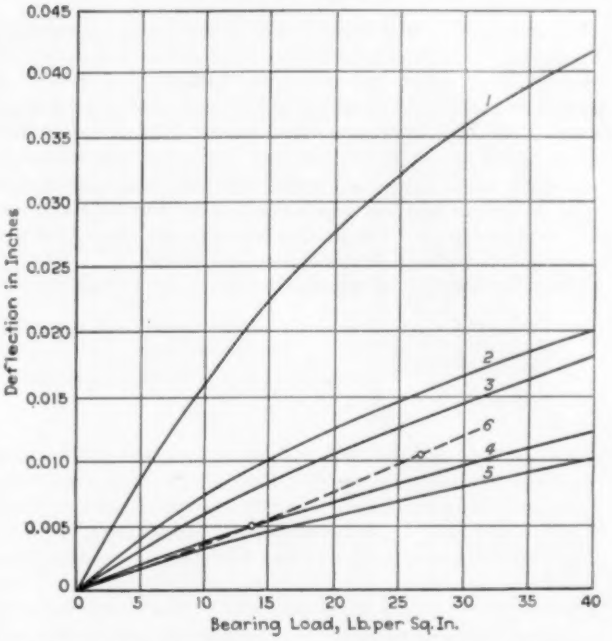

FIG. 13 ACTUAL DEFLECTION FOR TWO DIFFERENT LOADS

(Curves 1, 2, 3, 4, and 5 from authors' Fig. 12; curve 6, results of test of 16.50-in. by 25-in. fluted rubber bearing, maximum rubber thickness 0.435 in., 24 strips per bearing.)

(*Discussion by J. R. Adams and E. S. Glauch will be found following the paper by S. M. Weckstein.*)

AUTHORS' CLOSURE

It should not be understood, as was done in one discussion, that the static coefficient of friction of wet rubber is always over 0.8. We have found that the static coefficient of friction of dry rubber varies from about 0.3 to 0.8, while that of wet rubber is somewhat higher, ranging from around 0.33 to 0.9 or 1.0, depending on surface conditions, etc. However, this relatively high static friction does not mean that industrial and marine types of rubber bearings which start under full load will not give good service, for the friction immediately drops to lower values as soon as the shaft moves over the surface.

The difference in the minimum frictions shown in Figs. 2 and 9 is probably due to differences in the contact areas and the condition of the surfaces in the two tests, and also, to some extent, to inaccuracies in the machine used to get the data of Fig. 2. This machine was made to show only the relative effect of surface roughness and speed on the friction, and all later data were taken on the more refined machine shown in Fig. 3.

The figures Mr. Sharp presents on the deflection of a 16.5-in. × 25-in. turbine bearing at various loads are a good example of what can be done through proper designing to reduce the shaft deflections where necessary. The deflection data given in Fig. 12 show that even marine bearings which are designed primarily to resist sand abrasion give deflections much smaller than most people would expect. Bearings can be designed for roll necks which would have deflections much lower than those of turbine bearings.

IS-54-3

Straight Copper-Lead Alloys Versus Leaded Solid-Solution Bronzes for Heavy-Duty Bearings

F. R. Hensel

L. M. Tichvinsky

By F. R. HENSEL[1] and L. M. TICHVINSKY,[2] EAST PITTSBURGH, PA.

This paper describes the metallurgical investigation of various bronze bearing metals and deals with a comparative study of the bearing performance of those metals. The technological possibilities of producing heavy-duty bearings were investigated. Experimental installations of bearings with severe requirements are under trial.

Introduction

Bearing bronzes containing a high percentage of lead have been used recently very extensively, and it appears to be the general belief that their main advantage over ordinary babbitt bearings is the increased tensile strength. The strength and hardness of the bronzes result from the fact that they are solid-solution alloys. There are, however, a number of factors related to the actual bearing performance which seem to have been somewhat overlooked. This has led the authors to a study of straight copper-lead alloys which show practically no solid solubility, and therefore only half the strength of bronzes, but which nevertheless show a number of very interesting features regarding their performance as bearings. The lower strength of these alloys was compensated by joining the bearings inseparably to steel shells. The methods of obtaining an inseparable joint were studied in considerable detail.

II Metallurgical Study of Bronze Bearing Metals

(*a*) *General.* The production of lead-bearing copper alloys is attended with considerable difficulty, because lead and copper are practically insoluble in each other, as seen from the copper-lead diagram in Fig. 1. The amount of lead used in these alloys is in the neighborhood of 25 per cent. The melting point of an alloy of that composition is approximately 1000 deg. cent. Crystals of pure copper form along the line *AB*. At a constant temperature of 953 deg. cent., copper crystallizes until the melt has the composition *C*. Along the line *CE* pure copper continues to crystallize until the eutectic point is reached at a temperature about 1 deg. cent. below the melting point of pure lead. The eutectic contains only 0.06 per cent of copper. This description shows that nearly all the copper freezes out, almost pure, before the lead becomes solid. The danger of liquation of lead in such a case is very pronounced. It depends to a large extent upon the velocity of crystallization. By increasing the speed of solidification and therewith the number of copper nuclei, it is possible to trap the lead within the growing copper crystals. The addition of certain alloying elements also influences greatly the crystallization characteristics of a copper-lead matrix.

(*b*) *Casting Characteristics of Straight Copper-Lead Alloys.* The casting experiments that were made to study this question are recorded in Tables 1 and 2. The main variables were casting temperature, chemical composition, and type of casting (sand or chill casting).

The alloys were prepared in gas-fired clay graphite crucibles. Pure scrap copper was melted down and deoxidized with 0.25 per cent P, added in the form of 15 per cent phosphor-copper, before the addition of lead was made. The material was heated to above 1200 deg. cent., then taken out of the furnace and cooled to the desired casting temperature. The casting temperature was measured with a chromel-alumel thermocouple. Before casting the alloy was thoroughly stirred.

For sand castings a pattern was used which permitted two pieces to be cast at the same time. The machined test pieces had a 2-in. gage length and 0.505 in. diameter test section. For chill castings a cast-iron mold $2^{1}/_{2}$ in. in diameter and 18 in. long was employed.

The lowest casting temperature for sand castings was found to be 1050 deg. cent. Below that temperature the metal froze in the gate. Sand castings showed only a small amount of lead on the surface.

All chill castings exhibited a lead coating from $^{1}/_{16}$ to $^{1}/_{8}$ in. thick which extended approximately 4 in. up from the bottom of the ingot. The surface of the chill castings was blowy, and a slight pipe formed during solidification. The use of split molds for chill castings increased the danger of losing lead, as it leaked through the joint when the lead content and casting temperature were high. The series 51 corresponds to an intended composition of 80 per cent Cu and 20 per cent Pb, the series 52 to 75 per cent Cu and 25 per cent Pb, the series 53 to 70 per cent Cu and 30 per cent Pb. (See Table 1.)

[a] T—top of ingot; B—bottom of ingot.

The series 51 and 53 of straight copper-lead alloys show a fairly constant amount of lead retained. The retained lead amounts to 60 to 70 per cent of that added in series 51 (20 per cent Pb intended), and to about 85 per cent in the series 53 (30 per cent Pb intended). Both series contain certain amounts of tin and phosphorus, which are taken up into solid solution by copper. The amount of tin averages 0.2 to 0.3 per cent and that of phosphorus ranges between 0.03 and 0.08 per cent. The casting temperature apparently has no great effect on the amount of lead retained if 1150 deg. cent. is not exceeded.

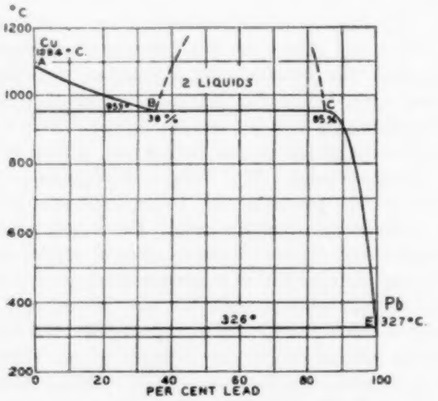

Fig. 1 Copper–Lead System

Conditions are entirely different in the series 52 (25 per cent Pb intended), which represents the purest copper-lead series, as there is only 0.05 Sn present and no phosphorus. Here the amount of lead retained varies greatly with the casting temperature, both in sand and chill castings. Although at a casting temperature of 1150 deg. cent. nearly 50 per cent of lead is lost; practically none is lost when the casting temperature is lowered to 1050 deg. cent. This large difference, however, is due to another cause. The 1150 deg. cent. castings were poured first and the 1050 deg. cent. castings last, from the same crucible. Although in every case the metal was stirred thoroughly before pouring, some segregation must have occurred in the crucible, as otherwise a lead content equivalent to 110 per cent of the intended composition could not have been retained in some of the samples. (See Table 1.) Fig. 2, in which the lead content as a function of the casting temperature is shown, therefore displays the combined effect of two factors—namely, the casting temperature and the crucible segregation on the amount of lead retained in the casting.

In the case of series 52-x, the lead content was constant and independent of the casting temperature or type of casting—i.e., chill or sand casting. Tin and phosphorus apparently keep the lead better distributed within the molten copper.

(*c*) *Tensile Properties.* The physical properties of the chill and sand castings are recorded in Tables 3 and 4. Some of the results are plotted in Fig. 3 and Fig. 4. From each chill casting two test pieces were cut, the location of which can be seen from Fig. 5. The chips for chemical analysis were machined from the tensile specimens after testing.

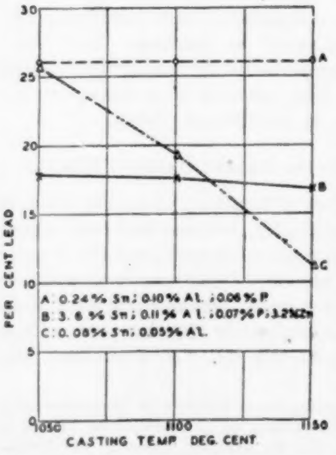

Fig. 2 Effect of Casting Temperature

(On amount of lead retained in Cu-Pb alloys as a function of their composition.)

The physical properties of straight copper-lead alloys are nearly independent of the casting temperature when temperatures from 1050 to 1150 deg. cent. are employed. The lead content seems to have relatively little influence upon the tensile properties such as ultimate strength, reduction of area, and elongation, although there is an unmistakable drop in most of the properties with increasing lead content. The Brinell hardness is a function of the lead content. While an alloy with 13 per cent Pb has a hardness of about 40 Brinell, the hardness of an alloy containing 26 per cent Pb is but 18. There is further a decided difference in Brinell values for sand and chill castings. The values for sand castings are considerably below those of chill castings. This holds true for leaded bronzes (52-x) also.

In the case of the copper-lead bronze (52-x), the highest casting temperature (1150 deg. cent.) yielded the highest values for ultimate strength, elongation, and reduction of area.

A comparison of the tensile properties of straight Cu-Pb alloys and babbitts is given in Table 5.

The tensile properties of the two types of bearings are not

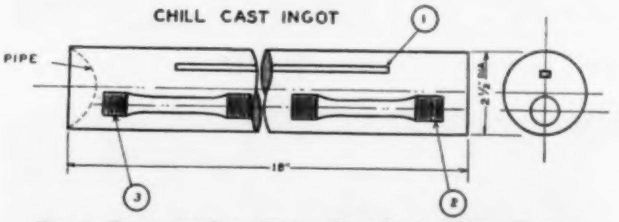

Fig. 5 Positions From Which Test Pieces Were Taken
(1, electrical-conductivity test piece, $^5/_{16}$ in. square by 12 in. long; 2, tensile-test piece from bottom of ingot, 0.505 in. in diameter, 2 in. gage length; 3, same as 2, except taken from top of ingot.)

greatly different. The advantage of the copper-lead alloys, however, becomes evident at elevated working temperatures. While babbitts lose practically all tensile strength above 200 deg. cent. on account of their low melting points (ranging from 225 to 240 deg. cent.) the straight copper-lead alloys still show more than 5000 lb. per sq. in. at temperatures just above 200 deg. cent.[3]

(d) *Electrical Conductivity.* The electrical conductivity of straight copper-lead alloys was determined, as it enables an approximate comparison of the thermal conductivity to be made. High thermal conductivity seems to be one of the main requirements of a good bearing because it assists in obtaining quick dissipation of heat and eliminates concentration of heat on certain spots, thus reducing the likelihood of burnt-out bearings.

The test pieces for conductivity measurements were machined from the chill castings. Their location can be seen from Fig. 5. The test pieces were machined to 12 in. length, $^5/_{16}$ in. square. The drop length was 8 in. The results on series 51, 52, 53, and 52-x are given in Table 6.

The electrical resistivity is a function of the chemical composition. In a mechanical mixture of two constituents, the resistivity of eutectiferous alloys can be calculated by means of the rule of mixtures from the resistances of the two pure metals.

For solid solutions there is an additional resistance due to the formation of the solid solution which in most cases seems to be but slightly dependent upon the temperature.

From the results in Table 6, the alloys can be classified into three groups:

(1) Pure Cu-Pb alloys with a conductivity ranging from 57 to 73 per cent according to Pb content.

(2) Cu-Pb alloys with small amounts of impurities (Sn, P), with a fairly constant conductivity near 33 per cent that is independent of the lead content.

(3) Solid solution Pb-Cu bronzes with a conductivity value of 16.5 per cent.

With regard to the effect of the impurities Sn, Zn, and P, it must be borne in mind that phosphorus and tin lower the conductivity of copper much more than zinc. For small amounts of P, Sn, and Zn, respectively, there must be added about the following relative amounts to decrease the conductivity of copper equally:

1 part P
5 parts Sn
60 parts Zn

It is therefore of utmost importance to keep the straight Cu-Pb alloys free from impurities which form solid solutions and decrease the conductivity, as do P and Sn.

(*c*) *Microstructure.* The microexamination was made on Brinell coupons of the tensile-test pieces of the straight Cu-Pb series 51, 52, and 53. In series 51 with a low lead content (12 per cent), the distribution of lead was found to be more uniform in the sand castings than in the chill castings. (See Figs. 6 and 7.) In the sand cast, series 52, the increasing lead content with lower casting temperature is easily noticeable. (See Figs. 8 and 9.) The size of the primary grains is largest at the highest casting temperature (1150 deg. cent.). The chill castings of series 52 showed a better distribution of lead. (See Fig. 10.) In series 53 excessive lead segregation occurred in the center of the sand-cast test piece. In Fig. 11 an average area is shown, while Fig. 12 shows the segregated center. The amount of lead in those sand castings is around 26 per cent. This percentage seems to be so high that uniform lead distribution cannot be secured in a straight Cu-Pb alloy.

By so changing the casting conditions that the distributing action is carried out mechanically, as by centrifugal casting, a much better lead distribution can be obtained, as will be shown farther on.

III PERFORMANCE OF BEARING-BRONZE METALS

(*a*) *General.* A series of tests was made in order to obtain some comparative results regarding the following bearing alloys:

Sample	Mark	Description
52-x	DW	Solid solution bronze
52-x	WE	Solid solution bronze
52	WE-0	Straight Cu-Pb alloy
52	WE-1	Straight Cu-Pb alloy
52	WE-2	Straight Cu-Pb alloy
52	WE-3	Straight Cu-Pb alloy

Tables 7 and 8 give some data on the properties of the bearings subjected to the tests described.

TABLE 7

Sample mark	Cu	Pb	Sn	Brinell hardness	Electrical conductivity, per cent of pure copper	Heat conductivity, watt-cm. system	Casting temperature, deg. cent.	Microstructure, figure

[a] Sand mold. [b] Chill mold.

The microstructures of the tested materials can be seen from Figs. 13 to 19, inclusive. The bearing alloys WE-1, WE-2, and WE-3 were prepared with the object of obtaining some information on the influence of the microstructure on the bearing performance. The material was supplied for test in shape of ingots, from each of which two bearings were machined—one from the top and the other from the bottom of the ingot. In the case of the ingots poured at 1200 deg. cent. and 1100 deg. cent. in sand molds, no difference in the structure of the machined bearings from the same ingot was observed. It is, however, noticeable that the ingot cast at 1200-deg. cent. showed a lead content of only 15 per cent, while the one cast at 1100 deg. cent. from the same ladle showed 20.3 per cent.

In the case of ingot WE-3 cast at 1040 deg. cent. in a chill mold, a considerable difference in the structures of WE-3-A and WE-3-C is seen in Figs. 16 and 17.

(*b*) *Test Set-Up.* The tests were made on the bearing-testing machine shown in Fig. 20.[4] The test bearings were mounted by means of steel bushings in a very rigid housing made in two halves bolted together. The load was applied by tightening the loading nut, the load being registered by a Chatillon spring dynamometer, the maximum load being 5000 lb. A flexible arrangement of the loading gear prevented eccentricity of load application.

In the tests there was used a standard shaft material having the following composition: C, 0.3 to 0.4; Ni, 1.0 to 1.5; Cr, 0.45 to 0.75; Mn, 0.50 to 0.80; $P_{max.}$, 0.040; $S_{max.}$, 0.045.

A sleeve-type shaft was designed as shown in Figs. 21 and 22. The interchangeable sleeves were machined to the same grade of finish.

The shaft was mounted on roller bearings and connected by a flexible coupling to a variable-speed motor, which provided a wide range of speeds by means of the Ward Leonard control system. The motor was carefully calibrated, so that by recording the field and armature currents, the torque at any moment and the value of the friction coefficient could be obtained. The diameter of the shaft was 2.5 in. The test bearings had the following dimensions: Inside diameter, 2.5 in. (+0.001, —0.000); outside diameter, 3.5 in.; length, 2 in. Thus the projected area was equal to 5 sq. in.

As shown in Fig. 23, the bearings were placed in the bushing, and the latter was placed in the housing, with the bushing and bearing split at an angle of 30 deg. to the horizontal housing joint. The key between the bearing and bushing prevented the rotation of the bearing with the shaft.

The bearing lubrication was supplied by an oil cup through a hole registering with a duct in the housing and was regulated by a needle valve. The oil cup was calibrated, and the oil feed could therefore be conveniently regulated. The oil used (M-2268) was of the same grade throughout the tests, its viscosity being 45 centipoises at 100 deg. fahr. and 5 centipoises at 210 deg. fahr.

---

[4] Described in A.S.M.E. Transactions, vol. 52, no. 7, 1930.

The temperature of the bearing in degrees centigrade was recorded by means of a thermocouple inserted in a small hole drilled about 1 in. deep in the axial direction and $^1/_8$ in. below the bearing surface of the lower half of the split bearing.

In the same manner, the temperature of the steel bushing was recorded in order to observe the heat gradient between the bearing and the bushing.

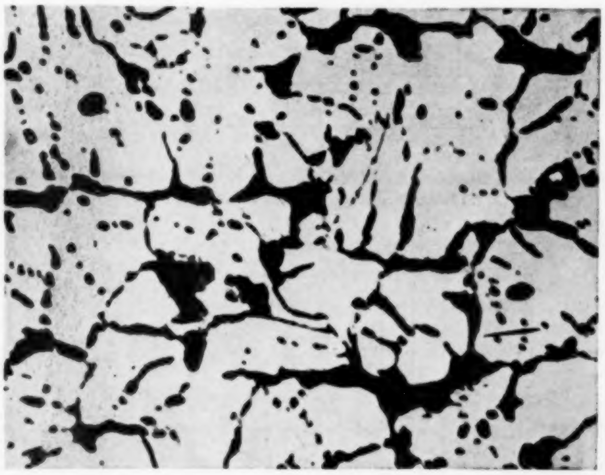

Fig. 18 Sample WE-1, Poured at 1200°C. in Sand Mold ×50

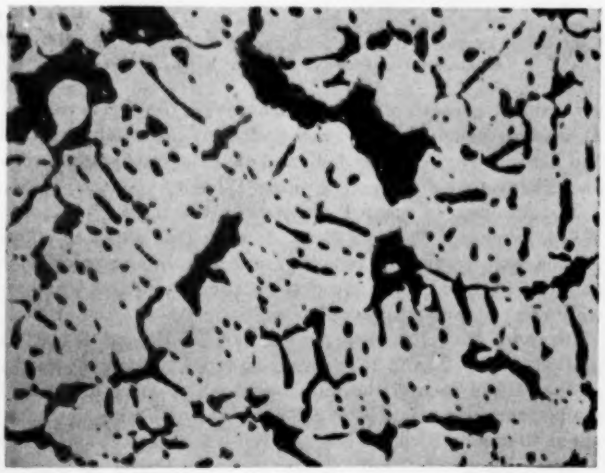

Fig. 19 Sample WE-2, Poured at 1100°C. in Sand Mold ×50

(c) *Method of Test.* All of the bearings mentioned were tested in separate groups, during which the bearings were subjected to certain definite conditions identical for each group; namely, load, speed, lubrication conditions, and, when possible, the time length of the test. These groups were:

1 Test of the bearings with continuous oil supply.

2 Test without continuous oil supply, the bearing being lubricated by the oil remaining between bearing and shaft.

3 Test without oil; the bearing assembly was washed in gasoline and dried.

This division of tests into three main groups permits a convenient comparison of the test results. The first group represents the usual operating bearing conditions, when the amount of

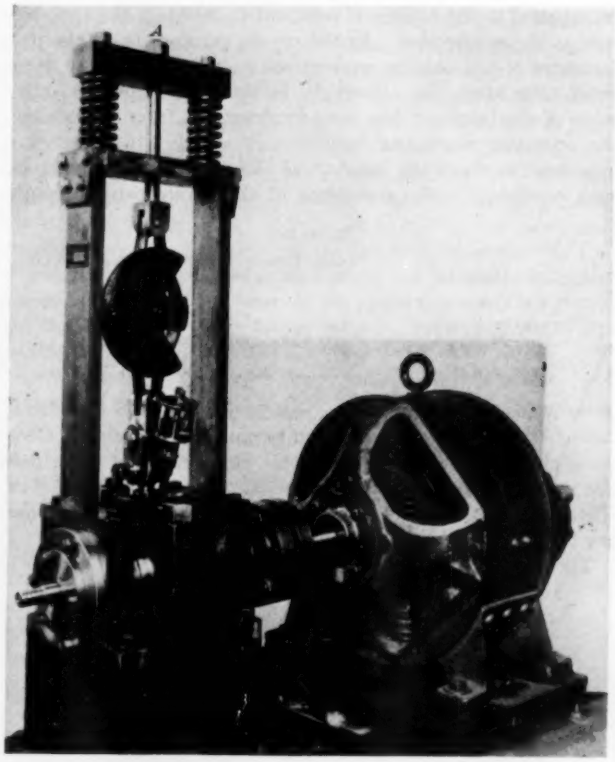

Fig. 20 Machine for Testing Bearings

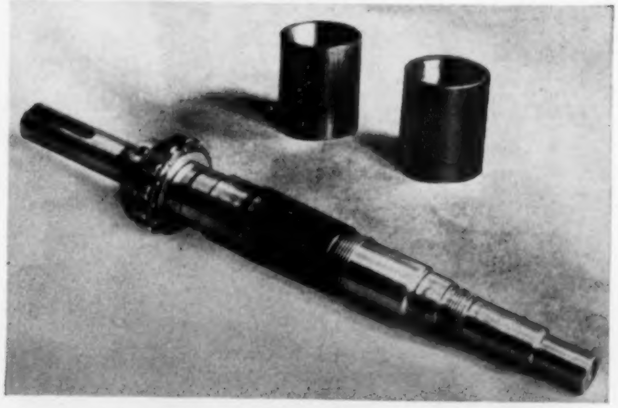

Fig. 21 Sleeve-Type Shaft Used in Bearings Tests

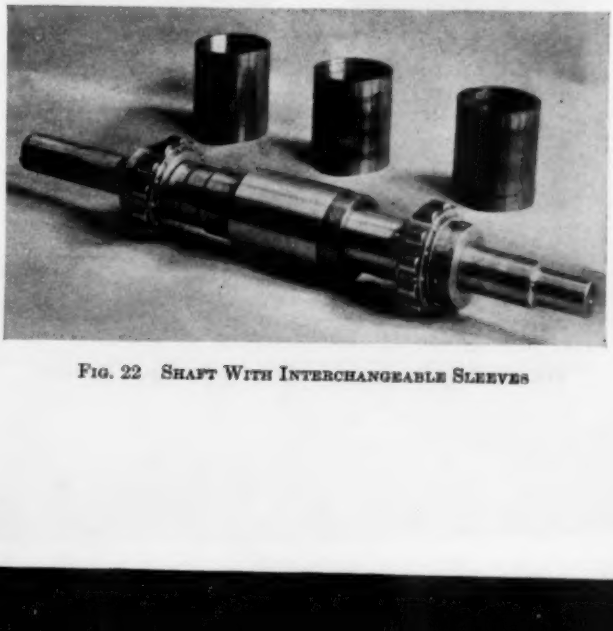

Fig. 22 Shaft With Interchangeable Sleeves

oil supplied to the bearing is sufficient to maintain the temperature at the rated value. In the second group of tests, the performance of the bearing remains the same as in group 1 for a short time after the oil supply is shut off. However, after some of the lubricant has been squeezed out from the bearing, the operating conditions become very severe. It is therefore important to know the behavior of the bearing materials under such conditions. The conditions of this group can frequently occur in practice when for some reason the oil supply is suddenly cut off—for instance, when an oil pump or oil line fails. Complete absence of lubricant, as in the third group of tests, does not generally occur in practice with these bearing materials. These tests were undertaken in order to obtain some data on bearing bronzes as to heat conductivity, wear, etc.

TABLE 9

Group	Material	Load, lb.	Pressure per sq. in.	Speed, r.p.m.	Time, min.	Curves in figs. nos.
1	WE-1, WE-2, WE-3	500	100	500 1000	60 20	26–29
2(*a*)	DW, WE, WE-0	250	50	400	80	24–25
2(*b*)	WE-1, WE-2, WE-3	500	100	500 1000	60 20	26–29
3	DW, WE-0	250	50	400	80	30–31

The tests of the bearings with continuous oil supply (group 1) were run for a length of time sufficient for the bearing to wear in. A constant value of the friction coefficient (constant armature and field-current readings) indicated that the bearing was worn in. The test conditions are given in Table 9.

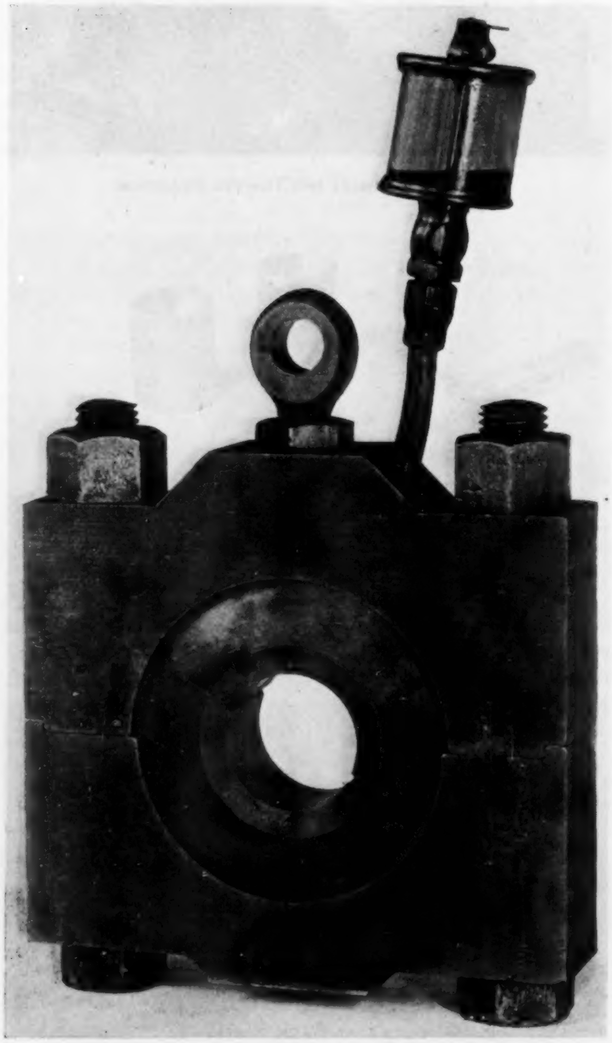

FIG. 23 TEST BEARINGS AND BUSHING PLACED IN HOUSING

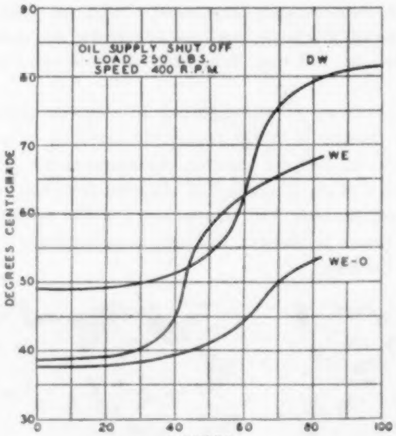

FIG. 24 TEMPERATURE-TIME RELATION OF BRONZE BEARINGS DURING TEST WITHOUT OIL SUPPLY

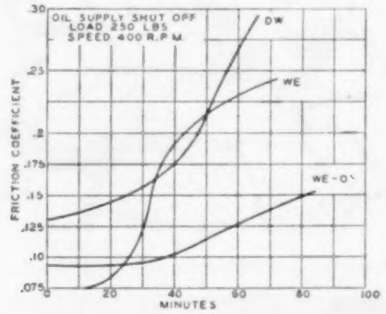

FIG. 25 FRICTION COEFFICIENT-TIME RELATION OF BRONZE BEARINGS DURING TEST WITHOUT OIL SUPPLY

Test Results. In group 1, the tests on the WE-1, WE-2, and WE-3, as plotted in Figs. 26 to 29, show that all three alloys can be well applied in practice, since the friction coefficient and the temperatures derived from their operations are well within the allowable working limits.

In group 2(*a*), the tests on the DW, WE, and WE-0, as plotted in Figs. 24 and 25, show, as expected, a temperature rise in the case of each of the three bearings. A sharp increase in temperature occurs in the WE bearing after 30 min., and after about 40 min. in both the DW and WE-0 bearings.

The friction coefficient changes correspondingly, as seen in the curve in Fig. 25. The values of the temperature and the friction coefficient do not change greatly within a time range of approximately 30 min., indicating that a safe performance of the bearings can be expected within that period. The DW bearing seized the shaft after 60 min., and the WE bearing after 45 min.

The micrographs, Figs. 13, 14, and 15, show the lead distribution of the three materials tested. The lead particles are very coarse in the DW (solid-solution sand casting) metal. A more even distribution of lead is shown in the WE-0 alloy (straight Cu-Pb, chill casting), and a very uniform structure is characteristic for the WE alloy (solid-solution, chill casting).

In group 2(*b*), as plotted in Figs. 26 to 29, quite different results were obtained during the tests of the straight copper-lead bearings WE-1, WE-2, and WE-3 when subjected to more severe

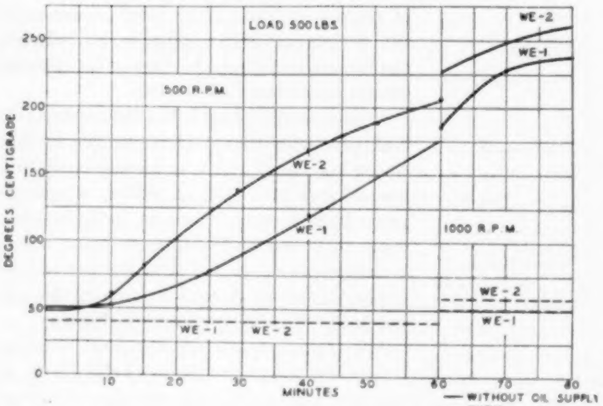

FIG. 26 BEHAVIOR OF TWO CU-PB BEARINGS DURING TEST WITH AND WITHOUT OIL SUPPLY

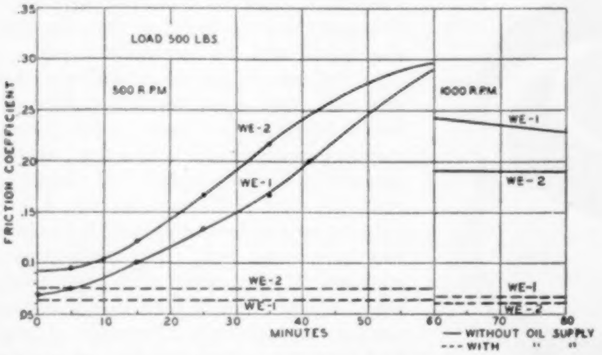

FIG. 27 BEHAVIOR OF TWO CU-PB BEARINGS DURING TEST WITH AND WITHOUT OIL SUPPLY

testing conditions under a load of 500 lb. at 500 and at 1000 r.p.m.

Since the microstructure of the bearings from each of the ingots 1 and 2 was the same, the average values of the data obtained are given on the curves in Figs. 26 and 27. In the case of the tests on the two bearings machined from ingot 3, where different structures were noticed, in the curves in Figs. 28 and 29 two values are plotted corresponding to the bearings machined from the upper part *A* and the lower part *C* of the ingot. Somewhat lower values of temperature and friction coefficient were observed in the case of the material with the finer structure.

The duration of the safe performance of these bearings can be seen from the curves in Figs. 26 and 27 (run at 100 lb. per sq. in. pressure and 500 r.p.m.) to be not more than 10 min. for the WE-1 and 5 min. for the WE-2.

Group 2 tests show that the bearing material will work satisfactorily for a short while after the oil supply is stopped while some oil remains in the clearance. The curves in Figs. 24 and 25 show that not only does the straight copper-lead alloy WE-0 give a lower temperature of operation than the solid-solution bronzes DW and WE, but also a lower friction coefficient and a more satisfactory period of operation during the conditions of this group of tests, when the bearings were subjected to 50 lb. per sq. in. at 400 r.p.m. The curves in Figs. 26 to 29 show that, if the load and speed are increased, the bearing will fail after a short time, the duration of the safe performance being only 4 to 5 min. The results obtained during the test of the bearings WE-3-A and WE-3-C confirm the general belief that fine structure is necessary for a good high-lead-bearing bronze. The effect of the microstructure was, however, less pronounced than originally expected.

In group 3, as plotted in Figs. 30 and 31, two bearing materials—namely, the solid-solution bronze DW and the straight Cu-Pb alloy WE-0, were subjected to dry test under a pressure of 50 lb. per sq. in. at 400 r.p.m. The first temperature reading at the start of the test was 24 deg. cent. in the DW and 27 deg. cent. in the WE-0. From the beginning of the test, the temperature in each case increased rapidly, especially in the DW bearing, where at any time the temperature was approximately twice that in the WE-0 bearing. The values of the friction coefficient are also higher for the DW than for the WE-0 bearing. It was in this group of tests that the wear of the bronze metals was first observed by a decrease of the load, the load being immediately increased to the initial value by the tightening of the loading nut.

Group 3 tests show that the heat gradient from the shaft to the outer frame surface was greater in the DW bearing than in the WE-0. This statement may be verified by comparing the values of the heat conductivity of the two alloys, which comparison shows that the straight copper-lead alloy has a heat conductivity four times that of the DW metal; in other words, the rate of heat dissipation from the WE-0 alloy is four times greater than from DW metal.

Summary. The results obtained during the tests of groups 1, 2, and 3 show that the straight Cu-Pb alloys are superior to leaded solid-solution bronzes regarding their general bearing performance.

IV TECHNOLOGICAL ASPECTS OF PRODUCING HEAVY-DUTY BEARINGS

(*a*) *General.* The object of this investigation was to provide means for strengthening leaded bronzes and straight copper-lead alloy bearings by means of a steel backing shell. There were a number of difficulties encountered in obtaining a perfect and inseparable joint between the leaded bronze and the steel without affecting the lead distribution of the bronze. After some experiments with straight casting methods, efforts were directed to the investigation of the suitability of a centrifugal casting process for making steel-backed bronze bearings. The materials used in the experiments described were solid-solution bronze WE and a 25%-Pb-75%-Cu straight copper lead alloy, which shall be called WE-x.

(*b*) *Preliminary Experiments.* Experiments proved that in immersing two steel half shells in a graphite crucible of molten bronze for periods varying from 2 to 10 min. an excellent bonding action was secured, indicating that a true alloying action between steel and bronze had occurred. After the steel was at the temperature of the molten bronze and "wetted" by the bronze, an increasing length of time did not seem to improve the joint.

Copper at a temperature just below its melting point can hold in solid solution approximately 3 per cent of iron. At the same temperature iron dissolves approximately 8 per cent of copper. In both cases the range of solubility of one metal in the other decreases with the temperature. Most alloys of the two metals, therefore, will consist of a mixture of the two constituents, both of which are solid solutions—one of iron in copper and the other of copper in iron. In order to minimize the formation of an alloy layer between the bronze and steel, the time of hot dipping should be as short as possible.

It may be mentioned that the methods for making copper-clad steel are similar in that a red-hot steel billet is momentarily immersed in a hot bath of molten copper so as to form a very thin and uniform alloy layer over the entire surface, after which molten copper is cast around the hot billets.

Fig. 32 shows a section through an unmachined bearing prepared in this way.

For making a few experimental bearings it was decided to use the steel shell both as crucible and mold, and therefore forgings were made as shown in Fig. 33. On one end of the steel sleeve *A*, a bottom plate *B* was welded, in the center of which a standard iron pipe *C* was fastened, so that the pipe was coaxial with the bore of the sleeve.

In one case the molten bronze was cast in a cold steel shell, which was then reheated to the melting point of the bronze, held at temperature for 1 to 3 min., stirred properly, and slowly cooled. In the other case, the steel shells were preheated in a reducing atmosphere, and the bronze was cast into the hot shell. Both methods were successful to the extent that good joints were obtained, but in each case a certain tendency to blowing and formation of large lead particles was noticeable. By using the first method and holding the metal molten in the shell for an excessively long time (10 min.), the lead coalesced to form very large particles, as shown in Fig. 34, as compared with the very small particle size characteristic of chill castings of the same bronze, as shown in Fig. 13. This hot-casting or "immersion" method was used for the preparation of four large rolling-mill bearings for a special experimental set-up. The dimensions of this bearing are given in Fig. 35, and the good appearance of the bronze is evident from Figs. 36 and 37. The

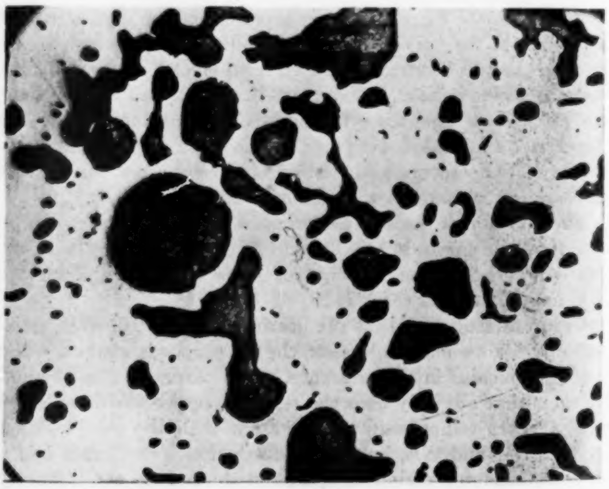

FIG. 34 LARGE LEAD PARTICLES IN BEARING MADE ACCORDING TO IMMERSION PROCESS

joint between the bronze and the bearing shell was perfect.

The hot-casting method was not applied to the straight copper-lead alloys, as their tendency to segregation is too strong.

Centrifugal Casting of Bearing Bronzes

The experiments were first performed with the bearing bronze WE. A small gas furnace was used for melting and to preheat the ladles and the steel shells. The temperature of the molten metal was measured with a chromel-alumel thermocouple and kept at 1050 to 1080 deg. cent. The steel shells were preheated by dipping them in the molten metal for about 2 min. They were then placed quickly in the centrifugal casting machine. As soon as the machine was up to speed, the bronze was poured into the mold through a hole in the front end of the machine. Immediately after pouring, a blast of cold air was turned on the outside of the steel shell to cool the bronze as rapidly as possible and thus prevent any large lead segregation.

In a preliminary experiment with the WE bronze the alloy was centrifugally cast into a cold steel shell. The joints so produced were poor; the lead distribution, however, was extremely fine, as shown in Fig. 38.

The object of the tests with preheated shells was to determine the influence of the rotational speed upon the qualities of the joint and the lead distribution.

The centrifugal force is a function of the inside diameters of the steel shells. Only small shells with $2^{1}/_{8}$ in. and $1^{7}/_{16}$ in. inside diameters were used.

The speeds employed were 1000, 1200, 1500, and 1750 r.p.m. The resultant joints are shown in Figs. 39 to 41. All of them are perfect and strong. The difference in lead segregation is not very noticeable up to 1500 r.p.m. At 1750 r.p.m., however, there are large lead globules near the joint. The large amount of lead did not weaken the joint when it was tested, but if the bearing should be run at elevated temperatures, as may happen in service, the excessive amount of lead may weaken the joint.

The strength of the welded joint was tested by a simple bending test, as shown in Figs. 42 and 43. For this test rings $^{3}/_{8}$ in. wide were cut out of the bearings. These rings were then bent flat in an Amsler tensile-testing machine. If the joint was poor, due to an oxidized surface, the bronze broke away easily, while a good joint could be bent flat without showing any signs of parting between bronze and steel. The joints tended to be poor at the extreme ends of the bearings due to the rapid cooling of the ends of the shell prior to casting, caused by contact with the cold metal parts of the casting machine. The joints in the central portion of the bearings were always strong.

The same series of experiments as with the WE bronze was carried out with the straight Cu-Pb alloys WE-x. Unfortunately, the small furnace available was unable to produce temperatures as high as was desirable. The maximum temperatures obtainable were 1050 to 1080 deg. cent., while a temperature of about 1150 to 1200 deg. cent. would have been required for satisfactory working. Another source of trouble with the WE-x alloy was the large amount of slag which formed very rapidly on the surface of the metal. Thus, in dipping the metal out of the crucible, some slag was always brought along, and part of it was poured into the bearing. The slag, however, was light, and most of it stayed in the inside of the bearing.

lead segregation was not greatly influenced by the speed, which was varied from 600 r.p.m. to 2000 r.p.m. A good bond between the steel and the bearing alloy was secured in every case. The lead is uniformly and finely distributed in a dendritic pattern. There is a sort of columnar arrangement of the lead streaks, while the bearings cast with the WE bronze showed the lead in a globular form.

At a speed of 1700 r.p.m. the WE bronze exhibited a decided lead segregation near the joint, while the bearing cast with the Cu-Pb alloy at the same speed shows hardly any lead segregation. The effect of the speed on the condition of the inside surface of the WE-x alloy was such that a slow speed (600 r.p.m.) produced a rough surface, while a speed of 2000 r.p.m. produced a smooth, glossy surface.

Conclusions

(1) The lead content and its distribution in straight Cu-Pb alloys depends primarily on the casting temperature, in that with lower casting temperatures, quicker solidification occurs and a larger amount of lead is retained in suspension.

(2) Pure Cu-Pb alloys (especially sand castings) have a tendency to pronounced lead segregation if the lead content exceeds 25 per cent.

(3) Small amounts of impurities have a notable effect in retaining a good suspension of the lead in the copper. They reduce the influence of the casting temperature on the lead content and upon the distribution of lead in the casting. A further study of alloying elements acting in this direction should enable improvements to be made in the properties of Cu-Pb alloys.

(4) The physical properties of straight Cu-Pb alloys are nearly independent of the casting temperature within a temperature range of 1050 to 1150 deg. cent. They depend but slightly on the lead content within the limits of 12 to 25 per cent Pb. The Brinell hardness is the only factor that is decreased with increasing Pb content. The physical properties of straight Cu-Pb alloys have values approximately one-half of those of solid-solution bronzes of the same lead content.

(5) The electrical conductivity of Cu-Pb alloys is about six times as high as that of solid-solution bronzes of the same lead content or of babbitts. The conductivity is lowered considerably by small amounts of impurities, especially by P and Sn.

(6) The performance tests of straight copper-lead alloys showed that they are very suitable as bearing materials, on account of low coefficient of friction and low working temperatures.

(7) The influence of the microstructure is such that, with a finer lead distribution, somewhat better bearing performance is obtained.

(8) The bearing temperatures during the performance tests were considerably lower with the straight copper-lead bearings than with the solid solution bronzes because of the higher thermal conductivity of the copper-lead alloys.

(9) It is practicable to produce steel-backed copper-lead bronze or leaded bronze bearings by a centrifugal casting process.

(10) A strong joint between the steel and bearing metal can be obtained if the steel shell is at or preferably above the melting point of the bronze when it is poured into the shell.

(11) The rotational speed for a 2 to 3 in. diameter bearing should be about 1500 r.p.m. for solid-solution bronzes. Any speed between 1000 and 2000 r.p.m. may be used for straight Cu-Pb alloys.

(12) It is suggested that a bath of tin bronze or pure copper without lead be used for preheating the steel shells to avoid the poisonous fumes from vaporized lead. The preheating temperature of the shells in the case of solid-solution bronzes should be 1100 to 1150 deg. cent.; in the case of straight Cu-Pb alloys, it should be around 1150 to 1200 deg. cent.

ACKNOWLEDGMENTS

The authors wish to acknowledge their indebtedness to the Westinghouse Electric and Manufacturing Co., in whose laboratories this work was done, for permission to publish the results. Helpful advice and criticism were given by G. B. Karelitz. Acknowledgment is also due to P. H. Brace and J. M. Lessells for encouragement of the work and to S. E. Amos and E. I. Larsen for assistance in the various tests.

Discussion

W. TRINKS.[5] It is well known that copper-lead alloys are excellent for light pressures. At most of the exhibits of mechanical engineering we see a salesman clamping a bearing of this material on or against a very rapidly revolving shaft without any lubrication. The bearing pressure is so selected that the bearing material finally becomes red hot. It is then allowed to cool and taken apart, and the salesman impresses upon the spectators that no harm has been done either to the bearing or to the shaft.

For heavy pressure the story is quite different. In 1923 it was the writer's goodfortune to make tests under conditions approaching those of a roll-neck bearing. A pressure was used of 3000 lb. per sq. in. and a rubbing speed of almost 800 ft. per min. A few grades of babbitt did well, but the copper-lead alloys failed markedly. As the pressure was increased gradually, the bearing behaved well until a pressure of 900 lb. per sq. in. was reached, and then the reading of the ampere meter suddenly shot up and the bearing became quite hot. In order to eliminate accidental happenings the test was repeated several times, with the same results. The copper-lead alloy bearing was then removed and the babbitt was substituted, when pressures up to 3000 lb. per sq. in. could be carried without any trouble. The copper-lead alloy was tried once more, and again it began to smoke at 900 lb. per sq. in. This test convinced that copper-lead alloys are not suitable for high pressures. The lubrication engineer of a large steel company states that he is not allowed to use copper-lead alloys for mill bearings.

ROBERT D. PIKE.[6] The writer would be interested in receiving some information on intended versus actual composition of centrifugally cast straight copper-lead alloys particularly as applying to Figs. 44, 45, and 46. As a result of several years' experience in making similar microstructures by centrifugal casting, the writer concluded that in order to get a centrifugally chill-cast straight copper-lead bushing averaging 25 per cent of lead, one must start with about 27.5 per cent in the pot; and if the melt were centrifugally cast into hot backs, invariably the actual analysis of the copper-lead liner showed 20 per cent of lead or less. The authors show a considerable reduction of lead intended versus lead introduced in the sand and chill castings, but give no parallel information in the case of centrifugal castings, where such information would, it is thought, be of great interest.

It has been the writer's experience that in centrifugal casting the lead is thrown out bodily, and nothing discernible in the microstructure would lead one to suspect that lead had been lost. Analysis alone will show this.

There also appears to be some discrepancy between the statement that all centrifugally cast joints were weak on the ends and that satisfactory working conditions were not obtained with the straight copper-lead alloys and the statement that all the bonds between straight copper-lead and steel were good. It need scarcely be pointed out that any process for making a satisfactory bearing in the commercial sense must produce a bond practically 100 per cent perfect over the entire bearing in all bearings. Short of this the bearings will fail disastrously in heavy-duty service.

(Discussion by J. R. Adams and E. S. Glauch will be found following the paper by S. M. Weckstein.)

AUTHORS' CLOSURE

With regard to the remarks of Prof. W. Trinks, it is our opinion that the alloys which he used in his tests in 1923 were copper-lead bronzes—in other words, solid-solution alloys. We believe that with our straight copper-lead alloys, especially if centrifugally cast, better bearing performance under high pressure could be obtained on account of the higher heat conductivity, which as we have shown is about six times that of a solid-solution bronze.

Unfortunately we are unable at the present time to furnish the information requested by Mr. R. D. Pike, since no chemical analysis of the centrifugally cast alloys was made. We agree, however, with Mr. Pike's assumption that in centrifugally casting, a certain per cent of lead is lost. With regard to his statement in the last paragraph we wish to point out that the weakness of the joint on the ends of the bearings was entirely due to unsatisfactory experimental conditions and can be easily overcome.

Application of Impregnated Fabric Bearings to Roll Necks

By ARTHUR J. SCHMITT,[1] CLEVELAND, OHIO

The suitability of celoron for roll-neck bearings has led to widespread use of the product in that field. Its resilience allows bearings to absorb severe impact loads without permanent deformation. Celoron bearings are most commonly lubricated with water, in which case the rate of wear and the power consumed in friction are much less than those of metal bearings. The application of a superior lubricant such as oil or grease improves their performance appreciably. Celoron bearings serve most efficiently on highly polished roll necks, and they have produced substantial power savings in comparison with metal bearings, and their life in numerous installations has been found to be many times that of metal bearings.

BEARINGS are made from several varieties of phenolic materials, which differ somewhat with respect to their method of manufacture, as well as in their properties. The statements which follow may be applicable in general to any phenolic material, but they should be considered as applying specifically only to the particular phenolic substance which is called "celoron."

Manufacture and Properties of Celoron. Celoron is manufactured by impregnating sheets of woven fabric, such as linen or cotton duck, with resin, superimposing one sheet upon another to provide the requisite thickness; then subjecting the laminated mass to accurately controlled heat and pressure in massive hydraulic presses. The simultaneous application of heat and pressure, called curing, converts the resin and fabric into a dense, hard, tough substance which is suitable for a wide variety of uses.

The hardness of celoron is about 40 Brinell. The material is considerably stronger in compression than in tension, having a compressive strength of about 35,000 lb. per sq. in. as compared to its tensile strength of 17,000 lb. per sq. in. It is resilient as well as being hard and tough, and is often molded to final shape, although it can be machined easily. Because of its laminated structure, celoron has definite directional properties; that is, its properties at right angles to the plane of laminations are not precisely the same as those parallel to that plane. The strength, hardness, toughness, and resilience, if necessary, can be modified within certain limits by means of minor variations in the characteristics of the resin and fabric and in the curing operation.

One of the earliest practical applications of celoron was in the construction of gears, piping, and agitators for use in chemical plants. The material is particularly well suited to this type of service because of its extremely great resistance to the corrosive effect of acids and other liquid chemicals, as well as its ability to withstand considerable mechanical abuse. Its suitability for use as a bearing material first became apparent when a chemist, eager to find a bearing material which would not be subject to rapid corrosion, constructed and installed some bearings made of celoron. This experiment resulted in performance so gratifying that the construction of this type of bearings continued and was rapidly carried into other industries.

Following this development, a comprehensive investigation was undertaken for the purpose of definitely adapting celoron to bearing use. This investigation demonstrated the capability of such a bearing to render satisfactory service under adverse conditions. It was found, also, that this characteristic could be improved for certain purposes by incorporating a lubricant in the material at the time of manufacture. Celoron is now often produced with an admixture of graphite, which is compounded with the resin, so that its distribution is uniform throughout the material. About 5 per cent of graphite is the maximum proportion which can be included in this way without impairing the strength of the material. The marked suitability of those bearings for service under adverse conditions suggested their application to roll-neck bearings; and their worth in this field, as in many others, has been proved by abundant experience.

Characteristics of Celoron Roll-Neck Bearings. The conditions under which roll-neck bearings operate are, without doubt, more severe than those of most other bearing applications. Roll-neck bearings are traditionally heavily loaded and poorly lubricated, and in some cases they are subjected repeatedly to severe impact loads. The constant presence of scale and other injurious substances constitutes an additional detrimental circumstance. Moreover, excessive wear of roll-neck bearings is extremely objectionable, because it may cause the rolled product to be off gage, and because it involves frequent delays for adjustment or replacement of bearings.

The degree of performance which may be expected from celoron roll-neck bearings is indicated by the following description of their characteristics:

Load-Carrying Capacity. In numerous installations, celoron bearings carry loads ranging from 1000 to 2500 lb. per sq. in. of projected bearing area. In one particular installation, where the space is severely limited, a load of 5000 lb. per sq. in. is carried. These figures compare favorably with the load-carrying capacities of other types of bearings.

Absorption of Impact Loads. Celoron bearings are resilient and are thereby able to absorb and distribute impact loads over the entire bearing area, so that excessive wear due to impact or vibration is avoided. As an illustration of this characteristic consider a piece of celoron which rests upon an anvil and which is struck with a hammer. The resilience of the material will allow it to distribute the force of such an impact so that the surface will not be injured, whereas an identical piece of bronze subjected to an identical impact would become distinctly dented or deformed.

[1] District Manager, Continental-Diamond Fibre Company. Mr. Schmitt received his education in the Chicago public schools and worked for several automobile manufacturers. He organized and was president of the Walnart Electric Manufacturing Company, of Chicago, from 1923 to 1928, when it was merged with the Continental-Diamond Fibre Company.

Contributed by the Special Research Committee on Heavy-Duty Anti-Friction Bearings and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

A considerable part of the long life of celoron bearings is attributed to this characteristic.

Coefficient of Friction. The coefficient of friction of celoron bearings, like that of other types of bearings, is quite variable and depends upon several factors. Its value under certain conditions have been observed in laboratory tests. The average coefficient of friction of plain celoron as determined in laboratory tests (shaft speed about 225 ft. per min.) is as follows:

Lubricant	Load (lb. per sq. in. of projected bearing area)		
	1500	2500	3500
Oil	0.040[a]	0.060	0.070
Water	0.042	0.063	0.076[a]
None (dry)	...	0.370	...

---

[a] Estimated.

These data apply only to plain celoron which has not been impregnated with graphite. The coefficient of friction of bronze bearings, observed in similar tests, has been found to be either slightly less or considerably greater than that of celoron, depending upon the type of bronze. The values listed were observed under conditions which were not comparable to those under which roll-neck bearings operate. Consequently, the coefficient of friction of celoron roll-neck bearings for given conditions of load and lubrication may differ somewhat from the corresponding value given.

In general, the significant facts are, first, that celoron bearings carry capacity loads with very moderate friction losses when water only is used as a lubricant; second, that the friction losses under capacity loads are minimized when oil is used as a lubricant; third, that with no lubrication whatever, capacity loads can be sustained for limited periods of time without destruction of the bearings.

Statements of power saving through the substitution of one type of bearing for another have little direct significance without accompanying statements of the circumstances. Although very large power savings have been made in certain cases by the use of celoron bearings, the circumstances in such cases were perhaps somewhat exceptional and would be of little general interest. Records show many actual cases, covering a range of more nearly average conditions, in which substitution of celoron for metal boarings has effected power savings considerably in excess of 10 per cent. It may be safe, therefore, to predict a minimum power saving of 10 per cent through such substitution, provided that the conditions, whatever they may be, remain unchanged.

Rate of Wear. The rate of wear of celoron, like that of other roll-neck bearings, is affected by many factors, such as load, lubrication, temperature, presence of foreign matter, and surface condition of the roll neck. Laboratory tests have indicated that the rate of wear increases slightly with increasing loads, as would be expected, and that the substitution of oil for water as a lubricant, other conditions remaining the same, results in a very marked decrease in the rate of wear. Comparative results obtained in practice show clearly that the condition of the roll-neck surface has an extremely great influence upon the rate of wear. Rough roll necks, being harder than celoron, have a filing effect upon the bearings, and although the roughness may ultimately be worn off the roll necks, a considerable portion of the bearings is likely to be sacrificed during the process. This leads to the interesting corollary that, if the roll necks carried in celoron bearings are initially smooth, they remain smooth and become highly polished during use, being subjected to almost negligible wear. The mirror-like surface, which celoron bearings impart to roll necks, not only reduces the wear of both neck and bearing, but is also partially responsible for the low coefficient of friction of these bearings.

The rate of wear is much less than that of most metal bearings operating under identical conditions. This comparison can probably be expressed most conveniently in terms of the tonnage rolled during the lift of the bearings. Experience has indicated that the tonnage ratio, with rolling and lubrication conditions unchanged, is 3 to 1 in many instances, and frequently even greater, in favor of celoron as compared to metal bearings.

In addition to the rate of wear, there is one salient difference between celoron and metal bearings from the standpoint of wear. Metal bearings, as is well known, wear more rapidly at the edge nearer to the roll body due to the deflection or spring of the rolls. This, together with the rigidity of the bearings, frequently causes the contact between the bearing and roll neck to be restricted to the bearing edge. The result is that the portion of the bearing nearer to the roll body gradually assumes a conical shape, while the outer portion of the bearing remains nearly cylindrical, so that however much or little the roll may deflect, the load must always be carried on a limited portion of the bearing area. When celoron bearings are used, however, the resilience of the material allows the bearing to follow the deflection of the roll neck, at least to some extent, so that the load, although slightly limited in distribution, can be supported on a larger bearing area than in the case of metal bearings. Consequently, the wear is more evenly distributed than with metal bearings.

Lubrication and Maintenance. It has already been mentioned that celoron bearings serve satisfactorily when water only is used as a lubricant. In this case, although the application of large quantities of water is not essential to successful operation, it doubtless serves to prolong bearing life by removing or preventing the entrance to foreign matter. It is known also that the increased cost of lubrication with oil or grease, instead of water, is more than compensated for by reduced friction losses and extended bearing life. Oil and grease have no destructive effect upon celoron, and they may be used as freely as desired. It has been found in practice that these bearings can be operated for short periods of time with no lubrication whatever. Operation without lubrication is not recommended, of course, but there is a distinct advantage in using bearings which can withstand such an emergency.

No particular care is required in the storage and maintenance of celoron bearings. They differ in this respect from wood bearings, which must be handled carefully and kept somewhat moist in order to prevent splitting. Celoron is unaffected by moisture or dryness, and can be stored indefinitely with depreciation. The life of such bearings can probably be extended by inspection and cleaning of the bearing surfaces during roll changes, although this precaution is not essential.

Cost. In general, the first cost of molded celoron bearings is comparable with that of bronze of lignum-vitae bearings of the same size. The first cost of a machined bearing may be somewhat higher, because of the additional material and labor which are involved in cutting a bearing out of a solid block. The cost of molds is not excessive; hence, molded bearings can be produced economically whenever about 200 bearings of the same size are required annually. The dimensions of molded bearings are held to a tolerance of 0.030 in. or less, depending upon the size of the bearing, so that no machining whatever is required.

The first cost is certainly not prohibitive. The fact should be emphasized, in addition, that the ultimate cost of roll-neck bearings involves not only the first cost, but also the length of life, cost of lubrication, cost of the power consumed in friction, continuity of operation, and maintenance of uniform gage in the rolled product. Comparison has already been made between celoron and metal bearings with respect to length of life and power losses in friction. With regard to the maintenance of uniform gage in the rolled product the following statement will be of interest: A producer of automotive axle stock in the Buffalo district, after installing celoron bearings, reported that off-gage rejections had been reduced from 7 per cent of total production to practically zero. Inasmuch as fewer shutdowns are required for the adjustment or replacement of bearings, the continuity of operation, in comparison to metal bearings, is greater. For these reasons, the ultimate cost of bearings is likely to be appreciably less than that of any other type of bearing which is in common use at the present time.

Design. The principles of design of celoron roll-neck bearings are quite simple. In addition to the elementary specifications (length and diameter of roll neck, radius of fillet at roll neck, and dimensions of bearing chock), only two precautions need to be observed: First, the thickness of the bearing section should not be more than 1 in. for neck diameters up to 20 in., to insure accuracy of rolling; second, the plane of the laminations of the material should be perpendicular to the axis of the roll neck, to provide the maximum resistance to wear.

The absorption of end thrust by bronze roll-neck bearings often calls for some special feature, such as overhanging section or a separable thrust collar. With the use of celoron bearings, no special provision is required unless the end thrust forces are unusually great, in which case provision can be made as readily as with bronze bearings. In any case, the portion of the roll-neck fillet or roll body which transmits end thrust should be smoothly polished to minimize the wear of the thrust surface.

Applications. Celoron roll-neck bearings have been applied successfully to a great many rolling mills of different types, such as bar, billet, sheet, strip, skelp, and rod mills. The experience which has been gained, by means of these applications, has shown conclusively that these bearings can be used advantageously under a wide variety of rolling conditions.

Conclusions. Celoron bearings, like other types of bearings, perform most efficiently under ideal conditions. Unlike many other types of bearings, however, these bearings perform quite well under adverse conditions. Consequently the advantages of their use are most evident when inadequate lubrication or excessive scale and grit make long-continued bearing operation very difficult, as in most rolling mills. This, being the chief distinction of celoron bearings, merits emphasis. It is regretted that the wide variability of the factors which enter into rolling-mill operation precludes a more extensive use of numerical data. It is hoped, however, that even with meager numerical data, the general statements which have been given will be of some assistance in the judicious selection of roll-neck bearings.

(Discussion by J. R. Adams and E. S. Glauch will be found following the paper by S. M. Weckstein.)

IS-54-5

Application of Tapered Roller Bearings in Merchant-Bar Mills

By S. M. WECKSTEIN,[1] CANTON, OHIO

Tapered roller bearings have played an important part in the numerous developments in the art of rolling metals. Their use has made possible a considerable decrease in the consumption of power by the elimination of friction, a considerable decrease in the cost of the electrical equipment required, a decrease in the cost of lubrication and general maintenance, an increase in the speeds of operation and consequently the tonnage produced, and a marked increase in the accuracy of the product. In this paper the actual experience, over a period of five years, in the proper design, mounting, and operation of bearings in merchant-bar mills is discussed. Extracts are given from the results of a series of power tests made on the same mills alternately equipped with plain and tapered roller bearings. Various means of lubrication of rolling mills, pinion stands, and gear drives are cited. The design of suitable bearing closures is also taken up and shown in detail. The illustrations shown are of equipment in actual operation in various mills.

THE art of rolling metals has seen numerous developments during the past few years. The general trend in industry to bring down manufacturing costs by a reduction in the number of operations has resulted in a tightening of specification on the material to be fabricated. This demand for higher standards and for a greater variety of special sections held to close tolerances has largely dictated the adoption of new equipment and new rolling practices.

It is natural that in rolling-mill equipment the bearings should come in for considerable investigation. Upon them falls the responsibility of decreasing the power consumption by the elimination of friction, decreasing the cost of the electrical equipment required, decreasing the cost of lubrication and general maintenance, increasing the speeds of operation and consequently the tonnage produced, and increasing the accuracy of the product. The importance of these points is very clearly illustrated in the number of cluster, four-high, and two-high mills for the rolling of strip and sheets and three-high and two-high merchant-bar mills for the rolling of ferrous and non-ferrous materials that have been built with anti-friction bearings in the last few years and that are now under contemplation. A study of these various installations would be very interesting. Because of the extent of the subject this paper will be limited to the use of anti-friction bearings in merchant-bar mills.

Tapered roller bearings have been successfully applied in merchant-bar mills and have the following advantages. With them it is possible to obtain perfect alignment and accurate setting of the rolls and to maintain this setting indefinitely. This is due to the fact that the wear in the bearings is practically negligible. It is possible to make provision on the mill for adjusting devices so that the setting of the rolls can be changed by any required increment in a minimum of time. With this accurate control of the mill, a product held to close tolerances is assured.

The bearing can be set with the required amount of radial clearance to suit the individual mill. In other words, by varying the lateral looseness of the bearing the desired amount of radial clearance can be obtained to suit either the roughing, intermediate, or finishing stand. The product can therefore be controlled all along the line, and proper tolerances can be maintained. Also because of the ability of the bearing to carry thrust as well as radial loads, accessory bearings or thrust washers are eliminated. The simplicity of the mounting and the ease of roll changes and roll setting are illustrated in Figs. 1 to 3, which feature an application on an 18-in. three-high bar mill.

Fig. 1 shows a general arrangement of the mill. The same size of bearing is used on all the roll necks, and the mounting is the same with the exception of the floating end of the middle roll. Each bearing is assembled in a bearing box, forming a complete unit that can readily be slipped on and off the roll neck. The bottom roll and bearing boxes are fitted directly into the mill housing. The middle-roll bearing boxes are made so that the top-roll bearing boxes can be fitted into them. In this way it is possible to locate positively the middle box on the ledge in the housing by means of wedges under the housing cap. The bottom roll is carried on the bottom screw, while the top roll is balanced from the top lifting rods. The right-hand half of the end view shows the fixed end of the mill, while the left-hand side shows the floating side of the mill.

Figs. 2 and 3 show the detail construction. Fig. 2 shows on the right-hand side the construction used for the fixed end of the top and bottom rolls. Each bearing is mounted as a unit in the bearing box, and the entire assembly, together with inside and outside filler rings, is slid on the neck and clamped by means of the nut shown. To reduce the cost of the rolls and eliminate threading them, a groove is cut in the neck and a two-piece threaded ring is fitted and doweled in the groove. The nut is bolted to the keyed filler ring after the bearing has been pulled up tight on the neck and against the inside filler ring. To obtain a very fine adjustment increment on the locking arrangement the following scheme is used. The keyed outer filler ring has a proper number of equally spaced tapped holes. The nut has an odd number (one more or one less) of holes drilled in it to receive the locking cap screw. The bearing box is provided with a special flange used for the alignment of the passes. With the bearing fixed to the neck, as described, the entire roll can be moved in or

[1] Industrial Equipment Engineer, Timken Roller Bearing Company. Jun. A.S.M.E. Mr. Weckstein was graduated from Stevens Institute of Technology in 1923 with the degree of M.E. In 1923 he joined the Industrial Engineering Department of the Timken Roller Bearing Company, making a study of the design and application of bearings in industrial equipment. In 1926 he was placed in charge of the department. In 1927 the Industrial Engineering and the Rolling Mill divisions were combined, and Mr. Weckstein took charge. Since that time he has been engaged in anti-friction bearing developments in the rolling-mill industry.

Contributed by the A.S.M.E. Research Committee on Heavy-Duty Anti-Friction Bearings and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

out the desired amount merely by adjusting the push-and-pull nuts in contact with the bearing-box flange.

The construction used on the floating end of the top and bottom roll is shown in the left-hand side of Fig. 2. It will be noted that the bearing mounting is the same as for the fixed end. The bearing box itself is made without a flange and is not located endwise in the mill housing. In this way it can float in the mill housing and properly position itself when pass alignment is made or when roll expansion occurs.

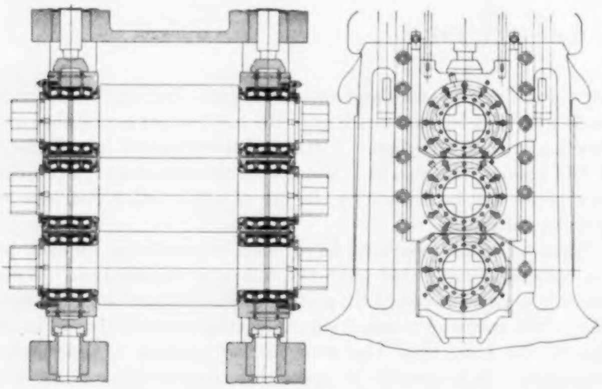

FIG. 1 GENERAL ARRANGEMENT OF THREE-HIGH 18-IN. BAR MILL
(In side view, left side of center line shows floating end and right side shows fixed end.)

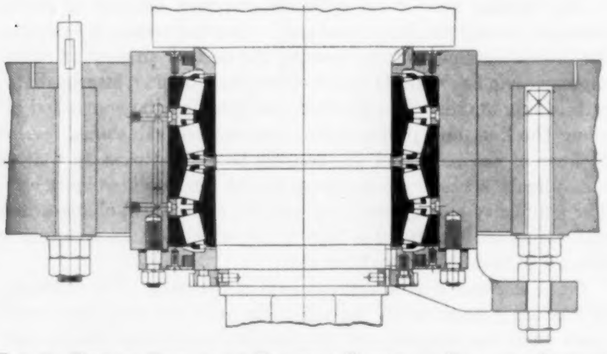

FIG. 2 DETAIL DESIGN OF BEARING BOXES ON TOP AND BOTTOM ROLLS
(Left side of center line shows floating end of top or bottom roll and right side shows fixed end of top or bottom roll.)

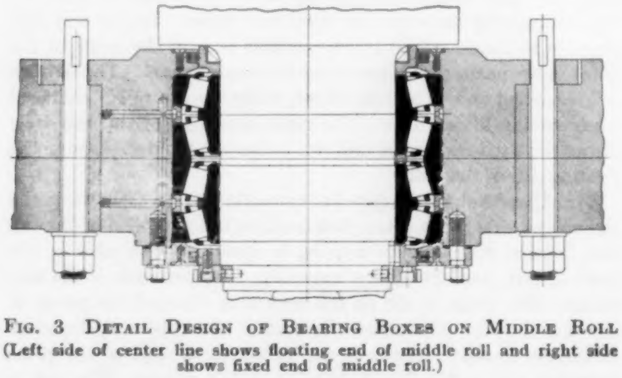

FIG. 3 DETAIL DESIGN OF BEARING BOXES ON MIDDLE ROLL
(Left side of center line shows floating end of middle roll and right side shows fixed end of middle roll.)

The mounting of the bearings on the middle-roll necks is slightly different at each end of the roll, as shown in Fig. 3. The two bearing chocks are made exactly the same and are rigidly clamped down on the ledge in the housing. They are also bolted to the housings through the flanges, as shown. Provision for expansion must therefore be made by the floating of the cones on one of the necks of the middle roll, as illustrated in the left-hand side of Fig. 3. It is to be understood that the roll necks are exactly the same at both ends. The provisions for floating are obtained by a slight change in the design of the inner and outer filler rings. The right-hand half of the illustration shows the fixed end of the roll, which is the same as the mounting used for the bearings of the top and bottom rolls.

The bearings shown in these illustrations are provided with cup and cone spacers. These spacers are ground to exact size so as to give the predetermined running clearance in the bearing and are supplied as part of the bearing. The inner and outer filler rings as well as the cone, or inner race, spacer ring are slotted to permit lubricant to reach the contacting surfaces and also to get down under the races, which are fitted with a given looseness on the roll necks. The grease for lubricating the bearings is supplied from two distinct inlets which register with the annular groove and holes drilled in the cup, or outer race spacers. This assures a uniform supply of lubricant to all parts of the bearings. It also has been found necessary to vent all the bearing boxes to eliminate air pockets, which in many cases caused lack of lubrication, with consequent bearing failures. The closures for retaining the lubricant and excluding water and scale are of special design. The details of the closures will be discussed farther on.

In view of the fact that the bearings are mounted loosely on the necks, it has been necessary to establish the proper looseness for various size necks. It has been found that the clamping arrangement used very definitely retards the amount of neck wear due to the loose fit. It has further been definitely established that on two- and three-high merchant mills in sizes from 28-in. to 16-in. roll diameter, the rolls are worn out long before the neck wear becomes a factor in the operation of the mill.

On smaller mills operating at higher speeds, the more rapid roll-neck wear has dictated a design calling for races fitted tight on the necks, as shown in Fig. 4. This layout features the use of a two-row bearing, but the same principle of mounting has worked out in service in a high-speed mill using four-row bearings. The mounting of the bearings on all the necks is the same. The inner races are fitted with a press fit of from 0.0005 to 0.002 in. tight and in addition are clamped up tight by the same locking arrangement as used on the slower speed mills. The design of the bearing box is altered so as to provide for the easy removal of the bearings. The boxes are made so that the inner closure plate is a separate piece. Also the inner filler ring is provided with a shoulder. When the inner closure is bolted to the bearing

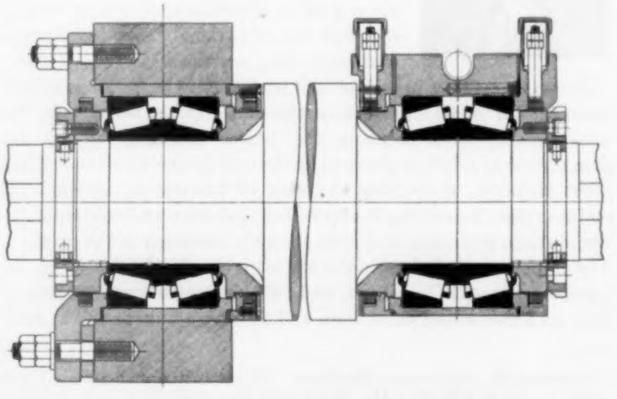

FIG. 4 DETAIL OF BEARING-BOX DESIGN ON ROLL NECKS OF HIGH-SPEED MILLS
(Upper side of center line shows horizontal section through fixed chock and lower side through adjustable chock.)

box, a special split plate from $^{1}/_{8}$ to $^{3}/_{16}$ in. thick is inserted between them. The bearing box, with inner filler ring, inner closure, separating plate, bearings, and outer closure, is assembled as a unit, heated in oil at about 300 deg. fahr., and easily slipped on the roll neck. The outer filler ring and locking nut are then added, and the assembly is complete. To remove the bearings, the split plate is removed, and the inner closure is drawn up tight to the bearing box. The shoulder on the filler ring then contacts with the inner closure, to which pressure can be applied by means of a press or properly designed puller. Very little difficulty is encountered in removing the bearings.

It is interesting in this connection to relate an experience in the removal of bearings mounted in this way on a two-high 12-in. mill operating at a little over 400 r.p.m. The bearings used were of the four-row type and of 6 in. bore. The fit of the bearing on one neck was found to be approximately 0.003 in. loose, and to remove the bearings, it required approximately 43,000 lb. Another bearing was found to be 0.0003 in. loose, and it required 35,000 lb. to remove the bearing. The third bearing was found to be 0.0002 in. tight, and 28,000 lb. was required to remove the bearing. The fourth bearing was 0.0007 in. tight, and only 15,000 lb. was required. This evidently shows that with the loose fit and the high speed the inner races creep excessively on the necks, roughing them up. There also is evidence of corrosion or oxidation between the neck and the races, making it hard to remove them. In other words, with the fit held somewhere between the limits of 0.0005 to 0.002 in. tight, the least amount of force is required to remove the bearings.

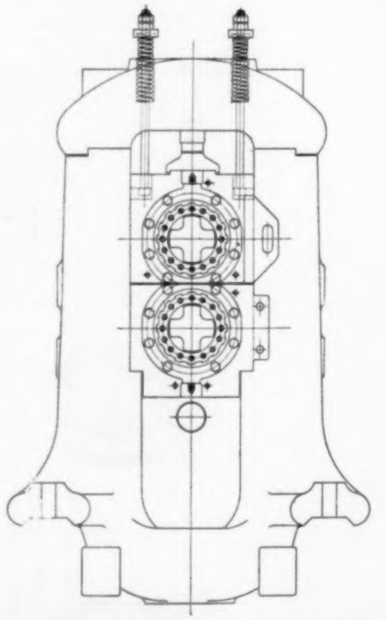

Fig. 5 General Arrangement of Two-High Mill

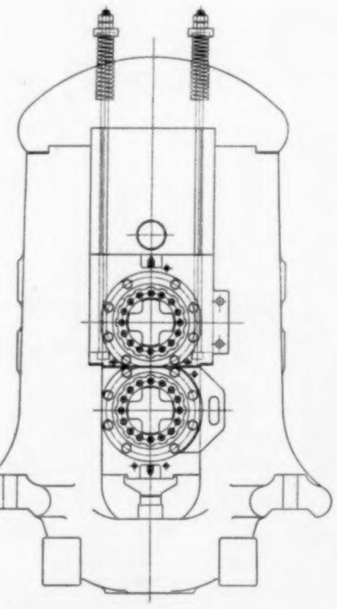

Fig. 6 General Arrangement of Two-High Mill

Referring again to Fig. 4 it will be seen that in a two-high mill one roll can be fixed and the other be made adjustable for pass alignment. On both rolls the boxes at one end are permitted to float to take care of expansion and ease of pass alignment, as previously described. The upper left-hand section shows the method of attaching the fixed roll to the housing. The lower left-hand section shows the scheme used to obtain pass alignment. The bearing box is made with a special flange, between which and the housing an adjustable wedge is inserted. By loosening the nuts holding the flange, the wedge can be adjusted in or out to give the desired setting of the passes in the rolls. A more detailed view of the construction of the closures is shown in the upper right-hand section. The lubrication is the same as for the lower-speed mills.

Figs. 5 and 6 show end views of the general arrangement of the bearing boxes in the mill housings. Fig. 5 shows the arrangement of the middle and top roll with the through spindle at the bottom. Fig. 6 shows the spindle at the top. In both cases the middle roll is fixed, while the top or the bottom roll is adjustable.

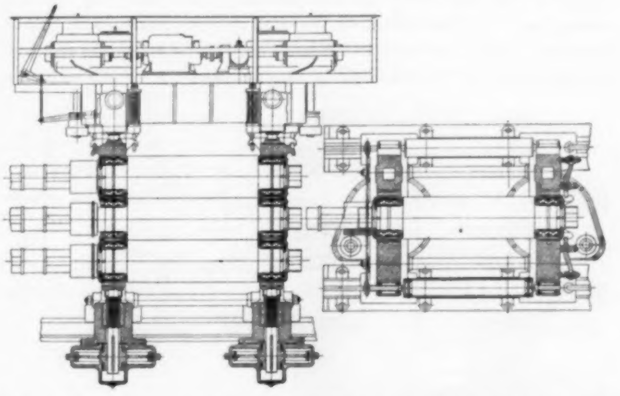

Fig. 7 Method of Aligning Roll Passes on 28-In. Three-High Mill

Before leaving the subject of the mills themselves and proceeding with pinion stands and drives, it will be interesting to study a few other methods, very successfully used on other mills, for the aligning of the passes on the rolls. Fig. 7 shows the design of the 28-in. three-high bar mill used in the plant of the Timken Steel and Tube Company. The general construction is the same as discussed for the other mills. The pass-alignment feature is different, as can be seen in the right-hand section. The bearing box is provided with lugs in which slots are machined. Special clamps fitting into the slots are bolted to the mill housing. By the use of ball seats and special washer, proper functioning of the clamps can be obtained from the push-and-pull nuts at the extreme ends. The holes in the clamps are elongated so that the clamps can be slid out of the way when a roll change is made. This design has worked out satisfactorily on this mill with one exception—the slots in the lugs pounded out. This was remedied by remachining them and inserting hardened steel liners or wedges.

Vertical mills, and especially vertical finishing mills, require suitable means for the alignment of the roll passes. The design shown in Fig. 8 shows the general application of the bearings on an 11-in. vertical finishing mill which has been in service for about two years. The mounting of the bearings is practically the same as for the horizontal mills. The closures must be more positive, and consequently flingers forming labyrinths have been utilized. The rolls are hung from the top bearing boxes. The bearings, because of their thrust carrying capacity, easily support the weights of the rolls and boxes and the thrust loads from rolling. The bottom boxes are permitted to float so as to take care of roll expansion and not to interfere with pass alignment, which is obtained from the top box, as shown in Fig. 9. The top bearing closure cap is designed with an extension having six threads per inch. A special bracket is bolted to the mill housing and attached to the threaded extension of the bearing box cap by means of two jam nuts and a specially designed adjusting plate. The bracket has 23 equally spaced holes and the adjusting plates 24 equally spaced holes. By loosening the jam nuts and by tightening or loosening the adjusting plate an increment of vertical rise and fall of the roll of 0.0003 in. can be obtained. When the desired set-up is reached the adjusting plate is locked to the bracket by means of a pin inserted in the two mating holes. The jam nuts are brought up tight to hold the set-up rigidly.

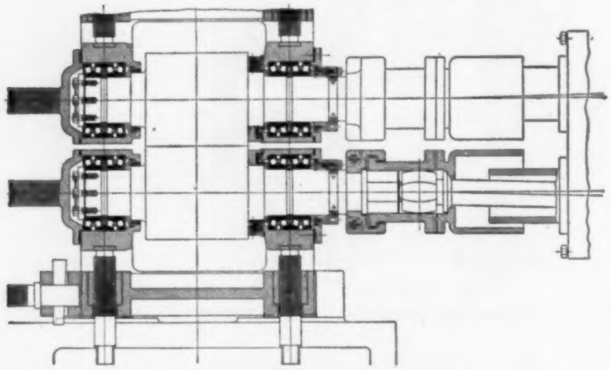

Fig. 8 General Arrangement of 11-In. Vertical Mill

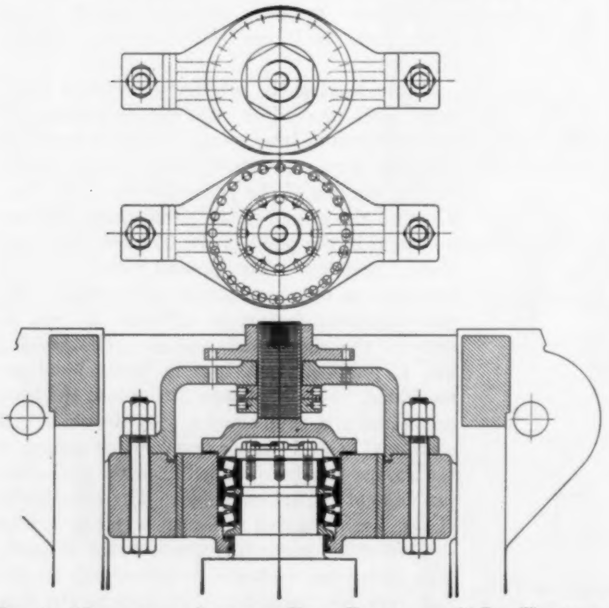

Fig. 9 Method of Aligning Roll Passes on 11-In. Vertical Mill

Pinion Stands

The application of tapered roller bearings on pinion stands has kept in step with their use on the roll necks themselves. In view of the lighter loads, less capacity has been required, and as a general rule one-half of the roll-neck bearing is used on the pinion necks; in other words, where a four-row bearing is used on the roll neck, a two-row bearing is used on the pinion neck. Originally the bearings were mounted loose on the pinion necks without clamping in order to allow for the float of the double-helical pinions. This type of mounting is gradually being abandoned in favor of the design shown in Figs. 10 to 12, which show the general arrangement of three-high and two-high pinion stands and a detail of the bearing mounting on the neck. It will be noted from these figures, and especially by reference to Fig. 12, that each bearing box is provided with a flange which is bolted to the pinion housing, thus positively locating the bearing boxes. The inner races are mounted on necks with a tight press fit. The outer races are given a loose fit in the bearing boxes, permitting them to float. The amount of float is controlled by the pilots on the closure plates. The outer closure plates are machined so as to permit about $^1/_8$-in. float. The inner closure plate pilot is cut off short, since its only function is to properly pilot the closure. The bearings, in addition to being press-fitted, are clamped on the necks by means of the usual locking arrangement. The inner and outer filler rings act as additional closures to retain the lubricant in the bearing boxes and to keep out the gear lubricant. To remove the bearings from the necks it is necessary only to take the assembled pinion and bearing boxes out of the stand, remove the locking nut on the neck, and

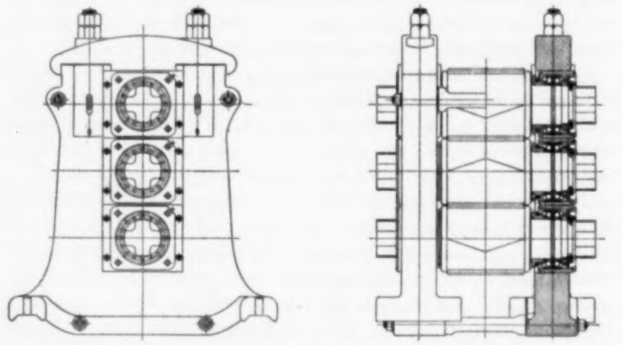

Fig. 10 General Arrangement of Three-High Pinion Stand

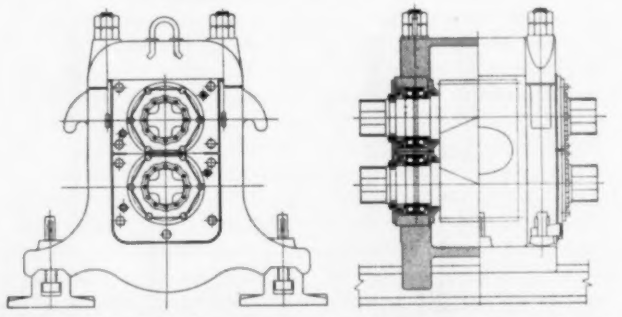

Fig. 11 General Arrangement of Two-High Pinion Stand

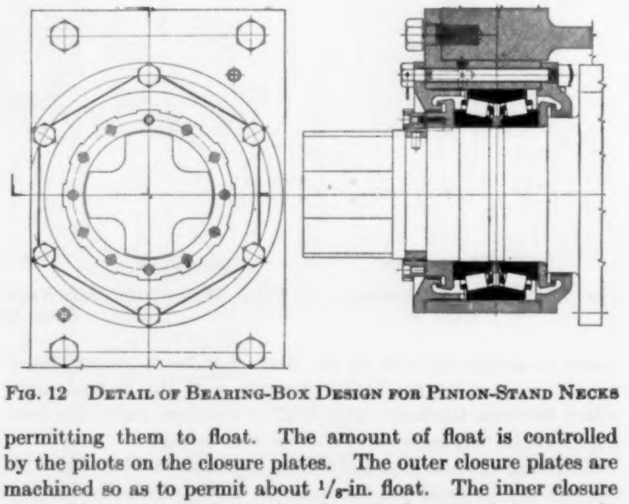

Fig. 12 Detail of Bearing-Box Design for Pinion-Stand Necks

apply pressure to the inner closure plate, which will automatically come in contact with the inner filler ring and push directly on the inner races. The bearing box, bearings, and closures can at all times remain as an assembled unit.

For the lubrication of the pinion-stand bearings, either grease or oil may be used and introduced to the bearings as shown in Fig. 12. It is important that the bearing box be properly vented.

Gear Drives

With the general increase in the speed of rolling and with the further development of the continuous and semi-continuous merchant-bar mills, gear drives have been called upon to operate at much higher speeds than ever before. To make this practical, anti-friction bearings were installed. Tapered roller bearings have been especially desirable because of their ability to carry the thrust loads from the mills and gears. A number of various designs have been worked and have proved satisfactory in service over a period of more than five years.

Fig. 13 shows a typical single-helical-gear reduction unit. A double bearing is fitted tight on each end of the shaft and properly enclosed in a bearing box. The bearing box at one end is machined with an annular projection which fits into a groove in the gear housing and cap. This box rigidly locates the shaft against endwise movement and carries the axial loads. The opposite box is made similar except that the annular projection is machined off, thus permitting the box to float and take care of variations in machining and expansion. Each box is fitted with a round dowel pin extending down from the cap to prevent possible rotation of the box in its seat. This dowel pin is drilled so that the lubrication pipe can be threaded into the bearing box. The design, as shown in Fig. 13, is developed for separate lubrication of bearings and gears. The bearings are completely enclosed and isolated from the gears. The bearing boxes may be packed with grease or a level of oil may be maintained. This design is suitable for relatively small bearings operating at low speeds.

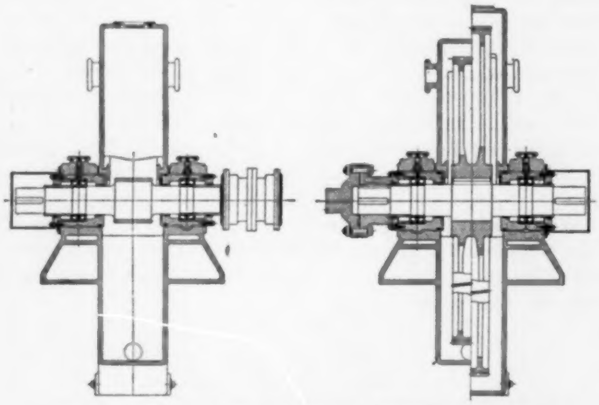

FIG. 13 SINGLE-HELICAL-GEAR REDUCTION UNIT

In quite a number of gear units using larger bearings and operating at higher speeds, it has been found necessary to incorporate more complete lubrication systems in order to keep the temperatures down. This has been accomplished in two ways. In one case the bearings have been completely isolated from the gears and a complete circulating oil system has been used to lubricate them. The oil is introduced between the bearings, and the returns from the bearing boxes are located so as to maintain an oil level around the bearings. The amount of oil to be circulated through the bearings is best determined by a careful check during the operation of the unit. In a number of other cases it has been found possible to lubricate the bearings satisfactorily from the splash of the gears. In these instances the inner closures on the bearing boxes are omitted, and the designs are made so that a level can be maintained around the bearings, with the excess oil overflowing into the gear case. To assure positive lubrication of the bearings it has been found best to locate baffles on the inside walls of the gear case. The splash from the gears is caught in these baffles, and is drained from these by means of pipes direct to the bearings. It is necessary to drill and tap the sides of the case at the baffles to receive the pipes which should carry the oil to the proper point in the bearing boxes. In this system it is important that the quality of the oil be such as to properly lubricate both gears and bearings.

Another satisfactory method of bearing mounting in gear reduction units is illustrated in Fig. 14. In this design the bearings are lubricated from the splash of the gears. The cost is considerably reduced by the elimination of the bearing cartridges featured in Fig. 13 and the mounting of the bearing direct in the gear case. For this purpose two-row bearings having unit outer races are used. The design shown is worked out for double-helical gears. The low speed or take-off shaft is fixed against endwise movement by means of the center bearings, thus taking care of the thrust from the mill and from the gears. All the other shafts are allowed to float so as to properly mesh with the mating gears. Another feature of this design is that the bearings shown are set at the bearing factory by means of spacers between the inner races. This completely eliminates the necessity of bearing adjustment during the assembly of the unit.

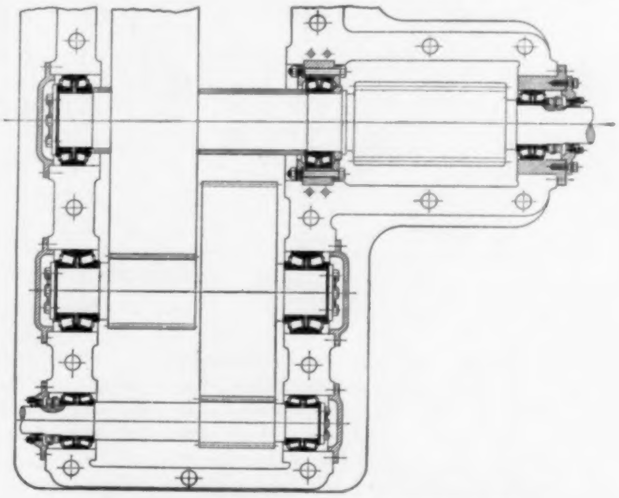

FIG. 14 DOUBLE-HELICAL-GEAR REDUCTION UNIT

Closures

In the preceding illustrations there have been shown various closures that have been used on the mills, pinion stands, and drives. The mill bearings, due to the presence of water and scale, naturally require a more positive closure than do the other applications. After considerable testing had been done, a closure was developed that has proved efficient under bad water conditions, and a small model was built. (See Fig. 15.) The bearing mounting is the same as that used on the actual mills. The closure consists of a strip of metallic packing properly jointed at the ends with a flexible joint. This packing rides on the outside diameter of the inner and outer filler rings. Around this packing is used a thin steel band, the two ends of which are drilled with a small hole to permit of connecting them with the specially designed threaded adjusting bolt which fits into a collar. This collar is round in the body, but upset at the bottom to keep

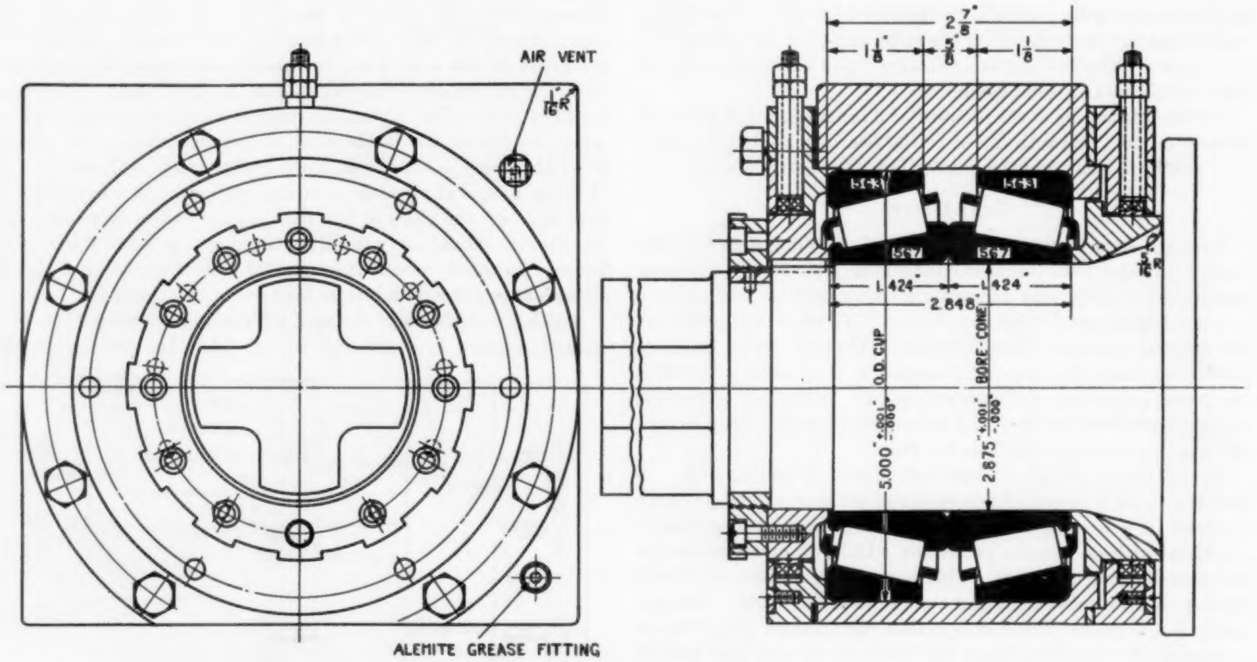

Fig. 15 Details of Clock-Spring Closure

it from turning when inserted in the closure plates. By tightening the two nuts on the adjusting bolt, the required fit of the packing on the filler ring is obtained. In mills where other closures were used ineffectively to keep water and scale out of the bearings and to stop grease leakage, this type of closure has practically eliminated both conditions. A slight improvement over this design has been made by the addition of threaded pipe caps to protect the adjusting nuts, as shown in Fig. 4. Another improvement is being contemplated in that tests are now being made on the possibility of making this closure automatically adjustable by the addition of suitable springs.

It will be of interest to cite some savings in power and maintenance that are being obtained by the use of anti-friction bearings. In a series of power tests made by the General Electric Company at the plant of the Timken Steel and Tube Company it was possible to make comparative tests on two stands of 22-in. three-high mills equipped with plain and with Timken bearings. The tests were made while rolling 8-in. by 9-in. blooms down to 2$^{11}/_{16}$ in. square in 15 passes, 7 passes being taken in the first stand and 8 passes in the second stand. The steel rolled was carbon 0.45, manganese 0.67, and nickel 3.50. Table 1 shows the results obtained.

From these results and from other tests and study of merchant mills equipped with anti-friction bearings a power saving is indicated of from 25 to 50 per cent, with an average saving of about 35 per cent. This means a large saving, in building a new mill, on the cost of the electrical equipment.

TABLE 1

Plain bearings		Timken bearings		Per cent
Roll speed	Hp-hr.	Roll speed	Hp-hr.	saving
83.5	30.653	82.5	15.800	48.5
71.0	25.001	75.2	14.888	40.5
61.0	25.874	63.2	13.362	48.3
52.0	22.806	52.7	13.546	40.6

The saving possible on the cost of lubrication is also an important item. In Fig. 7 is shown a 28-in. three-high mill. This stand is one of a complete unit consisting of two stands of 28-in. three-high mills and one three-high pinion stand. The mills are equipped with bearings of 16 in. bore, 24 in. outside diameter, and 12$^1/_2$ in. wide. The pinion stand is equipped with two bearings, each of 16 in. bore, 24 in. outside diameter, and 3$^5/_8$ in. wide, separated by a spacer so as to make the bearing box practically as wide as the mill bearing box. These 12 mill bearing boxes and 6 pinion-stand boxes consumed 350 lb. of grease in one week's operation of 24 hours per day. This is equal to 58.3 lb. of grease per day, or 3.25 lb. of grease per day per box.

With the further improvement being made in the bearing design and mounting and the improvement in closures and general operating condition, greater savings in power and maintenance may be expected.

Discussion

A. G. Witting.[2] There of course cannot be any question about the desirability of having the bearing-friction losses in a rolling mill reduced to a minimum nor that the anti-friction bearing of the roller type may be particularly suitable. Such bearings may, besides, offer special advantages for cold-rolling mills and sheet mills or in general for mills where the gage tolerances are extremely small.

There may, however, be two sides to the question when this type of bearing is urged for mills rolling ordinary merchant-bar products. It has been brought out in the paper and the discussion that the greater difference in roll and roll-neck diameters may require more expensive material for the rolls; also, much more accurate machining, including polishing of the roll necks, will be necessary, and the question may be raised if this additional cost brings corresponding benefits in cases where the maintenance of an exact gage is not of paramount importance.

There is another factor that may have to be considered because it may affect the rolling costs more than the expense for rolls and the bearings themselves; this is the ease with which a roll change can be made. In a mill where such changes occur frequently, perhaps several times a day, it is out of the question to have bearings that must be pressed off the rolls, whether it takes 80 or only 10 tons. It is also impractical and expensive to have a great number of spare sets all made up beforehand.

---

[2] Chief Engineer, Illinois Steel Company, Gary, Ind.

To make the application of roller-type bearings practical for an ordinary mill, even provided that the saving in power and longer length of the bearings compensate for the higher first cost, it is necessary that the bearing is assembled in one piece and that the roll neck and the inner race of the bearing are made tapered so that the bearing can be quickly slipped on the roll neck and located in its proper place by a whack of a sledge hammer and similarly loosened, ready to be lifted off, by a hammer blow

(The two following discussions apply to all five papers in the symposium on bearings.)

J. R. ADAMS.[3] The question of modernizing older rolling-mill installations is dependent very often on the space available between the window housings of the mill and the roll necks. In many cases these mills were originally designed for rolls made of cast iron. Later these mills may have been changed over to make use of forged-steel rolls, but maintaining the same roll-neck diameter. The fact the necks of forged and heat-treated steel rolls are very much stronger than the necks of the cast-iron rolls originally used had meanwhile been lost sight of.

There are probably many cases where the neck diameter of forged and heat-treated steel rolls may be reduced without danger of failure, thereby enlarging the space between the neck and the window housings a sufficient amount to permit the use of anti-friction bearings.

E. S. GLAUCH.[4] Papers have been presented on various types of bearings, and one might obtain the idea that the bronze and babbitt types of bearings for steel-mill service are obsolete. However, the writer is of the opinion that there are still quite a number of places in steel-mill service, especially on rolling mills, where the bronze and babbitt-lined bearings are giving good service and meet the requirements imposed upon them.

Cases have been reported where the various bearings showed a lower friction loss than had been obtained with metal bearings, prior to the installation of some of the bearings mentioned.

The writer is quite sure that in many cases these large savings would not have been possible had the bronze or babbitt-lined bearings been well lubricated, for he has made a great many tests in the past few years on rolling mills and has found that, by substituting better grades of lubricant, in some cases power savings as high as 25 to 30 per cent could be accomplished without any change in bearings.

Up until a few years ago it was rather hard for an outsider to get some steel-mill superintendents and engineers interested in the subject of roll-neck lubricants, as they felt that no matter what lubricant was used, a large percentage would find its way to the sewer.

However, since the advent of roller bearings for this service and the possible savings in power, which are of course due to the design of the bearing, and also the fact that the roller bearing is completely enclosed and well lubricated, more interest has been taken in obtaining better lubricants for plain bearings in roll-neck service.

Also, some of the systems which have been developed for supplying grease to these roll-neck bearings have resulted in reducing power consumption greatly on the bronze or babbitt-lined bearings due to constant lubrication.

There is of course an advantage in bearings of the celoron and lignum-vitae type in that they will operate with water only, whereas brass or babbitt-lined bearings require a lubricant, which on rolling mills is usually grease. On a special test equipment which the writer has been using in making a large number of tests, it has been found that if only a very small percentage of the bearing is allowed to operate without a lubricant, power consumption increases very rapidly.

The positive system of feeding a lubricant as obtained with pressure systems will eliminate the possibility of the bearings operating partially lubricated, which condition has existed to a large extent in roll-neck service with the old method of packing the necks with a heavy grease.

Also, the writer has found in making tests that some of the heavy roll-neck greases that have been used were made very stiff and adhesive in order to stay in the openings provided and resist the action of water, and these greases would provide a heavy sticky coating, which while to some extent serving as a protection to the bearings would consume considerable power.

This is especially true if the mill was shut down and allowed to cool, as it would require considerable power to start the mill, and for the first several hours of operation the power consumption would be quite high.

Greases can be secured which will lubricate the roll necks with a much thinner film of lubricant and with a much lower power consumption.

In connection with the various cases cited, as to savings obtained by the use of bearings mentioned in the various papers, the writer would be interested in knowing if any of these comparisons are made on mills which were lubricated by pressure systems, for he is quite sure that had the mills been lubricated with a positive system, the savings would not have been as great as indicated by the comparisons given.

The writer might also mention a case where bronze bearings on a bar mill rolling tool steel had been lubricated with suet or tallow. This the mill operators felt was the best lubricant up to that time, but have changed over so that the bronze bearings have graphite inserts placed in them, and then also a graphite grease is used for lubrication, and power consumption was reduced about 25 per cent.

This is another case of power savings due to better lubrication. The graphite inserts in the bearing are somewhat of a safety feature in that if the grease did not stay up against the neck, the bearings would not be without some form of lubrication.

In fact, on the initial test brass with the graphite inserts was operated without the addition of grease, but water was of course used, and the brass ran eight weeks and then failed due to breakage, whereas brass on the opposite end of the roll, which was lubricated with suet in accordance with their previous standard practice, was worn out in three weeks' time and the neck of the roll was scored.

As mentioned in the beginning of this discussion, there are and undoubtedly will be a great many places where the bronze and babbitt-lined bearings will be used with good results, providing of course that they are lubricated, and with positive force feed much better results will be obtained than with the old method of applying the grease by packing the necks or using the paddle application.

Production Management Applied to the Drafting Department

By WILLIAM J. KUNZ,[1] NEW YORK, N. Y.

This paper aims to bring out some of the more important factors in the management of the drafting department of one corporation. The output of this drafting department was in excess of 10,000 drawings in 1928 and 12,000 in 1929, varying from 1 to 10 sq. ft. There are three divisions, known as the boiler, stoker, and pulverized-fuel divisions. Each is divided into squads working on specific types of equipment. The management plans for a straight-line curve by moving experienced men from one division to another so that each division will carry a full allotment of work. The essence of the production is the speedy accomplishment of the work on the lowest cost basis and the unification of all interests in any specific feature of design.

IT IS NOT within the scope of this paper to give any lengthy discourse on the fundamental practices that might be followed in the production management of a drafting department, but it is the intention to bring out some of the prominent factors in the management of the drafting organization of Combustion Engineering Corporation.

This company, in the design and fabrication of its equipment, employs in its drafting department a personnel of as many as 280 men, the number employed being dependent on the amount of work on hand. The combined effort of the department resulted in a production in excess of 10,000 drawings in 1928 and 12,000 drawings in 1929, varying from 1 sq. ft. to 10 sq. ft. per drawing.

The drafting department is divided into three separate divisions—namely, boilers, stoker, and pulverized-fuel divisions. Each of these divisions is again divided into squads in accordance with the specific type of equipment for which design and drawings they are responsible. The organization chart, Fig. 1, is illustrative of the department's formation and some of its functions.

There are two classes of design established in each of these divisions—namely, the individual or specific equipment class, comprising a boiler or stoker or any other single product manufactured by this company. The second class of equipment is composed of a combination of any or all of these products as the contract requirements may demand. In the former class the design and drawing work will permit to some extent the use of so-called "standard drawings" which illustrate typical standard products. Drawings which are reproductions, the original of which was established and used on previous contracts, are also used wherever possible in the fulfilment of drawing requirements in this design class. In the latter class the possibility of using standard drawings is remote, as in almost every case the contract involves equipment of combinations and sizes that are rarely the same, with such exceptions as true duplications of previous contracts.

With the physical limitation of building enclosures and the ever-increasing demand of greater steam output per cubic foot of building space, it is obvious that design work in this latter class is of a more or less special nature, and while a definite principle of design may be followed on more than one contract, the possibility of using standard drawings is remote.

Boiler-Drafting Division

The boiler division comprises five squads and has a personnel of from 40 to 100 men, dependent on the amount of work on hand. In this number are included squad leaders, checkers, draftsmen, detailers, and bill-of-material clerks. The function of this division consists of producing designs and drawings necessary to fabricate and erect bent-tube boilers, sectional-header boilers, box-header boilers, economizers, and water walls. Also included in the responsibilities of this division is the development work necessary to keep abreast of present-day requirements and the standardization of designs and drawings in line with this development work.

Upon receipt of an order or contract for a boiler or other item of equipment in this division, the contract capacities and guarantees are checked by the contract calculating department. Concurrently the boiler engineers establish the designs preparatory to starting draftsmen on the layout or detail drafting work. The drawing work is more or less of a routine nature and occasionally a duplication. With the exception of special designs, extensive use is made of standard drawings, form drawings, and form bills of material, which have been made to suit a variety of conditions for each type of equipment.

Stoker-Drafting Division

The stoker division is similar in structure to the boiler division and has a personnel of from 30 to 50 men. Included in this number are likewise squad leaders, checkers, draftsmen, detailers, and bill-of-material clerks. The function of this division consists of the establishment of designs and the making of drawings necessary to fabricate and erect chain-grate stokers, multiple-retort stokers, and single-retort stokers. Development and standardization work likewise is an important function of this division. The responsibilities of engineering and drawing work on a contract are similar to those of the boiler division.

Pulverized-Fuel Drafting Division

The structure of this division is radically different from either the boiler or the stoker division. Its personnel varies from 50 to 150 men, according to the work on hand, and includes in its organization squad leaders, job leaders, checkers, designers, draftsmen, detailers, bill-of-material clerks, and in addition a

clerical force for the proper compiling of departmental indexes. This group is divided into squads having the names of "Lopulco" "Rayco," and "air heater."

Unlike the boiler and stoker groups, the percentage of standard design in this group is relatively small, and the possibility of using standard or form drawings is very limited. Advantage is taken, of course, of the use of drawings established on previous contracts wherever possible, but such occasions are rare.

"Lopulco," a trade name, also designates a squad of men whose efforts are concentrated on producing designs and drawings that combine a number of products when used on indirect-fired boiler and furnace installations. "Rayco" designates a similar squad, but concentrates on direct-fired boiler and furnace installations.

The air heater squad is responsible for all layouts and detail drawing work required for the fabrication and erection of all types of air heaters and duct work.

SPECIAL DRAFTING DIVISION

Under this heading is included two squads, one of which is the machine-design squad. The efforts of this squad are concentrated on the designing of burners, feeders, blast gates, dampers, and numerous other parts that are required for a pulverized-fuel installation.

The second squad under this heading is the standards squad, which is a coordinating unit between all other squads and confines its design and drawing work to the establishment of standards and of standardization as it pertains to the products.

While a portion of the time in the Lopulco and Rayco squads is devoted to the establishment of designs of individual items of equipment such as boiler and furnace settings, pulverized-fuel transport systems, roll- and impact-mill systems, etc., by far the major portion of the work consists of making designs and drawings combining these various products.

While the boiler section is interested solely in the specific design of boiler equipment, and the stoker section is likewise interested in the specific design of the stoker equipment, it is within the scope of the Lopulco and Rayco sections to combine the boilers, stokers, pulverized-fuel equipment, furnace, steelwork, brickwork, ducts, fans, air heaters, water walls, casing, and other sundry items into one completed steam-generating installation. This requires the making of drawings which are not only suited for fabrication and erection purposes, but also are important to the customer in showing exactly of what the entire design consists, so far as the grouping of the products is concerned and their relation to each other.

Contracts for a combination of products are assigned to contract engineers who are the coordinating factors between customers and the corporation in the establishment of designs throughout the life of the job in the drafting department.

There is also assigned to this work a job leader who is responsible for all of the drawings made, and likewise is the coordinating factor between all other squads and the distributing agent for the dissemination of all information pertinent to the drafting work of the design as a whole.

As in the stoker and boiler work, the guarantees and capacities that have been established in the contract requirements are checked by a separate section of the engineering department, but it is the contract engineer under the supervision of the chief engineer who is vested with the responsibility of supervising the establishment of the designs and drawings of the job in its entirety.

The relation of the contract engineer and job leader to all squads, to the chief engineer, and to the manager of drafting on a combination contract is illustrated in Fig. 2.

It is obvious, from the nature of the work in this division, that the requirements demand skilled designers of steel, brickwork, furnaces, and a multitude of machine parts. However, this does not eliminate the fact that these men are draftsmen since their designs are worked out in drawing form at a drafting table, and as such they are included in the drafting organization.

Control of Production

In a drafting department such as this, the control of production does not involve alone the knowledge of what is being done by groups of individuals or squads, but also it is essential that the capabilities of, as well as the work on hand for each individual in such groups or in the department as a whole must be known.

In order to be fully informed as to the amount of work on hand for each man in the department, we have for ready reference a drafting department log sheet, Fig. 3, which is brought up to date as frequently as is deemed necessary. This log sheet contains the name of every draftsman, checker, job leader, and squad leader, and they are shown under the heading of their respective squads.

Periodically a survey is made of the work on hand, and against each individual is allotted an estimated time that is deemed necessary to bring to completion such drawings as are assigned to each man. This time, which is plotted in days, is then incorporated on the log sheet and forms a rather accurate estimate of the amount of work on hand for the individual or the particular group to which each individual is assigned and for the department as a whole.

The amount of work on hand for each squad can become very much unbalanced when considered in terms of man-day work for each squad, unless there are ways for correcting this condition.

The significance of this statement is brought out on the log sheet in the variation of the average day's work shown for each particular squad, and unless prompt steps are taken to overcome this condition, it will result in a part of the department being overloaded with work, and possibly necessitating overtime, while another part will be idling, with a scarcity of work.

There are two ways in which this unbalanced condition can be overcome: (1) by assigning such new work as may come in to those squads that are not fully occupied or by transferring a part of the work from one squad to another, or (2) by changing individuals from a squad that is not fully occupied to one that is overloaded. In both of these methods there are apparent handicaps, and it is only after diligent study as to the capabilities of an individual as well as to the nature of the work that either of these methods can be followed.

A condition must be taken into consideration where the designs of some product must be drawn essentially to completion within a definite squad. There is, however, a certain amount of leeway in most work of this nature which permits the interchange of individuals and squad facilities to other squads in the department than just the one more or less specialized on one specific product.

To permit transferring an individual from one squad to another, it is not sufficient that he have a good background of experience, but also that he has a fundamental understanding of his employers' products or equipment. A comprehensive knowledge of numerous products made by one company is seldom acquired except over a considerable period of time. There are, however, certain features of the equipment that are similar in nature of material or fabrication, such as structural steel, casings, brickwork, etc., and in such instances the interchanging of individuals from one squad to another can be done without reflecting increased drawing costs or decreased production.

DOTTED LINES = FLOW ON SPECIFIC EQUIPMENT
SOLID LINES = FLOW ON COMBINATIONS OF EQUIPMENT

Fig. 2 Flow Chart for Combination Contracts
(Dotted lines, flow on specific equipment; solid lines, flow on combinations of equipment.)

Over a period of time we have been able to determine which of our men are most versatile and flexible. These men can be interchanged between squads as conditions demand.

There are certain squads which can be definitely termed "specialist squads," functioning in the design of equipment, the major portion of which holds no relation to any other item of equipment. In such cases, the possibility of interchanging men is a difficult one and should be avoided. The individuals of such squads have been trained along certain definite lines and have grasped the short-cut methods of their individual problems, which are duplicated, if not entirely, to a great extent, on the contracts that are received over a period of time.

The transferring of work from one squad to another is also important in the maintenance of a balanced work curve throughout the department. Those features of the equipment that permit the interchanging of men likewise permit the transferring of portions of a contract, if not the contract as a whole, from a squad that under ordinary conditions would complete all such contract drawings to another squad that is less occupied. This change is made without increased costs or delays in production.

On the aforementioned procedures depend to a great extent the straightening up of the work curve so that all squads will be carrying a full allotment of work and so that no squad which in-

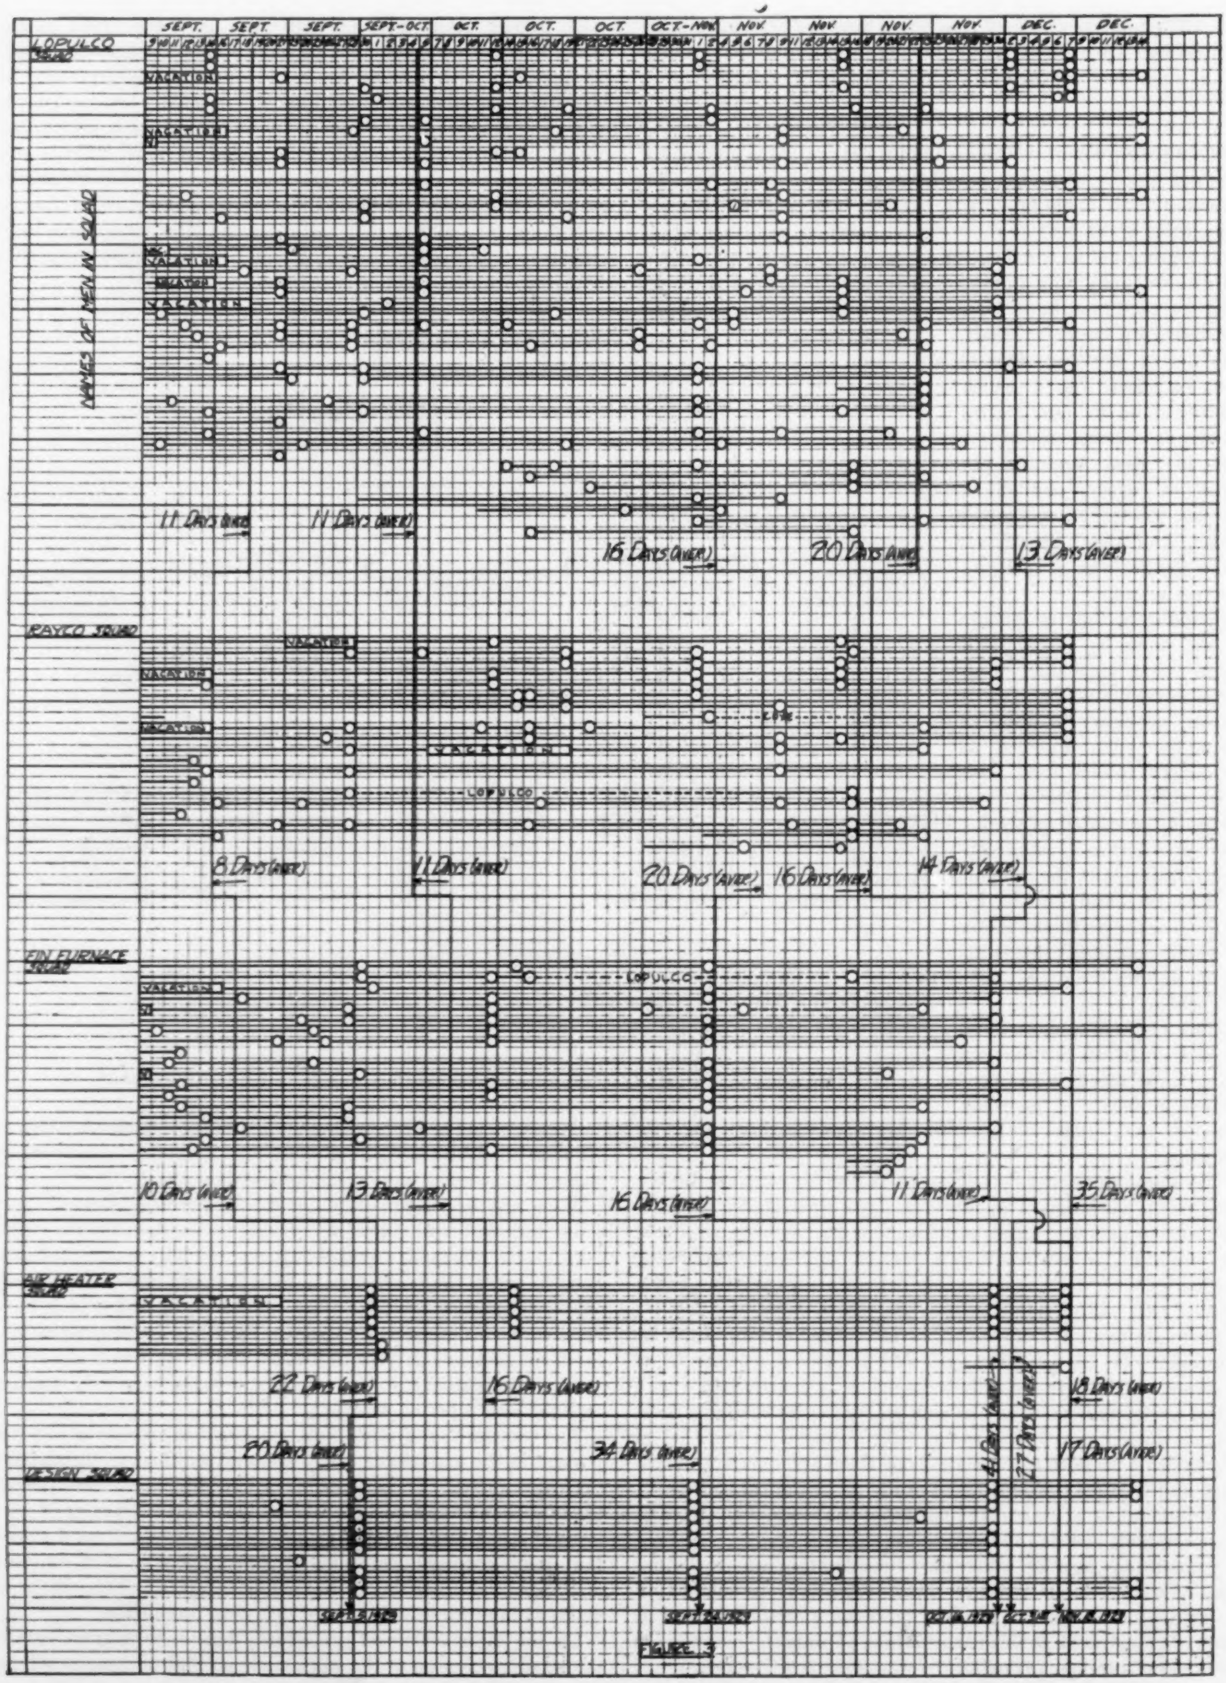

Fig. 3 Log Sheet of Drafting Department, Covering Time From September 9 to December 14, 1929

cludes the individuals of that squad will be suffering from lack of work. By following these two methods, the work curve of the department will more or less be made into a straight line, Fig. 3.

In the foregoing there has been one point definitely established—namely, that in an industry such as this, with the magnitude of the work and the diversification thereof, it is of paramount importance that the engineering talent, as well as the drafting talent, be located in one central place and be responsible to one management.

If it were only a question of designing the specific products without relation to any of the other products, it would be practical to maintain at each shop an engineering department.

But with the boiler shops located at St. Louis, Mo., and at Chattanooga, Tenn., the plate and structural shop at Phoenixville, Pa., the machine shop at Chicago, Ill., and a combined machine shop and foundry at Monongahela, Pa., it would be a difficult matter to design combination contracts in shop offices without jeopardizing drawing costs or production and would result in lack of united responsibility in establishing overall designs.

The essence of production is the speedy accomplishment of work on the lowest cost basis and the unification of all interests concerned in any specific feature of design or the design as a whole.

Control of Drawing Costs

The control of drawing costs in a drafting department of this size, with the variety of products that we are called on to design and the diversification in the combining of these products, is no small problem in the management of the department.

In order to have an accurate cost record of all individual drawings as well as the total drawings required for a job, we have in use a time record system that gives us, not alone cost data, but also an accurate story of what takes place on the job throughout its life in the drafting department.

It is required that each individual in the department make out a detailed time card, which, in addition to the date and the name of the individual, includes the contract or job number, the type of work that the individual is doing on that day (namely, checking, drafting, or tracing), the title of the drawing or a description of the work done, and the number of hours chargeable to such work. These cards are issued in two colors to distinguish regular time from overtime. They are given to the time clerk at the end of each day. From the information contained on these daily time cards, there is compiled a drafting-room cost card, as shown in Fig. 4. These cost cards are made up for a period of one month, allowing a line for each day of the month. They show the regular time, the overtime, and the total time in hours charged against the particular contract for which the card is issued.

With this time and a given hourly rate, the cost of the drawing work on any job is continuously kept up to date, the cost as well as the hours being given in accumulating figures. On this card is also shown the engineering allowance that has been set up in the estimate for the making of drawings.

An estimate is made each week on each job of the percentage of drafting work completed based on the knowledge of drawing requirements for the entire job. With this information we are able to strike a balance weekly to determine whether the drawing costs are within the estimated allowance or whether this allowance is being exceeded.

On this cost card there is also kept a record of the number and sizes of drawings made within that month to enable us to arrive at the cost of these drawings per square foot at the end of the month or on completion of the job. The significance of the information contained on this card is apparent at any given time.

There is one possibility of error that enters into this index, however, which cannot be avoided as it is directly dependent on the ability of the man in charge of the work to establish the correct percentage of the amount of drawing work that has been done as compared to all of the drawings that ultimately will have to be made on the job. It may be necessary at times to reconsider the percentage established for the work completed, although with our specific products the amount of drawing work is definitely known and the percentages established will in most instances be consistent with the work done.

In order to cope with this situation, however, and also as a check on the job, a notification card is sent to all squad leaders once a week notifying them of those jobs on which the drafting costs are in excess of what they should be on the basis of the percentage established for work completed and the allowance set up in the estimate. In such instances where these cards are sent out it is necessary for the squad leader or job leader who is responsible for the work to fill out a drafting-cost report, giving the reasons why the costs are excessive.

Fig. 4 Drafting-Room Cost Card

It has been found in the cost analyses of drafting work that there are a number of factors that contribute toward increasing costs. Some of these factors are common to all drafting departments and can be contended with readily by changing the personnel, revising systems, eliminating superfluous details, avoiding complicated designs, and so forth. One of the more prominent factors that tend to increase drawing costs on some jobs is the numerous changes to drawings that are necessary either for some one drawing or for all of the drawings required to fulfil contract obligations.

In the fabrication work of materials and equipment in general, one fact is never lost sight of, and this is that changes to the material itself or changes affecting the machine work that has been done or is to be done require an outlay of additional money by the fabricator over and above what was figured on originally for doing such work, and it is customary that the company authorizing such changes compensate the shop for the additional expenditure.

This likewise holds good in such instances where it is necessary to scrap material and to do a job over because of some change in design, and it is recognized by the industry in general that changes requiring the scrapping of materials necessitate additional compensation for the loss involved.

In the scrapping of materials or in changing the fabrication methods of such materials or equipment in general, we are dealing with something tangible, something that represents mass or weight or machine production, and something that is comprehensible in dollars and cents. In the drafting department the same feeling does not seem to exist, and at times one is led to believe that drawings have no monetary value and, therefore, can be changed at will or scrapped entirely without regard to cost.

FIG. 5 CARD TO DETERMINE COST OF DRAWINGS

Quite often in the normal course of design and drafting work, and particularly after one or more drawings have been more or less completed, a change of idea takes place for a better design. This is perfectly justifiable, for regardless of drawing costs or the number of drawings that have to be changed, superseded, or scrapped, it is an obligation of all industries to furnish the best possible in the way of designs and equipment; and the establishment with clarity of these designs on paper, so that they can serve as the true interpretation of the designer's ideas to the purchaser, fabricator, erector, or operator, as the case may be, is of paramount importance.

The fact holds good, however, that although design changes are necessary they are reflected in increased costs of drawings, with the result that there are instances when the estimated allowance for drawing work is insufficient, resulting in some cases in not only depleting the allowance but encroaching on the profits of the completed product.

High cost of drawings is ofttimes a result of an individual not having established designs that were based on thorough investigations or considerations of the problem at hand. There are times when groups of individuals cannot agree. It is then necessary that a series of study drawings be made so that the various angles and phases of the problem in question can be considered by all individuals concerned.

There are instances where the purchaser himself may have individual opinions of a design, either by virtue of experience or operation of such equipment, and in order to have all parties interested agree, it requires extensive study drawings or drafting work in general, with numerous revisions, to reflect ultimately the ideas of every one concerned.

All of the foregoing conditions are proper and within the natural function of the engineering and drafting departments, but it is a function that accounts for much of the excessive cost in the making of drawings.

There are other factors that account for excessive drawing costs, but those mentioned, we have found, are by far the more predominant ones.

To enable us to determine the actual cost of all drawings made in the department and to maintain a definite record of these costs for future reference, we have in use a card system, Fig. 5.

A card is issued when work starts on a drawing. In addition to the drawing number and contract or job number, there is recorded on this card the dates on which time has been charged against the drawing and the distribution of such time. Under the heading of "regular" is shown such drafting or checking time in hours as is considered normal and chargeable against the drafting allowance set up in the estimate for the job. Under the heading of "revision" is shown such drafting or checking time in hours as was spent in making drawing revisions due to changes by interests outside of our organization or for reasons beyond our control. With this method we can readily determine the proper distribution of drafting charges for any one drawing or all drawings on a given job. The remainder of the headings on this card are required to complete the cost analysis of a job in its entirety.

CONCLUSION

As in other industries, the establishing of overall designs on some contracts requires the combining of our products with those of other manufacturers. In such cases the control of drafting production, as well as drawing costs, is influenced to a great extent by the cooperation received from the outside manufacturers, and in some instances by the purchasers.

On such jobs a certain amount of interchanging of designs and drawings between companies is necessary so that the arranging of all of the component products of the overall design can be accomplished without infringing on each other, either by physical interferences or capacity characteristics. In all instances the purchaser of the combined unit must be consulted in the establishing of definite locations and clearances, within building enclosures, and with respect to auxiliary power-plant equipment being furnished under separate contracts.

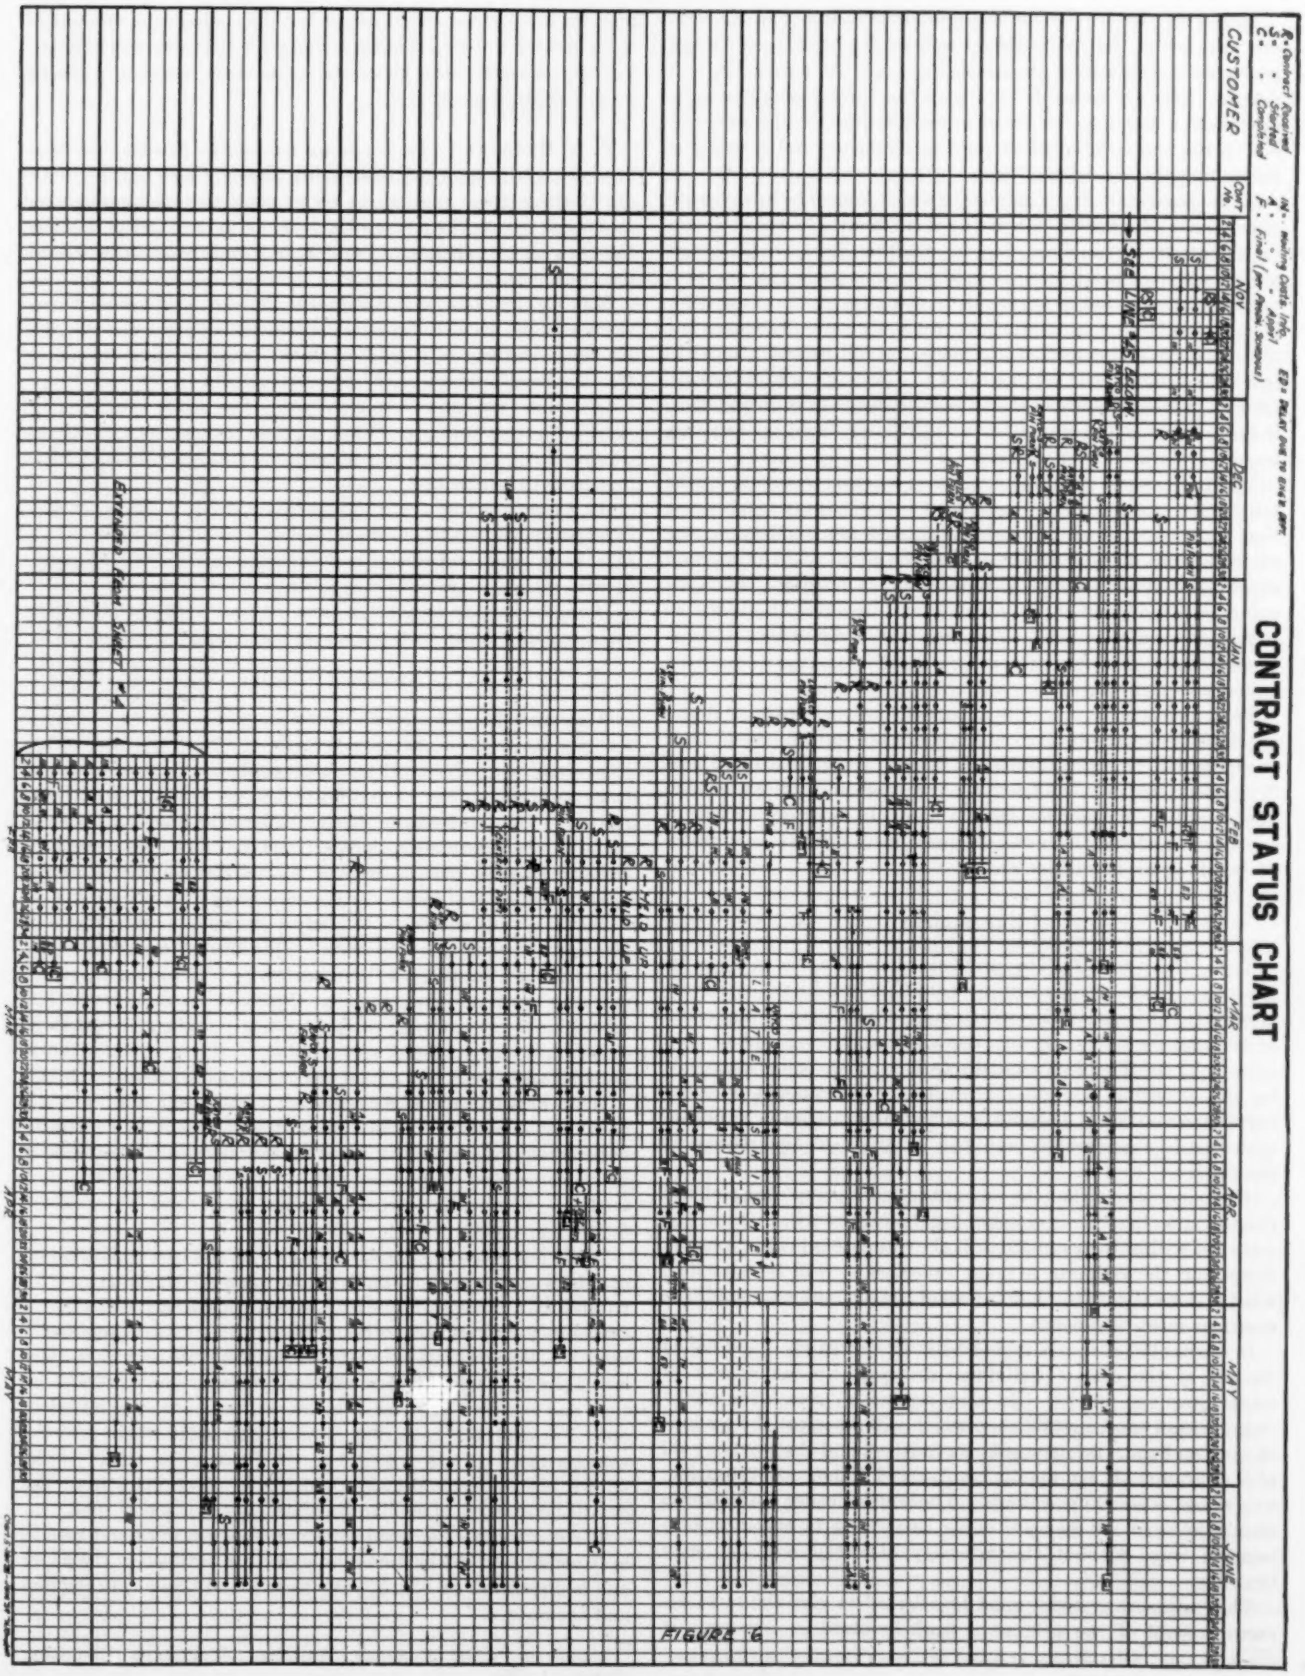

Fig. 6 Contract Status Chart

Unless all parties involved in a combined contract of this kind are working at the same speed, each coping with their design problems in the proper sequence, there will be difficulties and delays. Dilatory methods by any of the parties usually results in extensive drawing changes of a costly nature to all concerned, and in the end is reflected in delayed shipments and erection of the equipment as a whole.

As an illustration of the manner in which some jobs have passed through our department in a period of six months, we have drawn up a contract status chart, Fig. 6. On this chart, where letters are shown over solid lines, it indicates that although we were awaiting information or approvals to complete our drawing work it was possible for us to continue work on some drawings, but that delays in giving us this information would necessitate, within a known period, the holding up of all drawing work on the contract. In instances where the letters are shown over dotted lines, it indicates that drawing work was definitely held up awaiting required information or approvals.

Due to the short time that is allowed on some contracts for the fabrication and erection of equipment it is of utmost importance that design and drafting work be started immediately on the award of such contracts so as to give the shops and the erection department the benefit of as much time as possible. Such instances are indicated on the chart where the letter "S" is shown previous to the letter "R." This procedure is necessary, as sometimes two weeks or more elapse before the actual signed contract papers are received.

From this chart it is readily apparent that the control of drafting department production and costs is not entirely within our province, but to a great extent is directly dependent on others. With the exception of contracts that are true duplications, or such jobs requiring our smaller specific products, one job is rarely a criterion for another in terms of square feet of drawings, number of drawings, or drawing costs.

Discussion

T. G. Crawford.[2] The problem of drafting in a large organization has been very well presented. Flexibility is extremely essential in an organization which must of necessity be composed of different sections or groups more or less independent of each other. There should be some discussion in the outline suggested for the recording of costs of drawings. The amount of bookkeeping involved in keeping a sufficiently accurate record of drawings is considerable, and the accuracy of the records is debatable.

The paper states that the amount of work completed and still remaining to be done is closely checked each week, to see if the costs are within the estimate or if the estimate is being exceeded. Supposing the estimate is being exceeded or will be exceeded, what is done about it? Regardless of the amount estimated, the drawings must be finished.

It seems that it is advisable to eliminate entirely the detailed records of the cost of individual drawings by square foot or group drawings per job. In each section a "measuring stick" of some kind can be established which will represent the amount of work on hand, the amount being finished, and the total payroll of that group. It can readily be observed if the cost of drafting, as a whole, is going up or down. The section leader of this group should know if his men are doing their work in the most economical way, without the necessity of detail cost on each drawing.

The "measuring stick" must be selected to give the most accurate record of the volume of work involved in a group. It may be the number of drawings, but only where the amount of work on each drawing is easily comparable. It also may be drawing lists, material lists, kilowatts, horsepower, number of panels on switchboard work, etc.

F. A. Widdows.[3] As to elimination of the checker, we have been doing this, up to a certain point, for some time back. While our drafting force is small in comparison to the organizations discussed, we use the squad idea as much as is practical, making the designer the squad chief, and he in turn is responsible for the drawings, design, and accuracy.

Making the designer and even the detailer responsible, causes them to take more interest and pride in their work. We also like to keep them in contact with the building of the machine; this has been productive of very good results.

Of course, we run across some men who, while they may be good designers, have good ideas, and are fast, yet cannot be depended upon for accuracy, interferences, etc., and all their drawings have to be checked.

As to scheduling drafting, we have done nothing as yet; it probably will be rather difficult in our work, but not impossible. Our work is not repetition and the placing of standard parts; it calls, rather, for considerable inventing, new ideas, etc.

It will be hard to establish a time limit on work of this nature; yet a schedule could be made up after the design is approved.

Author's Closure

Answering Mr. Crawford's discussion, the salary expenditures for clerical work in keeping records of drawing costs, either individually or collectively for entire contracts, are not excessive in terms of percentage when compared to the drafting department payroll. (This percentage varies between 0.5 and 0.7.) The value of the information derived from these records cannot be compared to the cost of keeping them when considered in the light of accurate estimates of engineering costs for new work.

These records enable us to analyze drawing costs in terms of contract expenditures and extra expenditures necessitated by changes made and beyond our control or for work done as an extra to contract requirements. From these records we can determine what drawing work is actually costing in terms of dollars or hours per ton of structural steel, per square foot or per pound of plate work, per pound of castings, or per thousand brick.

While drawings must be completed, it has been found, with the possibility of a periodical analysis of drawing costs, that intricate designs requiring extensive detailing can at times be modified if all concerned are confronted with the cost of work as it is proceeding. Frequently excessive design costs lead to excessive fabrication costs.

While our records automatically give us the cost of individual drawings or groups of drawings on the square-foot basis, this is by no means a "measuring stick" when considering the cost of drawings for a contract in its entirety. The "measuring stick" used for the cost of drawings on combination contracts was established by analysis of numerous contracts over a period of time and is known in terms of hours per ton, per thousand brick, etc. For contracts requiring specific equipment where drawing work is more or less repetitious, the "measuring stick" is the known cost of each drawing which was determined from the detailed cost cards of similar drawings over a period of time.

The control of a balanced condition between work and men in each squad or the department as a whole is outlined in the paper and is illustrated by Fig. 3. We have found this record definite and accurate.

MAN-54-2

Improving Drafting Management

By F. D. NEWBURY,[1] EAST PITTSBURGH, PA.

A system of improvement in drafting management extending over four years of experience is described, the use of these methods having cut drafting costs in half, while average salary rates have been increased, design quality has been improved, and drafting accuracy has been maintained. A feature of the plan is that each draftsman checks his own work, this resulting in increased responsibility and improved accuracy. Record charts showing the results attained are given.

DURING the past four years some new ideas have been applied to drafting management in several design departments of the Westinghouse company that may be of general interest. The use of these methods has cut drafting costs in half, while average salary rates have been increased, design quality has been improved, and drafting accuracy has been maintained.

These results might not be significant if they had been obtained in only one instance. The same methods have been successively applied in three different departments and have worked successfully in each.

The department in which these ideas were first developed handles the design of alternating- and direct-current machinery of medium and large size, and contains about 120 people, mainly technically trained engineers and draftsmen. This new plan of operation was started early in 1927. In the fall of 1929 the same plans of organization and operation were started in a transformer-design department, which at that time contained nearly 200 engineers and draftsmen. A few months later the plan was introduced in a third plant that builds steam turbines and a wide variety of other mechanical equipment. This department contains about 250 engineers and draftsmen. All of these design departments serve factories that in normal times have from 1500 to 2000 workmen, and so may be classed as large plants. More recently still, these ideas have been introduced in the reorganization of a much smaller design department serving a 400-man plant.

Much of the work in all of these departments is special, in the sense that it must be designed after receipt of sales contracts and to meet purchasers' specifications. Very little apparatus can be manufactured for stock in advance of sales. Much time and thought, however, have been given to the design of standard lines of parts from which a wide variety of special requirements of customers can be met with only moderate drafting and other special development expense. On account of the nature of the business a large amount of experimental engineering work is continuously under way. Approximately 30 per cent of total engineers' time and 20 to 30 per cent of draftsmen's time is devoted to this standard development effort that is not related directly to work on current customers' orders. The fact that as much as 70 to 80 per cent of drafting time is required by current orders, which must be handled as received, makes the problem of maintaining an adequate standard development drafting force a particularly difficult one and one that was not handled successfully in these departments until the present management methods were developed.

Before these new ideas were introduced, these departments were organized along conventional lines. Each department was divided into a number of separate engineering sections or groups, each of which was responsible for the initial design work connected with a specific class of apparatus. There was one common drafting section for the entire department in charge of a chief draftsman who usually was responsible for the structural or mechanical design of the product. In these several departments these single drafting sections each contained as many as 60 to 140 draftsmen.

This general type of organization results in divided design responsibilities that are not joined in a complete piece of equipment until the position of manager of the entire department is reached. In these particular departments, their size was too large to make this arrangement as effective as could be desired.

In the type of organization that has been developed, each of these departments is divided into a suitable number of design units (called divisions), each complete with electrical or mechanical engineers (or both), design draftsmen, and detail draftsmen, and in charge of one engineer-executive who directs and coördinates the work of both engineers and draftsmen. Everything possible is done to break down separation lines between engineers and draftsmen in the same division; these names carry no significance as to technical qualifications. Many of the engineers working with drafting equipment are better qualified as engineers by education and experience than many of the younger technical assistants who may be rated as engineers. It is important that all engineers and draftsmen in a division report to one executive; hence the division cannot be too large (15 to 50 people constitute good limits); and there is no place for a chief draftsman, either in the department or in the division.

A second distinctive feature of this type of organization is the grouping of draftsmen of each division into relatively small squads containing one to five men. Each squad is in charge of a squad leader, who is a qualified designer. He makes the general layouts assigned to his squad, assigns the work to his assistants, and supervises their work. The squad leader has a definite design and production responsibility for the work assigned to his squad. The squad is set up as a permanently established group, and the members, as far as possible, are located at adjacent tables. The size of the squad depends upon the character of work assigned to it. Changes in squad personnel, when necessary, usually affect the least experienced detail draftsmen; i.e., men are added to or subtracted from the bottom. Squads are specialized both as to the kind of work assigned to the squad and as to the kinds of work performed by the individual members of the squad. A broad distinction is

He has been with the Westinghouse Company continuously since leaving college. He introduced these methods of drafting management while he was manager of the Power Engineering Department, and extended them to other departments as General Manager, Machinery Engineering.

Presented at the "Three-M" (Management, Materials, Maintenance) Congress held in Cleveland, Ohio, April 13 to 17, 1931, under the auspices of the A.S.M.E. and the S.I.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

made between design work, such as covered by layout drawings, and detail drafting work, represented by the production of working drawings. It is not efficient to have designers make working drawings, nor is it wise to intrust very much designing (beyond that required by the individual working drawing) to less qualified detail draftsmen. There has been a marked improvement in quality of design since this specialization has been carried out and squad leaders of small groups have been given this definite design responsibility. Furthermore, the improved methods affecting drafting, to be described later, have been possible only because of this distinction between design drafting and detail drafting.

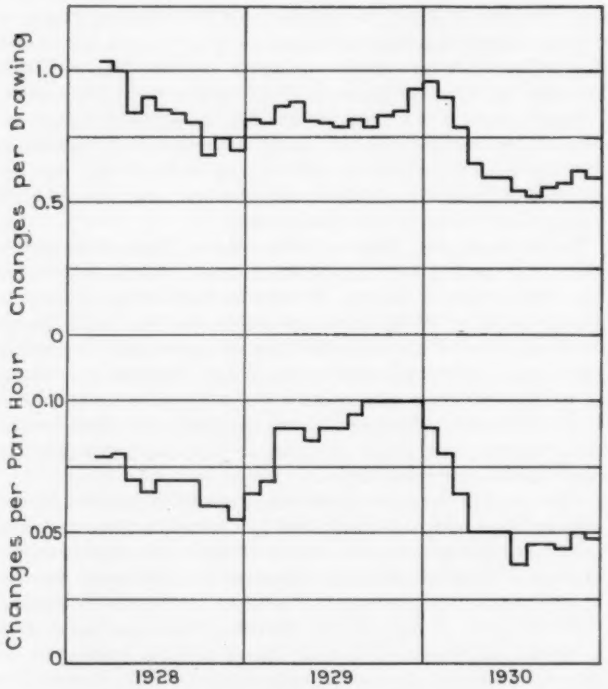

Fig. 1 Curves Represent a Three-Month Moving Average of Both Quantities

The flow of work through the department (and particularly that part directly related to customers' contracts and orders) is controlled by a production supervisor who has no responsibility for drafting management. Under the direction of the division head he assigns new work to the squad leaders, assigns completion dates for each detail drawing, and conducts all negotiations with the works production men as to production schedule dates for manufacturing information. His first duty is to set up production schedules for manufacturing information that will enable the factory to meet contract shipping dates. Bear in mind that no complete machines, and few parts, can be built in advance of customers' orders. During the past four years there have been very few instances where a schedule satisfactory to the factory could not be set up. The standard development schedule may be delayed temporarily to provide for emergencies in the customers' order schedule, and occasional overtime on a specific job may be resorted to. The rather common practice of working an entire force on a definite overtime schedule of several nights a week has not been used and is not looked on as good management.

Under this plan of organization, the head of the design division must take a considerable interest in drafting personnel and production, if the desired results are to be attained. Too frequently the supervision of the drafting part of the design organization is delegated to an executive who lacks close touch with the commercial, technical, and manufacturing aspects of the whole design problem. The division engineer has these broad contacts and is expected to handle directly all personnel and management problems connected with drafting, as well as those connected with engineers. Obviously this one-man plan is practicable only when the division is kept small in total size (15 to 50 people, as mentioned previously). The plan is feasible, even with these numbers, only because of the grouping of engineers and draftsmen in small operating units, with each unit in charge of a squad leader having definite responsibilities, and because of performance records that have been developed which give the division head, regularly, a quantitative measure of each draftsman's performance. A requirement for success of this plan is, quite obviously, the availability of good executives for division heads and, conversely, an advantage of the plan is that good material is given a chance to develop.

A large design department of the conventional type is apt to be unwieldy and slow to respond to changing conditions. When this is true, it is frequently the fault of the type of organization. Even good men can function successfully and with speed only when they are free to act in relatively small groups. If a large group must act as a unit, the inevitable inertia makes it slow to move. Speed of action, in this sense, includes mental ability to quickly change ideas and methods, as well as the more obvious physical ability to produce results.

The proper size of a design unit, for best results, cannot be defined by a single figure; this best size depends upon the quality of leadership and the character or type of work. Whether a given design unit is too large can be answered only by the results it achieves.

It is possible, in our experience, for a large design organization to combine the strength and ability inherent in the large group with the speed and mobility inherent in the small group, if the large group is divided into a sufficient number of small groups, each constituting a complete self-contained design unit.

In producing a specific design required by a customer's order, the engineer prepares a written design specification which is intended to give the draftsman-designer complete information so that he can immediately start the general layout drawing of the structure. If this design specification is not complete, much time can be lost by the draftsman while obtaining necessary information verbally, and because the engineer, under such circumstances, is apt to give ill-considered information which, later on, may be changed. In connection with lines of machines based on standard parts, the design specification covering a new combination of standard and variable parts can be made so complete and so specific that very little, if any, general layout drafting is required.

Practically all checking of drawings by separate checkers has been eliminated by training detail draftsmen to check their own work. Careful records of drawing changes are maintained to show the class of change and the responsible individual. This practice of draftsmen checking their own work may be questioned by those who believe all drawings should be checked by an independent checker. Carefully maintained records have shown no increase in errors per drawing due to this system. Records have shown a very considerable difference in accuracy among men; some men are inherently accurate and others are not. This difference in men is much greater than any difference in results due to checking methods, and indicates that good results can be attained most certainly by keeping individual accuracy records and by releasing or transferring men who are not sufficiently accurate to do satisfactory drafting work.

Experience has shown the weakness inherent in the divided responsibility for accuracy that exists when separate checkers are used. When separate checking is a part of the established routine, the detail draftsman leans more and more on the checker with an increasing deterioration in his own thoroughness and accuracy. When the proposal to eliminate separate checkers was first discussed (in July, 1927) an experiment was tried to discover the accuracy of detail draftsmen independently of the accuracy of the checker.

In a division containing 25 draftsmen, the first week's record showed five errors and omissions per drawing discovered by checkers. Within ten weeks, this figure dropped to two-tenths of a change per drawing. Out of this experience, the plan was developed whereby a detail draftsman was allowed to check his own work as soon as he had demonstrated his own accuracy by the inability of the separate checker to discover errors or omissions. It was found that good draftsmen welcomed this added responsibility and tried hard to earn it. A real check on individual accuracy was maintained by recording all errors and omissions (however minor) discovered during the factory work. This record for the electrical machinery department is shown for the past three years in Fig. 1. Fairly complete elimination of separate checking had been accomplished by the middle of 1928. It will be noted that, during the introductory period, there was an improvement in accuracy; there was considerable deterioration during 1929, caused by a 50 per cent increase in size of force, and a gratifying improvement during 1930 with a reducing size of force.

Unless the cost of separate checking is visualized by a study of the different kinds of drafting operations, its magnitude and cost are apt to be overlooked. In these three large departments the percentage of total time used in separate checking before the conventional practice of separate checking was modified and the relation between checking time and time used in making new detail drawings is as follows:

	Initial Conditions			
	Percentage of total hours			
Department	Detail drafting making new drawings, per cent	Separate checking time, per cent	Ratio of checking time to detail drafting time	Separate check, end of 1930, total hours, per cent
1	42.4	14.3	0.34	0.3
2	44.8	11.6	0.26	0.3
3	32.5	11.8	0.36	3.5

Tracing has been eliminated (except for special cases, such as Navy jobs) by making tracings from pencil drawings by the photolithoprint process, and in the case of variable parts, used only on one order, by making blueprints directly from pencil drawings made on special tracing cloth.

The work of making new detail drawings has been reduced greatly by providing so-called master tracings (only partially complete) from which lithoprints are made, and the new lithoprint "tracing" is completed by the detail draftsman. In many cases of drawings of standard parts, only dimensions need to be filled in to complete the lithoprint from the master tracing. The photolithoprint process was first used in all divisions of one department in May, 1927. In December, 1927, 188 of 424 new drawings (44 per cent) were made from existing tracings; in December, 1929, two years later, 352 of 511 new drawings (69 per cent) were made from existing tracings. This increase in the use of existing tracings for making new tracings is one of the major reasons for reduction in drafting costs.

Distribution of Drafting Time

Accurate record is kept daily of draftsmen's time by work orders, by drawing number (for certain operations), and by drafting operations. The kind of operations recorded and the distribution of total drafting time among these kinds of work are shown for a recent month as follows:

		Percentage of total hours		
No.	Operation	Dept. 1	Dept. 2	Dept. 3
1	Layout design and supervision of detail draftsmen (mainly by squad leaders)	25.8	34.2	38.8
2	Making new pencil drawings	25.7	32.7	25.1
3	Making new drawings from lithoprints	24.1	14.8	7.4
4	Changing old tracings; this may be changing old tracings for new orders, making customers' changes, or correcting mistakes	13.4	7.9	14.4
5	Checking new drawings (separate checkers only)	0.3	0.3	3.5
6	Tracing	2.2	5.5	5.0
Misc.:	Vacations and holidays	8.2	4.5	5.8

Par Time Plan

In measuring the useful output of a drafting organization, the single drawing—large or small, simple or complex—is most frequently taken as the unit of measurement. Sometimes the total square feet of drawings produced is used, but this measure also has obvious shortcomings. In the plan developed in the first design organization under discussion, the range of working drawings produced is divided into nine classes, depending upon the amount of work involved in making the working drawings, ranging in time from 2 hours to 40 hours. This time allowance, covering making and separately checking the pencil drawing, is intended to represent the time the drawing should require under ideal conditions. This means that the detail draftsman should be an experienced draftsman and a specialist on that particular kind of drawing. He should have, at his elbow, all necessary design information, and should not be compelled to repeat work because of changed information; in short, he should be able to work continuously at his drafting table. Each drawing, after it is completed, is given a "par-hour" rating by the production supervisor. This figure is analogous to the "allowed hours" for factory jobs.

In the beginning an attempt was made to give an accurate estimate of par hours to each new drawing when it was completed. It was found that a limited number of "classes" and corresponding par-hour values served the purpose with sufficient accuracy and were more satisfactory in use.

The allowed hours is called "par time" to distinguish it from the analogous standard time (or piecework rate) in factory operations. The par time is set up as an ideal time that the average draftsman is not expected to attain, at least for some time. This permits a difficult scale of par times to be adopted in introducing the plan, and a difficult mark is set up that can be used to stimulate improvement over a long period. In the corresponding factory standard-time plan, the "allowed hours" represents a practical limit that the average workman is expected to meet after a relatively short instruction period.

In the operation of the par-time plan, the actual time charged by draftsmen to the operations of making and checking new detail drawings (operations 2 and 5 or 3 and 5 in the list previously given) is recorded daily, and after the drawing is completed, the par time (i.e., drawing class) is set by the production supervisor, who is not directly responsible for drafting performance. For each completed detail drawing there is available the actual hours charged to the drawing and the par hours allowed; the ratio of actual hours to par hours for a drawing, a draftsman, or any group of draftsmen is the measure of performance—a low ratio indicating good performance.

It will be observed that the par-time plan affects, most directly, production of new working drawings. This amounts to one-third to one-half the total drafting hours (see table of distribution of drafting time). The entire drafting time is brought within the influence of the plan, however, by considering the ratio of total hours (instead of operations 2-3-5 connected with the production of new detail drawings) to par hours of new drawings produced. This ratio is the sum of the "new drawing production" ratio and an overhead or expense ratio which includes design and layout, supervision, changing old tracings, etc. (operations 1-4-6-7). This total hour or overall ratio is the summation of all performance factors. It is the ratio of total input (represented by total hours paid for) to total useful output (represented by par hours of new drawings produced). It is analogous to the total cost per standard hour in the standard cost plan as applied to factory operation.

Both ratios (new drawing ratio and total ratio) may be applied to individual draftsmen, to squads, divisions, and departments.

The results of the operation of this par-time plan in the electrical machinery department are shown in the accompanying charts, Figs. 2 and 3. Fig. 2 shows the various performance ratios that have been described. The first curve, showing the ratio of actual hours to par hours for new pencil drawings, is of most value as a measure of individual man efficiency. In the case of the second curve, for new drawings made from lithoprints, the par-time allowance is the same as for a completely new pencil drawing. This ratio, therefore, should be materially better (lower) than the ratio for new pencil drawings. If it is not, it means that poor judgment was used by the squad leaders in using existing tracings as a basis for new drawings. This second curve and the third, which is the combination of the first and second, is of value mainly as a measure of squad, division, and department efficiency. Satisfactory performance, as it is now judged, can be achieved only by producing a major part of the required new drawings from existing tracings (operation 3).

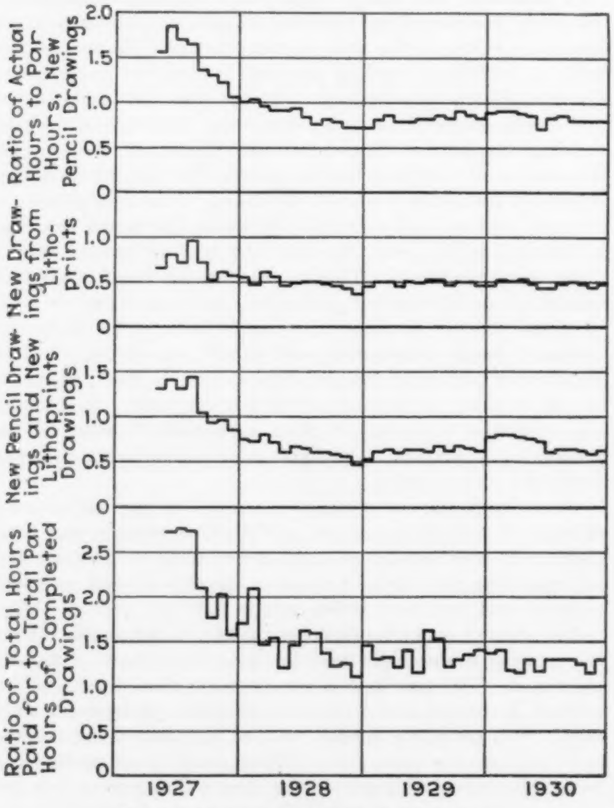

FIG. 2 VARIOUS PERFORMANCE RATIOS

The fourth curve represents the total or "overall" ratio, which is the most important. This curve is more irregular than the others because it includes absent time paid for. This is the reason for the relatively higher peaks in July and August of each year.

It is interesting to note that initial performance (in the first curve of Fig. 2) was approximately 75 per cent above par (poorer than par), but that par performance (ratio 1.00) was achieved in nine months, or by January, 1928. Since then, the ratio has been continuously under par, and in 1930 the average ratio for the year was 0.84. It is possible to "shoot better than par," for two reasons. The original par scale, which has not been changed, was too lenient and was based on separate checking. A draftsman capable of checking his own work is given credit for the saving.

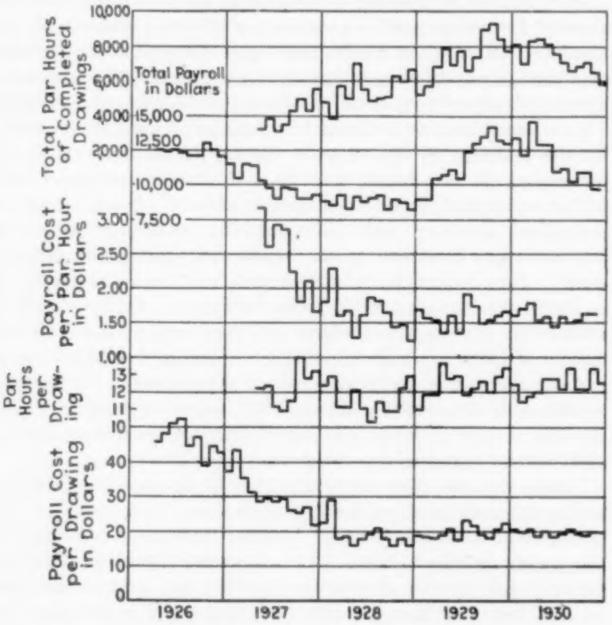

FIG. 3 RESULTS IN TERMS OF COSTS OF DRAFTING

Fig. 3 gives results in terms of costs of drafting. The total useful output is shown in the curve of total par hours of completed drawings; the total payroll cost is shown, and the other curves are derived from these.

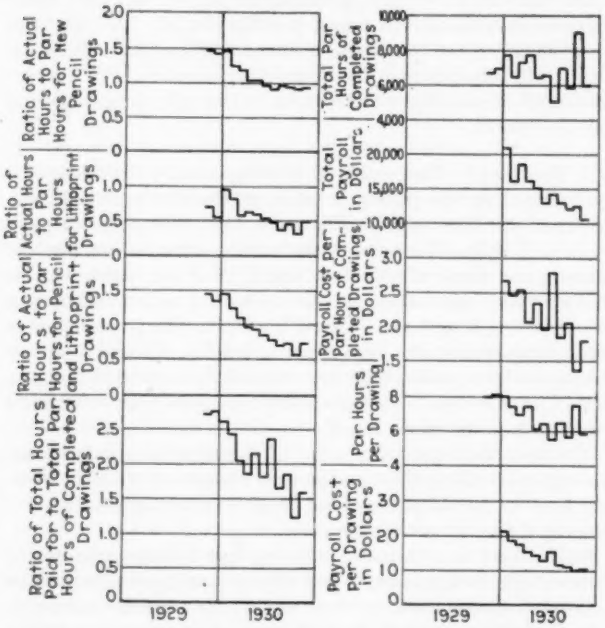
The curve of average par hours per drawing is interesting in showing how the "work content" of drawings may vary from month to month, even in the same department. When these same data are taken from different departments handling different types of apparatus, the differences are much greater, as shown by the following examples taken from divisions of three different departments (the figures are averages of several months):

	Par hours per drawing
Instrument transformers	4.0
Small distribution transformers	5.5
Large power transformers	8.1
Steam condensers	8.8
Alternating-current rotating machines	10.5
Direct-current rotating machines	15.5
Large steam turbines	17.7

The curves of Fig. 3 illustrate four distinct periods or phases occurring in successive years. During 1927 there was a slightly increasing drafting load and a substantially decreasing payroll.

During this period operating ratios were improving, and the payroll costs per par hour and per drawing were considerably reduced. This was a period of rising standards, due to improvement in individuals and to the elimination of men who were not able to meet the new standards of performance.

During 1928 there was a considerable increase in drafting output due largely to increased production of standard-part drawings as a part of a standard development program. The payroll and force did not change materially. There was continued improvement in performance, but at a decreased rate.



Figs. 4 and 5 Results From the Transformer Engineering Department

During 1929 there was a further considerable increase in drafting load (mainly caused by increased customers' orders) and a corresponding increase in payroll and personnel. The notable fact is that, in spite of this large influx of new draftsmen, the performance ratios indicated only a slight loss in efficiency. The effective assimilation of new employees is to be attributed to the small squad type of organization. Ten new men distributed among ten squads, having ten good leaders, can be assimilated without loss of efficiency where the same ten new men added at one time to a single large drafting section, and attempting to work independently, might do more harm than good.

This experience during 1929 brought out an interesting fact that has been illustrated many times in similar factory situations: new men brought into the group met the existing average pace of the group in a much shorter time than was required for the original group to achieve the faster pace.

During 1930 there was a decreasing load, a decreasing force, and an improved efficiency. This illustrates the most difficult administrative problem: to maintain individual output and efficiency with a seriously falling load.

Figs. 4 and 5 show corresponding results from the operation of the transformer engineering department. They are interesting in that they confirm the initial results of Figs. 2 and 3.

It will be noted that the performance ratios for new drawings started at 1.5 (as compared with approximately 1.75 in Fig. 2) and came down to 1.0 in nine months, which was the period in Fig. 2. The ratio of total hours paid for to par hours started at 2.7 (which was approximately the same value in Fig. 2) and came down to 1.5 in twelve months. In Fig. 2 the overall performance ratio was reduced to 1.5 in ten months.

Another indication of the greater value of "par hours" as a unit of output is afforded by the close agreement in these two departments in "cost per par hour" ($1.35 minimum value in Fig. 5 as compared with $1.25 in Fig. 3), while minimum "cost per drawing" varies from $16 in Fig. 3 to $10 in Fig. 5. The greater difference in cost per drawing is caused by the difference in average par hours per drawing.

It cannot be over-emphasized that these records do not automatically produce improvement; improvement has resulted only because the several division engineer-executives have used these records as a tool to achieve results. They have analyzed the records of each draftsman and have used them effectively in carrying home to the individual his position in his group.

Probably the most important factor in administering this plan has been the individual basis of all records. Each draftsman producing detail drawings has been advised each month of his production ratios and the errors affecting his drawings. He has been given his own standing and the maximum, minimum, and average figures of his division. A sample individual record is shown in Fig. 6. This record is one of the best, but is typical as to improvement during the first 18 months of the period this par-time plan has been in operation.

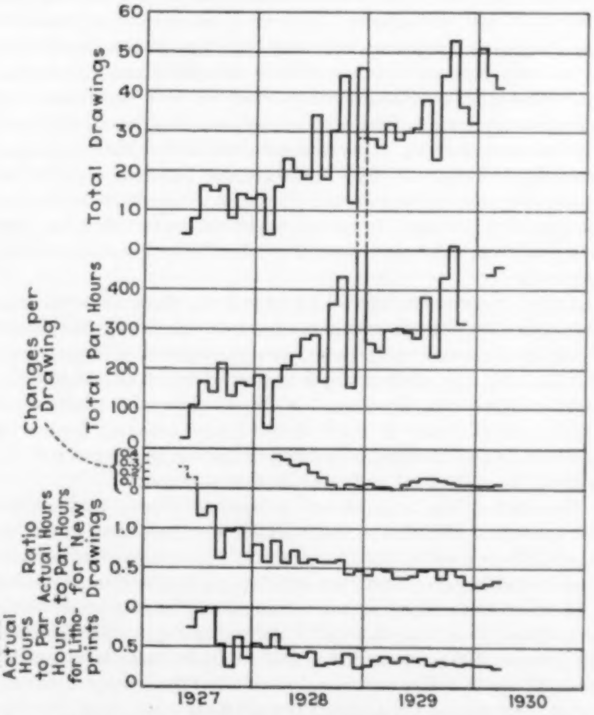


Fig. 6 Production Ratios and the Errors of an Individual Draftsman

The results have been used, even more effectively, to improve methods and working conditions. Probably a greater share of the improved performance has been possible because of improvements in the sphere of management than in those things for which the individual draftsmen could be held responsible.

Incentives

The performance ratios obtained by the par-time plan have not been used directly to determine salary payments. However, there has been an indirect relation that has been effective. Salary rates of individuals have been increased with due regard to production and error records. Individuals falling considerably below average performance have been released or transferred to other work.

It may be possible to base salary payments directly on these performance ratios, but up to the present time the dangers inherent in such an inflexible, mathematical application of the ratios have been considered too great to risk. When a plan of measurement directly affects the pay envelope, every figure used in the formula will be questioned. This par-time plan has been effective partly because it has been used with good judgment. Draftsmen have accepted occasional "bad breaks" because they have known that they would be judged only on the basis of long-term averages and with a complete understanding of circumstances and conditions. The plan has been looked upon as a valuable guide to judgment and not as an inflexible measure that could be applied with a slide-rule.

Discussion

J. P. Jordan.[2] For a great many years management of progressive companies, aided to a considerable extent by the professional industrial engineer, has done much in the betterment of manufacturing operations, but very little has been accomplished in the other departments, particularly the selling and engineering.

In the selling function only the surface has been scratched.

In the engineering division there has been even less of constructive betterment effort. One reason for this is that the engineering function, including all of its ramifications, has been regarded as measurable only in the results of the devices which have been designed and in respect to the aid which the department has been able to give in the betterment of product from a manufacturing standpoint.

But whenever any suggestions have been made as to the possible reduction of engineering expense through careful analysis of the detailed operations necessary to any engineering department, there usually has arisen a storm of protest which would indicate that an engineering department is a precocious sort of institution which must of course be more or less temperamental, topped off with a halo, and in many other ways regarded as a portion of the business to be treated with care and deep respect.

The author has brought out a common-sense, businesslike, and perfectly practical scheme which not only looks well on paper and on graphs, but to the writer's knowledge has actually worked and has produced very satisfactory and profitable results.

It strikes the writer that any comment on this paper may better be confined to an appeal to all engineering departments to take the ideas at 100 per cent value and to apply them in every-day life. The author has very clearly exhibited the results of managing an engineering department by methods other than the consideration of the awesome nature of the people that inhabit the average engineering office. He has proved distinctly that engineering departments are just as susceptible to cost and volume control as any other department. He does not in the slightest degree depreciate engineering as a profession. But he does prove conclusively that the various functions within an engineering department are subject to just as much control as the functions of any other department. In fact, if any one will analyze the operations of the average engineering department, it will almost invariably be found that a considerable portion of the cost is for work which, under proper regulation, can be done at a considerably less cost. Much of the work of any engineering department is in a way similar to the work of other departments, and there is no reason whatever to think that in such common operations there should be any excess cost.

The author's plan of measuring the output of draftsmen is a workable plan, as is not only proved by his own graphs, but as also has been proved through the observation of the writer and his associates.

Therefore, the main object of this discussion is not so much to comment on the author's plan as to urge engineers in general to take the contents of the paper as something other than theory—in fact, to take it as honest-to-goodness practical stuff which can be and should be applied to the management of any engineering department.

The times which we must go through from now on, where sharp competition demands the lowest possible cost, are just the times where engineers can contribute their share to the lowering of costs if they will seriously look their own department right in the face and apply the principles as set forth in this very interesting and valuable paper.

A. D. Hunt.[3] The system of drafting-room control, described by the author, was placed in effect at the South Philadelphia Works of the Westinghouse Electric & Manufacturing Company on Feb. 1, 1930. The type of engineering organization, also described, was made effective on March 17 of the same year, so that a revised organization in both engineering and drafting began to operate as a unit about April 1. Up to the present time a rapid improvement has been made in drafting efficiency, and on the basis of the results thus far obtained it is expected that the rate of improvement experienced over the past year will extend for many months in the future.

The new plan establishes a line of demarcation between engineering and drafting effort and permits a control of drafting work, which under the old plan was not possible on account of the overlapping of the two activities.

While there is a clean-cut dividing line between engineering and drafting work, it is important that all men in a design division be located in one room, as close contact between all engaged in a particular branch of the work tends toward cooperative effort, and permits close supervision.

As the author emphatically points out, the chief draftsman of the conventional engineering organization is missing in the new order, in which the division engineer directs the activities of both the engineers responsible for design and the draftsmen who translate the engineers' ideas into detailed drawings for manufacture. The control of both engineering and drafting by the division engineer is of prime importance, but as personal guidance throughout the group is essential, the total number under one division head should be relatively small. In such an organization the younger outstanding engineer may assume greater responsibility than in larger conventional design groups by reason of the investing of greater responsibility in a relatively small number of men.

To insure high efficiency in the new drafting system, the engineering instructions (design specifications) must be definite and sufficiently complete to permit the steady flow of drafting work. The par-time plan provides a means of measuring group or individual capacity and efficiency and is extremely valuable in scheduling drafting work. It is invaluable in relating personnel to increasing or decreasing loads.

The individual drafting records are of material assistance in determining the relative ability of draftsmen, as these records show drafting efficiency, number of errors made, and cost of such errors. Emphasis is laid on the importance of small drafting squads under capable squad leaders. It is the experience at South Philadelphia that a squad of four to six men forms the most efficient drafting-room unit.

The use of master drawings and the employment of parts of old drawings, from which lithoprints are made, are important means of reducing the time in making detailed drawings. The par-time drafting system encourages the use of these short process drawings, as their use improves the performance records o the individual and the drafting room as a whole. At South Philadelphia the lithoprint process has been used since 1927, but a determined effort during 1930 to make a greater use of this labor-saving method doubled the percentage of lithoprints in eight months, and it is expected to greatly increase this percentage in the future. In May, 1930, the drafting room produced 1041 drawings, of which 177, or 17 per cent, were lithoprints, while in January, 1931, production had fallen off to 626 drawings, but of these 215 were lithoprints, or about $34^1/_2$ per cent.

---

[2] Stevenson, Jordan & Harrison, New York, N. Y. Mem. A.S.M.E.

[3] Westinghouse Elec. & Mfg. Co., South Philadelphia, Pa.

Experience with the new system of drafting management is limited to one year, and during this time drafting costs have been greatly reduced, as the author points out. However, it is believed that the future will show still greater reductions in drafting costs, as we have, in reality, only begun effectively to use the principles of management as set forth in the paper.

It has been definitely proved that this kind of drafting management may be successfully applied to the design of both electrical and mechanical machinery, and in the writer's opinion this same management may be successfully applied to many other engineering organizations.

John M. Russ.[4] The paper suggests two points, to either one of which the writer cannot entirely apply the author's fundamental premise, that of dispensing with the checker.

In the first place, it is wondered if the available supply of inherently capable men would be sufficient, if business conditions were what one would like to think of as normal and if the author's policy as outlined were generally followed.

It has been the writer's experience in the engineering offices of the machine-tool industry that to train the rank and file of the drawing-room personnel for the position of checker is an expensive process, often painful, and to pin this responsibility on the average draftsman in addition to his normal load seems potentially dangerous.

This would suggest the reiteration that the supply of individuals whose personal equation incorporates both accuracy and the acceptance of responsibility is limited—possibly too limited to permit all the engineering offices in the country to follow the author's plan.

In the second place, the writer questions the applicability of the principle of the draftsman checking his own work in either of the following fields:

1 In the plant producing a large output of interchangeable parts over a considerable period of time, the jig and fixture investment is high. It is also reasonable to assume that the same drawing may be used again and again, and the repetition of shop operations becomes enormous. It would seem here to be of the highest importance that the drawings and specifications should be as accurate when leaving the engineering office the first time as it is humanly possible to make them.

2 In the case of the consulting or contracting engineer, where various units are purchased from different plants geographically separated, it would appear to be of vast importance that the boundary or connecting dimensions of these individually fabricated units should tie in. This could be effected only by careful checking, and if the volume of business were great enough, it would take the entire time of one or more men, i.e., special checkers.

R. A. McCarty.[5] The author has pointed out that seldom during the past four years has a schedule for new drawings been unsatisfactory to the works department. He also might have said that during the five years preceding the period it was rather the exceptional case, in at least one of the four departments in question, when a drafting production schedule was wholly satisfactory to the manufacturing department.

This unsatisfactory situation arose from a lack of flexibility in the working force which made it fail to respond to the day-by-day changing demands of the load. If there existed a current load of new drawings which would keep the drafting force busy for 30 days, the "starting time" (the elapsed time before any new work could be started) was 30 days. Obviously, such a condition made it impossible to satisfactorily handle new orders for short-delivery apparatus.

With the responsibility for overall results placed in the hands of a single head, he was in a position to review the entire program each day, to readjust schedules and shift men—impossible under the old form of divided organization. This direct control obtained the flexibility necessary to satisfactory drawing dates.

On the matter of accuracy of drawings, it may be argued that Fig. 1 of the paper does not give a correct picture of the results, if a fairly large number of standard development drawings is made which may not go into immediate production. In order to check this possibility, errors discovered in the manufacturing department have been plotted against man-hours of productive labor in the factory using the rotating machinery department's drawings. This curve, covering the latter part of 1929, all of 1930, and the first two months of 1931, follows the same general trends shown in Fig. 1. It is believed that this method of comparing accuracy offers, perhaps, the most reliable basis yet developed.

Experience has shown that if a man's accuracy record is appreciably poorer than the average, the expenses of correcting his errors will later prove him unsuited for the work. Such records as these, therefore, make it possible to determine in a shorter period the accuracy qualifications of a new employee.

Author's Closure

The author appreciates highly the discussion presented by Mr. Jordan and all the more because of his wide experience in this field. After all, no plan of organization or management can be moved bodily from one plant to another and be expected to function, nor is any plan automatic in its operation. The success of a plan depends very largely on the skill with which it is adapted to local conditions and to personnel and the skill with which it is administered. The author has no thought that the details of his plan can be adopted without change, but he is confident that the principles involved and the more accurate method of measuring drafting output can be adopted in many kinds of design work with improved quality of design and with lower cost.

Mr. Russ questions the wisdom of eliminating separate checkers on two counts. He questions, first, whether the available supply of competent draftsmen is sufficient if this plan were generally adopted. This is not a matter of interest to the progressive manager interested primarily in his own operations. Certainly, no one would decide against a desirable action for the reason that, if every one took the same action, it would become impracticable. But answering this question more directly, no difficulty was found in obtaining a sufficient number of competent detail draftsmen from the existing forces in these three departments to eliminate separate checking as a routine operation. It should be remembered that, with separate checkers, there will usually be one checker for every three detail draftsmen, which at once provides a source of high-grade draftsmen to replace detail draftsmen who cannot measure up to this new opportunity and responsibility.

Mr. Russ questions, also, whether separate checking should be omitted in certain cases. This is one of those questions that should be settled by local conditions. The methods of operation advocated by the author do not prevent separate checking from being used in special cases, and a small amount of separate checking is usually being done in the design departments under his supervision. The fact that it is a special operation, and not a routine operation, makes this occasional separate checking more effective, because the detail draftsman does not know that his work will be separately checked.

The author has been interested in finding a confirmation of his experience in that of the author of a similar article.[6] By properly selecting detail draftsmen, who proved their ability to check their own work, the number of errors was not increased, and the cost of separately checking drawings was reduced from 35 per cent to 15 per cent of the drafting time.

MAN-54-3

Variations in Maintenance Costs and Procedure

By E. V. Stoody[1] and G. I. Ross,[2] Boston, Mass.

The paper treats in a new way the important function of maintenance in industry. It is an analysis of the ratio of the maintenance forces in 20 industrial plants. The authors give reasons for the discrepancies shown by the analysis. The paper should be of assistance to managers wishing to conduct their maintenance activities economically. The charts indicate by the wide dispersion of ratios that there is a large field for improvement in the general treatment of the maintenance problem.

E. V. Stoody

G. I. Ross

MAINTENANCE, as a function of plant operation, is often regarded by management as a necessary evil. It is too frequently considered to be non-controllable and is permitted to function independently within what are regarded as reasonable limits of expense. These limits are usually determined by guess. Maintenance departments are enlarged for emergency maintenance or for construction, and are allowed to operate with increased personnel long after the emergency work has been completed. On the other hand, due to the hazy conception of what maintenance costs should be, the maintenance department, in periods of economy, is too often depleted beyond justification and with eventual detriment to the company.

If two identical plants manufacturing the same product were placed side by side under unified executive direction, it is safe to assume that any inconsistencies in operating costs between the two plants would be quickly discovered. If the maintenance force in one plant were twice as large as that in the other, the management would soon take steps to determine the reason. The variation would warrant this attention, and each plant would serve as a yardstick to measure the other. Yet this condition exists in more than 75 per cent of the plants which we are called to study, and many of these plants enjoy the very best of managerial talent.

True, the plants studied are not identical, nor are they side by side under unified direction, but they need not be if studied carefully and the variables be given due consideration.

This relatively large difference in maintenance ratios is illustrated by the accompanying charts. The 20 plants which are used for purposes of comparison are typical of the many studied. The grand total of the plant forces represented by the chart, Fig. 1, is 28,872 persons, and the total of the maintenance forces is 1797. There may be some difference of opinion regarding one or two of the groups selected as pertaining to the maintenance function, but such difference would be small and would not alter the general relation of the forces.

The variations in maintenance forces expressed as a per cent of total employees may be explained by:

1 Different standards of plant maintenance
2 Variations in the efficiencies of maintenance forces
3 Physical differences in plants, equipment, and processes.

The chart, Fig. 1, shows the 20 plants arranged according to number of employees and indicates that, in the group selected, the size of plant alone has no bearing on the maintenance ratio.

In plants in which no maintenance employees are listed under any particular classification, the total absence of such classification can be explained by a variation in definition, the work is handled by employees classed as productive, or, due to the nature and size of the plant, the work is so minor that it is handled by employees listed under other classifications. Consequently, in the discussion of any particular classification, such plants are not considered if the classification is totally absent.

The chart, Fig. 2, indicates that the greatest variations occur in the following order:

Class	Groups	Minimum per cent, exclusive of 0 per cent	Maximum per cent
J	Janitors, sweepers, porters, etc...	0.22	4.12
E	Machinists, machine repairmen...	0.24	3.59
L	Yardmen........................	0.12	2.82
B	Belt repair, oilers, millwrights....	0.32	2.42
H	Masons, plumbers, tinsmiths.....	0.11	1.69
K	Watchmen.......................	0.16	1.59

The wide variation in the janitor-sweeper group can be easily understood when it is considered how widely the opinions of managements differ with respect to the cleanliness and tidiness of their plants and offices. Another factor which affects this classification is the type of industry. A factory with a large machining department requires the disposal of many turnings and chips which may be done by this force. The highest ratio in this group is attained by a plant of 170 persons and is due to the fact that the plant is housed in an extremely poor group of buildings and the maintenance force is poorly supervised.

This brings forth an important point, namely, that inherent property conditions may exact a heavy penalty from the company in the way of high maintenance charges. These would include not only such items as sweepers and janitors, but also building repairmen, watchmen, etc. This consideration is something

Note: Statements and opinions advanced in papers are to be understood as individual opinions of their authors, and not those of the Society.

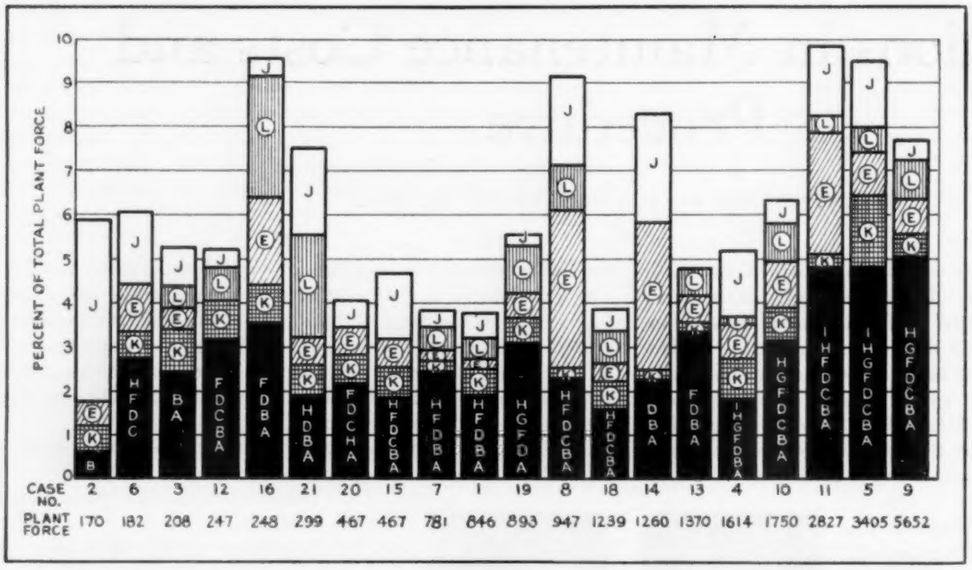

Fig. 1 Ratio of Maintenance to Plant Forces in 20 Typical Plants Arranged According to Size of Plant

(Legend: A, supervision and clerical; B, belt repair, oilers, millwrights; C, blacksmiths and welders; D, electricians; E, machinists, machine repairmen; F, carpenters, pattern makers; G, painters; H, masons, plumbers, tinsmiths; I, truck repairmen; J, janitors, porters, sweepers, etc.; K, watchmen; L, yardmen.)

which may be accepted or equated against the capital cost of a change.

In group E, machinists and machine repairmen, the variation is undoubtedly due to a large extent to the disparity between repair requirements in different industries and to the policy in some companies of letting out major machine-repair work to outside contractors.

In the case of the largest variation, case No. 8, the maintenance force was found to operate very inefficiently, and this fact, coupled with the character and age of the plant equipment, was conducive to a high force. The next largest ratio is found in case No. 14, where an excellent operating department was found to exist. The plant in question, however, is very highly mechanized, and therefore is inclined to run high on machine-repair work.

Group L, yardmen, is bound to be a large variable due to the differences in industries. Plants which have a considerable amount of loading and unloading of sheet metal often call upon the maintenance yard crew to perform this work. This is exactly the reason for the high ratios in cases No. 16 and No. 21.

The variation in group B, belt repairmen, oilers, and millwrights, is not so readily explained. Of course there is a certain amount of dispersion due to a difference in the nature or condition of the plant equipment. Other variations will creep in due to the difference in definition of the trades in the various plants. In some plants the electricians take care of the motor oiling on their routine electrical inspection, while the millwright work may be done by machinists, carpenters, etc. In this group the effectiveness of the force probably plays as large a part as any other cause.

The masons, plumbers, tinsmiths, etc., group H, seem to vary principally due to plant and equipment differences. Obviously, however, maintenance standards and the efficiency of the department play a large part. The highest ratio in the group of plants under consideration obtained this questionable honor due to all three causes, but principally to plant conditions and departmental inefficiency. The plant is a large one carried over from the war period and is encumbered with many more buildings than are required. Operating at productive capacity, the ratio would probably have been lower.

In the watchmen, group K, the same plant, case No. 5, had the highest ratio. This is again traceable to many buildings to be policed, many gates to be guarded, and street and railroad crossings to be watched.

Inefficiency in maintenance departments can be largely attributed to the following causes:

1 Poor or no supervision of operating force
2 Poor physical arrangement of quarters
3 A lack of adequate inspection routines and standards
4 The absence of a suitable order routine for flagging expenditures before they are made
5 Faulty organization, preventing an economic distribution of maintenance labor
6 Too many straw bosses.

In many cases, more than one of these causes is evident. Thus it is found that scattered maintenance shops in outlying buildings are often conducive to operating inefficiencies due to the impossibility of good supervision. Likewise, the absence of adequate inspection routines is often accompanied by frequent and unexpected machine failures. This places the maintenance function in the "corrective" class rather than the "preventive," and thereby introduces sudden demands for specialized labor. In addition, such a laxity is often responsible for interruptions in productive output.

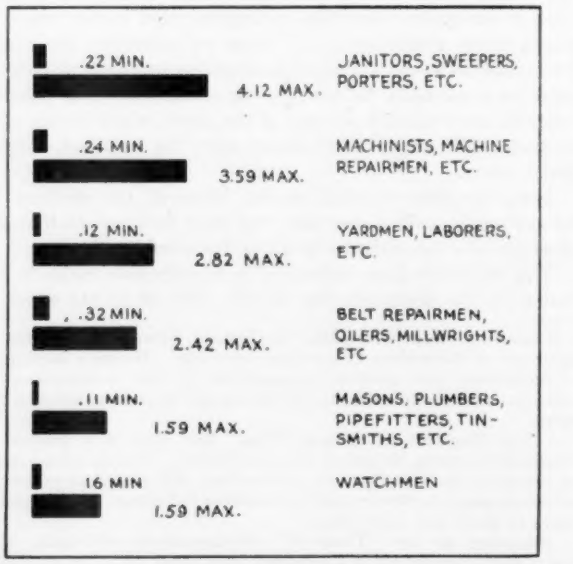

Fig. 2 Graphical Analysis of Variations in the Various Classifications

(Figures shown are percentages of the group to total plant force. Zero percentages not included.)

High maintenance costs are often charged to the inefficiency of the department when the real fault lies in the absence of suitable maintenance standards. This means that much of the work done may be unnecessary. It means that the standard of upkeep is decided by the individual worker and that the state of repair of both plant and equipment varies with the ideas of the individuals performing the repair work. In busy times, the general tendency is to slight "precautionary work" and in times of depression to overdo work of this nature.

The importance of plant maintenance cannot be emphasized too strongly, for it is the maintenance function that insures against interruption in production due to machinery breakdowns. A slight production tie-up may involve losses far greater than any maintenance cost. Furthermore, neglected equipment will very often wear out before its useful life has expired, thereby introducing hidden losses which will ultimately appear to the consternation of the management.

While maintenance must not be neglected, it also must not be overdone, for the plant which maintains within practical limits will outstrip quickly its competitor who goes in for "frills and fancies," all other things being equal. In other words, there is a point at which an economic balance exists between maintenance effort and operating costs, and this point is different for every industry. The determination of this economic balance involves the setting of maintenance standards, and these should be determined as carefully as product standards, for the maintaining thereof involves a definite charge against the operating income.

Because of the difference in standards, maintenance forces are not strictly comparable between plants, but if an unfavorable comparison is not interpreted to reflect inefficiency, it can be regarded to show an unwise difference in standards or an inherent penalty due to the condition of the plant property. The previous discussion of the chart, Fig. 1, shows how variations from the average can be explained in an analysis of the maintenance ratio.

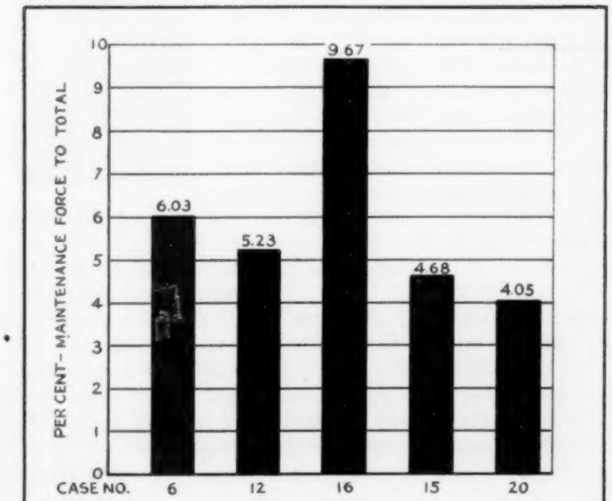

FIG. 3 RELATION OF MAINTENANCE FORCE TO TOTAL PLANT FORCE IN FIVE SIMILAR PLANTS PERFORMING STAMPING AND ASSEMBLY WORK

This analysis can be made even more searching by segregating the plants according to type of equipment and the character of the product. For example, let the same plants be examined as follows:

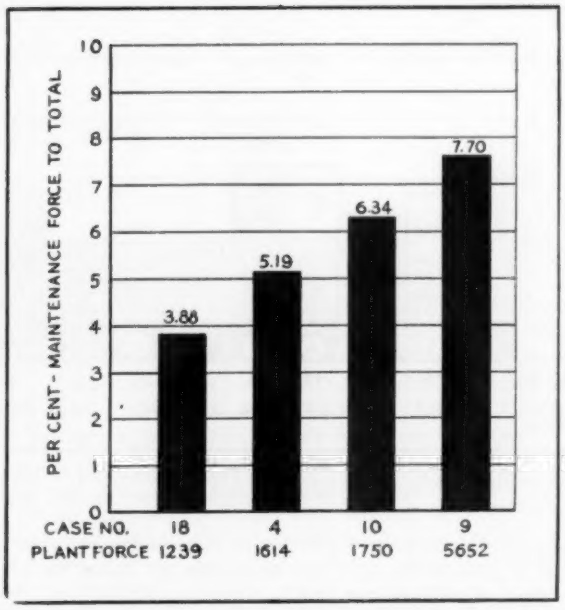

FIG. 4 RELATION OF MAINTENANCE FORCE TO TOTAL PLANT FORCE IN FOUR SIMILAR PLANTS FABRICATING AND FINISHING SMALL COPPER-ALLOY PARTS

STAMPINGS AND ASSEMBLY TO COMPLETED UNITS

Plant	Maintenance per cent to total plant	Total plant
6	6.03	182
12	5.23	247
16	9.67	248
15	4.68	467
20	4.05	467

This group is depicted by the chart in Fig. 3.

The five plants listed in the foregoing classification are considered as being comparable from the viewpoint of similarity of manufacturing processes. It is interesting to note that plants 15 and 20, with the greatest number of employees, show the lowest maintenance ratios. Plant 16 has the highest ratio, and when compared to the other plants listed in this class shows glaring inconsistencies. Reference to the chart indicates that in plant 16, classifications E, L, and B are the most out of line. A study of the plant reveals that great quantities of sheet steel are handled in the yard, which factor explains the excessive percentage in class L, yardmen. Further study fails to reveal any explanation for the excessive ratios in class E, machinists and machine repairmen, and in class B, belt repair, oilers, and millwrights. Consequently, in considering a reduction in maintenance costs, it is reasonable to look to class E and class B.

Plant 6 can also be considered to be somewhat out of line. It employs the smallest number of employees and shows the second highest maintenance ratio. In this plant, class J, class E, and class H show the greatest ratios of the total. Class J, janitors, sweepers, and porters, can be explained by the fact that the management takes extreme pride in plant appearance, and consequently the plant and grounds are maintained in excellent condition. Even so, the justification for this extra expense should be questioned. Class E and class H, although apparently high, cannot logically be considered for reduction due to the size of the plant. Although as percentages they are high, when reduced to numbers of employees, each shows less than two workmen.

Considering the points for reduction that appear to be possible in plant 16 and to a slight extent in plant 6, and considering

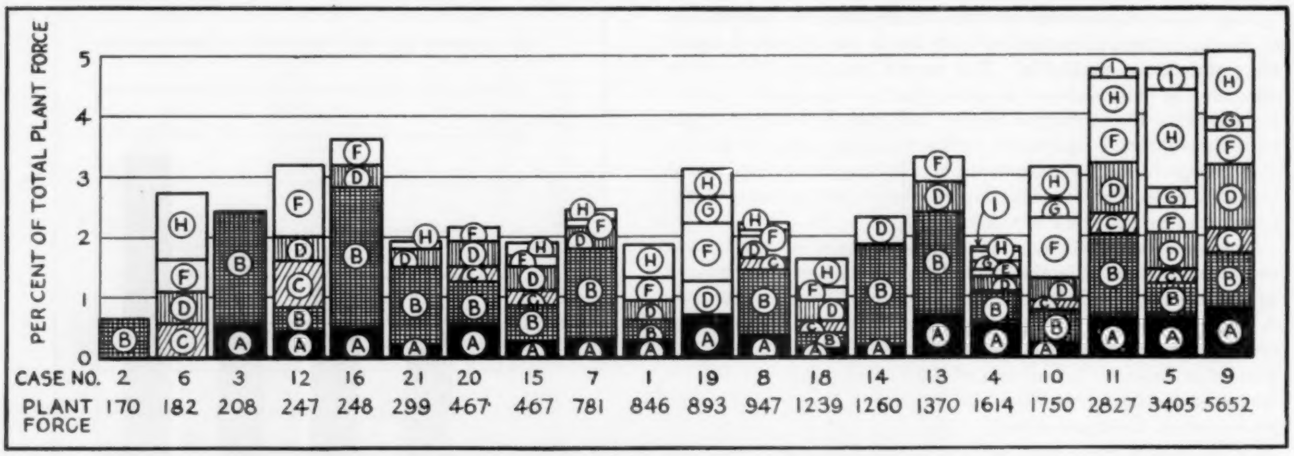

Fig. 5 Relation of Maintenance to Total Plant Forces

(Janitors, sweepers, watchmen, yardmen, etc., excluded. Legend for groups A to I, inclusive, same as in Fig. 1.)

that these reductions have been made, then the five plants in this industry classification become approximately equal from the viewpoint of maintenance ratio.

Another interesting comparison can be made of the four plants depicted on the chart, Fig. 4.

FABRICATING AND FINISHING SMALL COPPER-ALLOY PARTS

Plant	Maintenance per cent to total plant	Total plant
18	3.88	1239
4	5.19	1614
10	6.34	1750
9	7.70	5652

The four plants listed in this group are definitely comparable from the viewpoint of similarity of manufacturing processes and products, and also from the viewpoint of many old buildings housing the various manufacturing divisions. Reference to the chart fails to reveal any startling inconsistencies in any classification among the four plants listed in this grouping.

A detailed analysis of the maintenance departments in these four plants revealed that in plants 4, 10, and 9 the maintenance departments were too decentralized and split up into too many subdivisions, etc. All of this resulted in an uneconomical distribution of maintenance labor. Reductions were possible in each of these three plants.

In conclusion it can be said that maintenance costs are controllable. Standards can be determined and made to operate as effectively as production standards. Yardsticks are available for measuring the effectiveness of the plant maintenance department, and when applied intelligently, are of immeasurable benefit in controlling this function. Experience in numerous manufacturing plants throughout the country has proved these facts.

Coordination of Research and Engineering With Production and Sales

By CARL L. BAUSCH,[1] ROCHESTER, N. Y.

This paper is largely an exposition of the organization of the Bausch & Lomb Optical Company, Rochester, New York, in so far as it affects the function of research and engineering. This company went through a thorough reorganization several years ago and was fortunate in being of sufficient size to justify a distinct research and engineering division, and still small enough to make it possible to tie the functioning of these departments to that of the other departments without becoming involved in too much machinery and red tape. The company employs about 3000 people and has a research and engineering force of about 100. It manufactures a very large variety of small-quantity-production items, although there are a few items that are manufactured on what might be considered a quantity-production basis. It has, naturally, tried to minimize the amount of development work on articles that are expected to be sold in small quantities; still experience shows that quantity can have no great influence on the thoroughness with which the development work must be done, the company being often forced by circumstances to spend large amounts on work which will never result in large production.

The head of the Research and Engineering Department reports directly to the general manager and assumes full responsibility for all expenditures for development work. A yardstick has been set up by which accomplishments can be measured. This yardstick is the relationship between money spent on development work and the value of new business created, which consists of the amount of work of a regular production nature placed in the plant for manufacture, plus all special customers' orders requiring engineering-department design and follow-up. Figures are shown of this ratio for different classes of product.

Although the Research and Engineering Department assumes full responsibility for development work, sales and production are very definitely tied into the picture and must assume part of the responsibility when manufacture is finally started. Effective means are used to bring this condition about.

IT SEEMS quite necessary in presenting a paper of this kind to define the terms "Research" and "Engineering." A study of the dictionary convinces one that it is possible to make them mean very much the same thing or quite different things as one wishes. In industrial work the two functions are quite widely separated in the very large concerns and combined in the small ones. In the medium-sized concern there is a certain amount of overlapping and a flexible organization is necessary so that full advantage can be taken of the personnel available. The term "development" is probably a good one to use in describing the dual function of research and engineering in such a case.

Because of the flexibility needed in the organization great care has been taken to see that responsibility and authority are so vested as to bring about accomplishments without undue delay and friction. Organization charts, Fig. 1, help to visualize the problem involved in maintaining coordination between the activities of the sales, research and engineering, and production departments. The Scientific Bureau is the optical research and engineering department. All the optical designing is done here, regardless of the nature of the product involved or the division of the sales department it is for. Within the Bureau a division of work is made according to the type of design involved. In general these divisions are, ophthalmic lens, photographic and projection lens, instrument lens, ophthalmic instruments, and measuring instruments.

The Technical Bureau serves very much the same function as the Scientific Bureau except that it has to do with the mechanical problems in optical-instrument design. The divisions here are quite different, there being in general four separate divisions: (1) measuring instruments, (2) microscopic and ophthalmic instruments, (3) electrical and projection apparatus, and (4) industrial instruments.

The Optical-Machinery Development Department is a unit in itself having to do with the development of machines that are sold to the optical prescription trade. The Military Department is an individual one developing fire-control instruments such as range finders and submarine periscopes.

The department designated as Instrument Development is an experimental and sample department working with the Scientific Bureau and Technical Bureau in the practical development of projects that have reached the sample stage. The Spectacle Development Department is a unit by itself whose function is to develop new lines of spectacle wear. It also concerns itself with magnifying lenses and similar products.

The Drafting and Specifications Department is really what in most plants is known as the Engineering Department. It whips the creations of the other development departments into practical shape for manufacture. The Patent Bureau and the Final Inspection Department come under the Engineering Division for various obvious reasons.

Another function of the Research and Engineering Division is investigation of the possible uses to which the product might

---

[1] Manager of Research and Engineering, Bausch & Lomb Optical Company. Mem. A.S.M.E. Mr. Bausch was graduated from Syracuse University in 1909 with the degree of Mechanical Engineer, and entered the employ of the Bausch & Lomb Optical Company. He has served as foreman, assistant superintendent, superintendent, and mechanical engineer, and has had his present position since 1926.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

be put. This is a sort of general function of the entire division, and is only crystallized definitely in one department of the division. The Scientific Bureau maintains a chemical and physical laboratory where experimental work is done in an endeavor to find uses for the product.

It will be seen that the division of responsibility shown in the charts of the sales and manufacturing organizations is not the same as in the Research and Engineering Division. In the Sales Division there is an Educational and an Industrial Sales Department that may be handling the very same products, but selling them to different markets. This form of organization where the departmental classifications differ in the different divisions of the business, makes it rather difficult in some respects to bring about proper coordination of results, but the advantages of the set-up more than offset the disadvantages.

FIG. 1 ORGANIZATION FOR RESEARCH AND ENGINEERING, MANUFACTURING, AND SALES DEPARTMENTS

In order to bring about this coordination without involving the head of the division in too much detail a department is set up directly under him and keeps in touch through records with all the work that is going on, and crystallizes its findings in reports which are very helpful in maintaining control and expediting the progress of work.

The business of Bausch & Lomb is run on a very definite budget basis and the appropriation for the program of the Research and Engineering Division is included in this budget in some detail. This appropriation includes money for development work on special products for customers, development work on new regular products, development work of a research nature, development work on the improvement of old products, service work for the manufacturing department, service work for the sales department, study of further uses for these products, literary work on catalogs, papers, sales manuals, etc.

Instrument Description

FIG. 3 PRODUCT AUTHORIZATION FORM

To get a detail control of development work, no actual work is done without a form (see Fig. 2) being made out and an attempt made by the engineer in charge to answer the questions enumerated to the best of his ability. Looking over this form, it will be seen that there are questions which ordinarily would be put up to the Sales Department to answer, but in order to expedite action the engineer is made to feel the responsibility for getting the answers. He will naturally go to the different sales heads or others involved and get the facts that he needs to assume this responsibility. In work of a research nature, it is of course very difficult to answer the questions involved, but an attempt must be made in order to force thought on the subject.

The Engineering and Research Divisions are absolutely responsible for the money spent and for the results obtained, and it is their job to get the necessary cooperation to put the stunt over. Records are kept of expenditures against each of 20 different product classifications, and at the end of the year a comparison is made with accomplishments. For the purpose of accounting, accomplishments are assumed to consist of the dollar value of new products taken in work during the year including regular standard products and special customers' orders, minus the yearly sales value of products discontinued in the different lines during the year. This report for the year 1930 showed a ratio of value of new work created for the year against cost of development that varied from $58 to $0.50, with an average of $8.50 new products per dollar of development expenditure. Another figure that may be of interest is the ratio of expense of development to total sales for the year, which varied on the different classes from 0.2 per cent to 13 per cent, with an average of 2.8 per cent.

The Development Division does not carry the absolute responsibility beyond the creating of the product. In order to get the stamp of approval of the whole organization on new products resulting from development work a form (see Fig. 3) is used which is signed by all the departments interested before work is turned over to the factory for manufacturing. Here, under the head of design, the approval of the Scientific Bureau and Technical Bureau is secured on the optical and mechanical features, respectively. The Patent Bureau approves the project from its standpoint. The Inspection Chief indicates his approval and draws up inspection specifications for the production of the item. Under the heading of manufacture the superintendents involved sign the authorization. The Specifications Department gets from the superintendents an estimate of cost of manufacture.

The Sales Department signs up, indicating what data are required for sales manuals and catalogs, what items of manufacture will be affected, and indicates the prices to be charged based on estimates and market conditions. It also states the quantity wanted for one year's sales. The Advertising and Production Departments sign the authorization and the chief draftsman indicates what sort of specifications will be given to the factory to manufacture from. It is then noted by the managers of manufacturing, service, and engineering, and then, and not until then, is it a bona fide Bausch & Lomb product ready to be turned over to the factory.

Although up to this point the Engineering Division was entirely responsible, now the organization as a whole accepts the new product and its creation is charged up as a credit to the Engineering Division.

Discussion

Charles M. Mills.[2] The author has certainly rendered a service in the definition of "research," "engineering," and "development." He has pointed out that although in his own company the words used are, "Research and Engineering Department," the main function is that of development. From considerable corporation experience, the writer believes that the word "development" cannot be emphasized too much. Frequently the word "research" connotes a more or less isolated group of men divorced from the activity and heart of the company's business. To many line executives the word "research" is dissociated with everyday affairs.

Likewise there have been frequent clashes between groups known as "research" and "engineering." In some corporations the word "engineering" means an active group of men engaged on construction and replacement. In other companies "engineering" may include these men plus groups engaged in pure research. The word "development," therefore, appears to be a happy solution of the problem.

The author has clearly outlined his own organization. The various subdivisions of his department, Scientific Bureau, Technical Bureau, Optical Machinery, Development Department, Military Development Department, are clearly divided as to their functions. Further it is easy to see how the proper cooperation can be established between these departments and sales and manufacturing.

However, a general organization chart showing the relation between the heads of the larger departments would have been helpful. How do the heads of manufacturing sales and research and engineering tie in with the top executives of the company? Just where is limitation given to the research and engineering department to perform solely as a staff group? Is there a distinct ranking of the personnel that top the three major departments?

Joseph Geschelin.[3] Experience in the automotive field indicates that coordination is incomplete unless it includes the service field. The user has much of value to offer the research department. And the engineer must find the opportunity to contact frequently with this group.

Research is concerned not only with the development of new products, but also with improvements in the present line. Certainly no one knows better than the user just what the limitations of your product are. He can frequently suggest slight changes which may improve performance and acceptance profoundly. In a similar fashion the user may be a prolific source of ideas for new products.

Another reason for closer contact with the users and with one's own service organization is that in many cases the service man does not know as much about the product as he should. This should be a real source of concern to the engineer. In many cases observed personally, modifications are made in the field which are not reported to the factory and consequently do not appear in the products. Thus, slight inconveniences to the user are perpetuated at the expense of good will.

Accordingly for complete coordination of research and other company functions, include service as one of the most important elements.

[Discussion of this paper, jointly with that of Richard F. Wilder, by Walter E. Lee, B. Townshend, E. C. Rack, and L. A. Hawkins, will be found following the latter paper.]

Author's Closure

Mr. Charles M. Mills has suggested that a general organization chart, showing the relation between the heads of the larger departments, would have been helpful in this paper. He asks how the heads of manufacturing, sales, and research and engineering tie in with the top executives of the company. There are five divisions of the business heading up to the general manager. These are sales, research and engineering, manufacturing, service and maintenance, and comptroller. The five managers of these divisions are directors of the company and report directly to the general manager.

[3] Engineering Editor, *Automotive Industries*, Philadelphia, Pa.

Mr. Joseph Geschelin calls attention to the fact that the user of products has much of value to offer the research department. This is undoubtedly true. It has been the experience of our company that contacts with the user are absolutely necessary, if one wishes to bring about ideal designs. In our organization this contact is made mostly through our salesmen, who are practically all technically trained men. These salesmen often suggest that an engineer be sent out on the job to get first-hand information, which is often done. This hooks up pretty closely with what Mr. Walter E. Lee had to say; that is, that most of the problems recommended for research come from the field through the sales department. His description of the sales department as the ears and eyes of the whole organization is very well taken. We must cater to the department that produces the revenue and makes possible all the other activities of the organization. In the last analysis ability to sell the sales department the results of research is the true measure of the efficiency of the research and engineering departments.

Mr. L. A. Hawkins takes exception to the statement that the words "research" and "engineering" are sometimes used to mean much the same thing. The author tried to make clear that this was the point of view of a medium-sized concern. It is easy to understand how Mr. Hawkins, because of his connection with a very large corporation, feels that it is a pity that these two activities cannot be kept separated. Although it is true that the search for new scientific knowledge is a different thing from the application of scientific knowledge in developing new or improved processes of product, still it is found that in a medium-sized corporation the knowledge gained by the people in research can often be applied more efficiently by them than by passing it on to a separate department. An organization such as described makes it possible to function in both ways, depending upon the circumstances surrounding the project.

Coordination of Research, Sales, and Production

By RICHARD F. WILDER,[1] CAMBRIDGE, MASS.

This paper seeks to demonstrate how the various research activities are coordinated one with another, and then as a unit with sales and production, so as to consider related factors in the instigation and carrying forward of research projects. Likewise it aims to bring out how definite mechanisms of coordination may be established whereby the greatest benefits may be derived from the research activities through the development and manufacture of products which are both commercially and technically sound.

COORDINATION of research, sales, and production—what does this expression mean to company executives throughout industry? In the first place, "coordination" is the "process whereby advance agreement is secured regarding a policy and general methods of execution from several functionaries necessarily involved in its carrying out and the further process whereby their execution of it is secured in such a manner as to harmonize the special points of view of the several functionaries to the end that there is willing, orderly, and effective carrying out of the policy."[2] The principle of coordination is found to be, "Definite mechanisms and routines must be provided to the end that all groups within an organization function harmoniously in the attainment of a common objective."[3] We may take this definition and principle of coordination in connection with research, sales, and production to mean the marshaling of all forces connected with product and process development, the consideration of all related factors, and the combination of these elements into a smoothly working mechanism with the objective of manufacturing and selling a line of products that are commercially and technically sound.

The author has attempted to determine how such coordination is effected in a number of representative companies, and from these cases to draw certain general conclusions. Some fifty organizations, over a wide geographical range and representing many different types of industries, were studied. Manufacturers catering to the style element were excepted.

The expressions "centralized" and "decentralized" research functions will be used frequently. Centralized research is defined as the separation of the research activities from the line activities, combining all such into a department reporting directly to an officer not directly connected with a line activity. Decentralized research means that the research functions are found in the respective line departments to which they are related.

Justification of Research

Present-day industry is much more sympathetic with research of a technical nature than it is with such studies relating to markets. Research of the former type is a force for improvement in both manufacturing processes and products. It appeals to the average company executive because of its tangible nature. On the other hand, despite keen competition, a fastidious public, and the addition of hundreds of new products to an already diversified list, market research has not been generally accepted as a vital function of industry. There is a definite time lag between the results obtained from market research and those obtained from technical research, inasmuch as the former are usually far removed from the original research project, the product itself being usually the result of that work. Market research may not show results until many months later, when they may possibly take the form of increased sales and profits brought about through the development of a product for a market which was known to exist before the technical development work was ever started or had progressed to any large degree.

The predominant method of interpreting market conditions, reactions, potentials, etc., is through the use of sales executives and salesmen. It would appear, generally speaking, that such a practice is basically unsound. The function of the salesman is to sell the company's products and not to spend a large amount of time in market field work. Another factor is the method by which the sales force is paid. If this is on a commission basis, these men will not spend a large amount of time on work that will cause their sales volume to decrease. Also, the inherent characteristics of a salesman will hardly fill the requirements of a successful market research man, as one of the basic characteristics of a good salesman is optimism, and his market investigations may not be based upon impartial facts.

The responsibility of deciding as to the feasibility of instigating research work usually rests with a major executive or a group of such. In order to advance sound conclusions, sound information, reflecting every angle of the problem, is necessary. We find engineering, research, patent, and manufacturing research departments each contributing their part. Yet in many cases the only consideration made of the markets will be a round-table discussion of four or five executives, the reaction of several sales managers, and the suggestions of a number of salesmen.

In many cases, particularly in those companies manufacturing industrial goods, market research is viewed as a less necessary adjunct than in those companies manufacturing consumer goods. However, in these cases there is the danger that the company

executives will overestimate the degree of concentration of their market.

Need for Coordination of Research Activities With Sales and Production

There are generally two broad mediums through which research may be conducted—either by the research departments in an organization or by the employment of outside concerns. This paper will deal with the former, concerning the policies existing within an organization, and those types of research which have a specific objective.

Consider, for example, the development of a new product or a radical change in an existing product. Generally speaking, we must determine upon:

1 The product itself—what it is to be made from, the physical and chemical characteristics necessary, cost of material, its form, design, etc.
2 The manufacturing methods and processes—whether it can be economically produced, the production facilities necessary, the new equipment needed, the cost of equipment, the cost of manufacture, etc.
3 The market—whether there is one, the quantities it will absorb, the competitors in the field, distributing channels, type of market, etc.
4 The patent situation.

Here we have four distinct problems in four separate fields to investigate, with the view of making an addition to the regular line of products or of improving the process of manufacture. These activities have to be coordinated with each other and later to be translated into routine production and selling. Each of these is analogous to four sub-assembly lines feeding a main assembly line. Obviously, a delay in any one affects the whole production schedule. Yet there are those companies that will allow one of these research activities to proceed at a wide tangent to primary objectives and accept such a condition without taking definite steps toward remedying the trouble. Is not the development of new products, improvements in existing products, and improvements in manufacturing methods and processes important enough so that all activities can be coordinated to permit speed of operation and low operating costs, and at the same time to attain technically and commercially sound results?

Some of the outstanding dangers attendant to this so-called lack of coordination of these different functions are:

1 Spending money in development work on a project that turns out to be a failure owing to improper consideration of all phases in the initial investigation
2 Development of products that are not commercially sound, because of lack of markets or high selling price due to high manufacturing costs, etc.
3 Waste of time and money on research projects that have no application to the business
4 Product design developed without consideration of the manufacturing department
5 Failure to direct the activities of the different research functions into those channels giving the greatest benefits
6 Danger of personnel difficulties arising out of apparent conflicts of authority
7 Progress delays on a project due to the lack of cooperation of departments
8 Omission of periodic follow-up of research work to determine the advisability of continuance
9 Danger of not routing research projects, in relation to types of research to be performed, so as to eliminate impractical ideas in the early stages.

In addition there is the patent situation to consider. This is usually handled by having all projects approved by the patent department before any large expenditures, either in time or money, are made.

The Elements of Coordination

Granted that there is a need for coordinating these various industrial activities, how can it be accomplished? The principle of coordination is to establish definite mechanisms and routines whereby correlation of all functionaries and their activities in complete and harmonious operation can be maintained. The essential factors would seem to be organization, personnel, and the placing of authority, each with modifications and additions as individual cases might warrant. Before attempting to solve this problem, company executives should ask the following questions:

What is the personnel situation?
What is the size of the company?
What are the types of research with which we are most concerned?
What is the nature of our product?
What is the nature of our market?
Are we in a style industry?
What is the specific object of our research activities?
What seems to be the difficulty in our present method of operation, etc.?

Inasmuch as such great variations exist between different companies, no attempt has been made to analyze and compare different policies as to the individual steps which make up the development procedure and coordinating machinery. Rather let us consider what representative companies are doing, treating each one as an individual case. From these considerations, general deductions can be made. It should be borne clearly in mind that these cases represent a pattern of the company policy from which there may be certain divergencies as individual situations demand.

The companies interviewed have been divided into four general classifications on a basis of the position of the research functions in the organization, as follows: (1) Decentralized research functions, (2) partially centralized research functions, (3) completely centralized research functions, and (4) research in the largest type of organization.

Decentralized Research Functions

These organizations range in number of employees (as of the fall of 1930) from approximately 1500 to 11,000, while the range of all interviewed companies in this classification is from approximately 750 to 45,000 (only one company above 11,000).

Attention is first called to a large company manufacturing both consumer and industrial goods, the products of which are not manufacturing equipment and not of a mechanical nature. Fig. 1 shows a partial organization chart of this general type of company. In this case the market research function is divided into two general fields (not shown on Fig. 1), each being handled by a department reporting to the vice-president in charge of sales—namely, the study of further uses for the company products and the study of these newly discovered markets in relation to potential value, buying power, etc. Such a division is necessary due to the scientific nature of the investigations carried on by the department looking for new uses.

Generally speaking, all ideas and suggestions requiring technical research are referred to the vice-president in charge of manufacture, and in all probability the advice of the sales executive is sought by him before making a decision. If the suggestion seems to present worth-while characteristics, a preliminary investigation is made with respect to product research and manufacturing research. This investigation is not expensive and may eliminate impractical suggestions at the start. If the results are satisfactory, the project is turned over to the sales executive, who instigates a market analysis. On these two investigations it is decided whether additional development work is feasible. If decided in the affirmative, the manufacturing executive instigates further development work, and the project is completed up through the determination of manufacturing processes. If possible, a small-scale test of the market is made before any new development is released for regular production.

During this development period reports covering hours of work spent, progress being made, and cost are submitted monthly to the two vice-presidents. Each executive has authority to stop work on any project on a basis of the work done in his department. After all work has been completed a recommendation of the two vice-presidents is submitted to the president.

The policy of this company presents a clear-cut example of individual management of individual functions, with all functions being coordinated through the consultation and cooperation of the two executives concerned. Under such an arrangement the relationship between the technical research function and the line manufacturing function is likely to be close, as both are under the control of the same executive. This is true for the market research and the line selling. On the other hand, it is noted that a major staff function and a major line function are controlled by a single executive, and this condition brings the personal equation to the forefront. In some cases a line executive may have all the characteristics necessary for the control of line work and not be capable of administering the associated staff activities.

A direct contrast to this method of research control is found in another company of the same general type of organization. While the products vary in nature from those in the preceding case, they are not different enough to require another type of set-up and operation. In both instances the management feels that the heads of the different research functions should report to the head of the line departments to which they are related. The control of research work is vested in a committee composed of the heads of the merchandising, market research, manufacturing methods, engineering, and chemical departments, and a special staff executive who, as chairman of the committee, reports to the president. Research projects relating to changes in existing products or the development of new products usually arise in one of the merchandising departments, and are referred to the research committee for approval after the project has been investigated superficially by a staff division of the merchandise department with respect to markets, production methods, and means. If research work is approved, the committee will determine the sequence of operations (what type of research is to be carried on first, etc.), and then assign it to one man who will follow the work through. This development work is carried on up to the point of practical usefulness, and is then turned over to the appropriate line department. Every week a report on every project being studied is submitted to the committee covering (1) the title, (2) the progress being made, and (3) the amount of time spent in the study. Once a month these reports are condensed into a formal report, and the situation is reviewed by the committee.

A great deal can be said both for and against the committee system of management. The effectiveness of a committee would depend to a large extent upon whether it is for control or advisory purposes.

In a company which has the same general type of organization as the two preceding cases, but which manufactures consumer goods to a large extent, the market research is in the sales department, and all technical research is controlled by the vice-president in charge of manufacture. The procedure for handling research projects depends upon the nature of the problem and the point of origin. For instance, some one in technical research may suggest a project to the director of the department. This man may be authorized to perform the work, provided a large expenditure of time and money is not involved. In the event of considerable cost, the vice-president in charge of manufacture must be consulted. The same situation exists in the market research department, which is ultimately controlled by the vice-president in charge of sales. In either case, if a project arising in one department concerns the other, the contacts are made through the two vice-presidents in charge.

All research work in a department is listed each month, and the lists are exchanged between the manufacturing and sales departments.

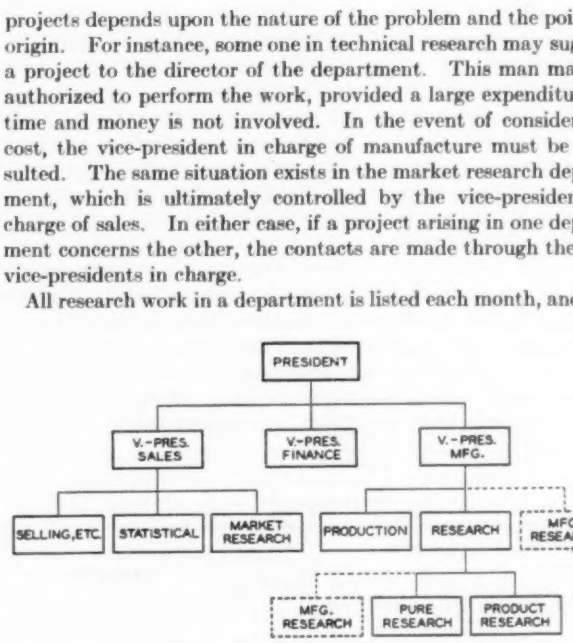

FIG. 1 PARTIAL CHART OF DECENTRALIZED TYPE OF ORGANIZATION
(Dotted lines indicate function may appear as indicated.)

Research projects for the development of a new product or a radical change in an existing product are referred to the president. If he sees merit in it, he turns it over to the vice-president in charge of sales. A sales committee of the higher executives in the sales department decide on the project. If they think it has commercial value, the market research department investigates competing products, potential markets, etc., and reports to the sales committee. There is also a committee of the administrative officers which is kept posted of all work being done (the vice-presidents in charge of sales and manufacturing serve on this committee). If the investigations up to this point have been satisfactory, the project is turned over to the vice-president in charge of manufacture for further development work. If this should uncover factors making a change desirable, the administrative committee is consulted through the manufacturing executive. After all product research is completed, the product is manufactured on a small scale and given to the sales department for a field test. If a market exists, the sales committee recommends to the administrative committee that the product be manufactured and marketed.

There is constant contact between the president and the vice-presidents in charge of manufacture and sales during the development period of any new product, a practice which carries down to the various departments, which frequently supplement one another with necessary information.

Let us now consider an organization that has no definite market research department. This company is organized along the same general lines as the three preceding cases, but the products are industrial goods of a mechanical nature.

The majority of the research projects come from the sales department through its contact with the trade. Problems relating to the products are referred to the sales manager, who, if he approves, contacts with the chief engineer. The chief engineer is in charge of research and design (except the design of tools, etc., and manufacturing research) and reports to the vice-president in charge of operations (this vice-president is also in charge of production and manufacturing research). It is the function of the sales manager to "sell" the suggestion to the chief engineer so as to have a budget set up for preliminary investigations. If the project meets with his approval, a preliminary investigation is made by the engineering and research departments, and rough sketches are submitted to the sales department, where consideration is given to the market. In some cases several salesmen go into the field to determine the potential market, competition, etc. If the results are satisfactory, the vice-president in charge of sales decides if further work is to be done. The engineering department then completes final specifications and the design of the product, after which the factory manager considers questions relating to the manufacture. A manufacturing committee, of executives of the engineering and production departments, is often used, and it is through this committee that all difficulties of design are eliminated. Sometimes a test product is made up to be sure that all production "bugs" are eliminated and also to test the market by offering this sample. This test is under the chief engineer, who has the cooperation of the sales manager.

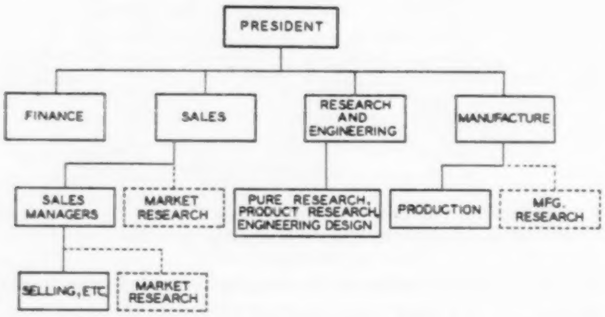

Fig. 2 Partial Chart of Partially Centralized Type Organization

(Dotted lines indicate function may appear as indicated.)

After consideration by all departments, the board of directors has final approval, in case of a new product or radical change in an existing product.

Whatever sales research is undertaken is carried on by the regular line salesmen. In cases where the product requires technically trained men to sell it, this plan has certain merits. Another point is that the relationship between the design and production departments is relatively closer than in the three preceding cases.

Partially Centralized Research Functions

The size of the companies interviewed, in terms of number of employees as of the fall of 1930, which fall into this section range from approximately 700 to 20,000.

In these companies one or more of the research departments are in a separate division apart from a line department and the remaining research activities are in some line department. In this type, the product and pure research functions are carried on by the separate division while the manufacturing and sales research are in their related line departments, although there are certain divergencies from this, as will be shown.

In this type there is greater specialization in the research and development departments, with closer direct contact with the administrators of the company. On the other hand, the relationship between the manufacturing and the product research departments is not likely to be as close from the point of control as where these two departments are responsible to the same executive.

Likewise, it would seem that the different activities should be coordinated through a committee, as the three functions of product research, manufacturing research, and market research are responsible to different executives.

An illustration of such an organization is a company manufacturing industrial goods of a mechanical and electrical nature. In this case the distinction is made between product research and engineering. See Fig. 2 for a partial organization chart of this type.

The work of engineering, research, and development is controlled by a development committee composed of the president, the vice-president in charge of sales, vice-president in charge of research and engineering, factory superintendent, research director, chief engineer, treasurer, and sometimes the three assistant sales managers in charge of the three major divisions of the sales department. In addition there is a smaller development control committee composed of the vice-president in charge of research and engineering, director of research, chief engineer, vice-president in charge of sales, and sometimes one or more other officials. It correlates the work of the research, engineering, and sales departments and saves the time of the larger committee by thrashing out points in connection with development work.

There is no market research department, as all such information is collected by the sales department. There is a feeling, though, that a market research department is advisable, and such an organization is contemplated.

All ideas and suggestions requiring research are first referred to the development control committee for a preliminary examination. If the project originates in the sales department, it is usually accompanied by a statement as to the probable market.

If the problem originates elsewhere, the sales departmen is requested (by the development control committee) to prepare such a statement. If the project seems to present merit, it is turned over to the development committee.

If desirable to go ahead with the project, the development committee orders the research or the engineering department to commence work. Periodical progress reports are submitted to the department head by the men actually doing the work, and he submits a summary to the development committee. If found satisfactory, it is sent back to the engineering department to be put into salable shape. During this period reports similar to the ones used in the development stage are submitted by the engineering department.

When all design work is completed, the development committee reviews the project again; and either sends it back for further work or turns it over to the production department, where the shop engineer (who reports to the factory manager) supervises the design of tools, production methods, etc.

The next step is to test on a small scale. The control is in the development committee or the production department, depending on the size and nature of the project. Sometimes the product of the small-scale operations is offered to the market for further test.

The salesmen often are accompanied by some one from the research or engineering departments. The sales department assigns a catalog number and submits an estimate on the amount that will be sold annually and the desirability of manufacture for stock. It is on a basis of this estimate that production schedules, etc., are set.

Another illustration of this general type is a somewhat larger company manufacturing a line of industrial products of a mechanical nature of relatively high unit values. The committee system is again used here, there being three committees acting on a major development before it is adopted. These are the executive committee, composed of the president and all the vice-presidents; the senior committee, composed of the three vice-presidents of manufacture, sales, and research and engineering; and a junior committee composed of sub-executives of the manufacturing, sales, and research and engineering departments. This company also maintains a market research department, which reports to the sales manager and through him to the vice-president in charge of sales.

The source of development and research problems has an influence on the initial investigations, but after a certain point has been reached, the procedure is the same in almost all cases.

Problems originating in the sales department are referred to the vice-president in charge of sales, who, if he approves, refers them to the market research department. Its report is submitted to the sales executive, and through him reaches the senior committee.

At this point the procedure becomes standardized for all projects. Therefore let us consider a project originating elsewhere than the sales department Such a project is referred to the vice-president in charge of manufacture, who, if he approves, turns it over to the engineering department. At this point it may be sent to the market research department. Then, if the manufacturing executive still believes the project to have merit, he refers it to the senior committee. The project may then be assigned to one of the junior committees for further study, without going to any expense. The junior committee refers the project again to the senior committee. If the senior committee thinks that further work is warranted, the executive committee can decide the extent to which funds are to be allotted to this development work.

Then the project passes to the engineering department, where the development work is commenced. If changes in the original plan become necessary, further authority must be obtained from the executive committee.

After all development work has been completed, the engineering department samples are taken out in the field. This field test is under the control of the engineering department, but the sales and manufacturing departments scrutinize the consumer reaction.

At the completion of the field test, the matter is again referred to the executive committee for final approval and the order for regular production.

Another example in this general classification is a company that manufactures industrial and consumer goods of a mechanical nature having a relatively low unit cost in comparison with the preceding case. We have here a product development department which lies between the manufacturing and sales departments, looking to the manager of manufacturing operations for control (issuance of orders, etc.), and to the vice-president in charge of sales for approval of work done and responsibility for money spent in the development department. Generally speaking, the vice-president in charge of sales has control over all development projects, but a committee composed of approximately six executives, representing every major phase of the business, acts in an advisory capacity in projects involving large capital expenditures.

Improvements in existing products or the development of new products are referred to the sales executive before any work is done. If the market is doubtful, he authorizes the market research department to make an investigation, and on this basis the product development department is authorized, through the manager of operations, to commence work. Progress reports are submitted monthly to the vice-president in charge of sales, and his approval is necessary for the continuance of work. Upon the completion of the development work the project is turned over to the vice-president in charge of manufacture, who sees that the manufacturing processes are organized in the manufacturing research department of the production division. After all production "bugs" have been eliminated, the project goes into the semi-works state, where it is further tested. This is in the production department, and the sample from these operations must be approved by the product development department. Sometimes these samples are offered to the market for a further test.

The two vice-presidents in charge of manufacture and sales are in close contact, and once a year they make out a request for a budget to cover the development work for the coming year, which is based on current work and a certain amount for additional projects that may arise.

The status of the development department is an apparent case where a man is serving two masters. It is obvious that such a policy would be possible only where personnel conditions permit, but wherever it is possible it would seem to be effective in closely relating all development work to the line activities of sales and production. An effective check is maintained, as both are represented at the outset and all along the development line through this dual contact. Then, too, any excessive enthusiasm radiating from the sales department is likely to be short-lived, since this department is responsible for the amount of money spent on development work.

This case also points out the principle that as the various research functions are drawn closer together, the importance of committees lessens.

In addition to the cases cited are those companies that are approaching centralization in a still greater degree. Some of these have all research functions, except those relating to the markets, in one department reporting to the president of the company, while others have all functions except manufacturing research so segregated. In these companies a broader initial investigation is usually made before accepting research projects. This investigation is in the hands of the originator of the idea and consists of gathering such information as expected cost of development, approximate number to be sold, expected selling price, assumed profit, the effect of this new development upon the existing line of products, etc. Such projects as these are first approved by the executive in charge of the development function, unless the individual department budgets are so constructed as to absorb this preliminary expense as part of their operating expenditure.

There are also those companies that have the market research function reporting directly to the president and the technical research under control of the production executive.

Completely Centralized Research Functions

The size of the companies interviewed (in terms of number of employees as of the fall of 1930) which fall into this section ranges from approximately 5000 to 17,000.

"Completely centralized research functions" is defined as the concentration of all research activities into one department which reports to the president or administrative committee. Under such an organization there is no connection with the line departments.

An excellent example of this type of organization and operation is a large company manufacturing industrial goods of wide distribution and a variety of uses. Fig. 3 shows a partial organization chart of this type of company. The research laboratory is interested in research of a pure or fundamental nature. The remaining divisions of the planning and development department are self-explanatory.

All ideas requiring research are turned over to the manager of the planning and development department. He first calls the proper project supervisor into consultation. It so happens that the heads of the divisions of the planning and development department are project supervisors. These two officials confer with others as they see fit and decide upon the value of the suggestion. If the suggestion appears to have merit, the project supervisor endeavors to develop information on its market possibilities and the necessary expenditure and work to produce preliminary samples for test purposes.

If the idea or product holds promise of value, the project supervisor will recommend that the manager of the planning and development department carry out the necessary development work. From this point on, the project is recognized as an organized development project.

Upon the approval of the latter, the project supervisor confers with technical and operating executives. From these conferences he can determine the scope and sequence of the investigation. He then goes to the department heads in the planning and development department and works out a plan of procedure. This plan incorporates the precise information desired and an estimate of the time necessary to obtain it. In other words, all work is preplanned within each department entering into the investigation.

When all programs have been laid out to the satisfaction of the supervisor and the department heads involved, the development work is commenced. In some cases, work is being done on the same project in two or more departments simultaneously.

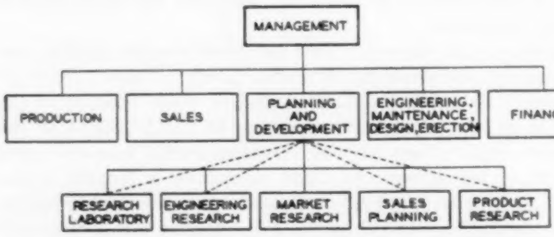

Fig. 3 Partial Chart of Complete Centralized Type of Organization

As the work progresses, constant follow-ups are made by the supervisor, who keeps the manager of the planning and development department informed as to the progress being made. Weekly reports are submitted to the supervisor on all organized development projects and monthly reports on all projects for investigation. If these reports show unlooked-for complications, the supervisor submits a report to the manager of planning and development. Likewise all planning and development department reports are routed to a group of company executives. The manager of the department also makes a brief report to the board of directors at their monthly meeting.

At the completion of the organized development project, a report is submitted incorporating the recommendations of the supervisor. The project must first be approved by the heads of the engineering research department, the research laboratory, the market research department, the project supervisor, and the manager of the planning and development department, and then later approved by an executive group composed of the vice-president in charge of sales, the vice-president in charge of manufacture, and the first vice-president.

If these approvals are forthcoming, the supervisor prepares the production plan, through the cooperation of the engineering research department and the production department. The engineering department is called upon to design and build the production equipment in accordance with the specifications of the engineering research department. The production plan must then be approved by the head of the research laboratory, the head of the engineering research department, the project supervisor, the manager of the planning and development department, the general plant superintendent, and the vice-president in charge of manufacture. Then follows the approval of the standard specifications (prepared by the research laboratory) by the chief inspector of the plant, the plant superintendent, the standards of production office, and the vice-president in charge of manufacture.

Next is the transition into production and experimental operation under the direction of the project supervisor. Sometimes a small quantity of the product is tested upon the market. The product must then be approved by the sales department, followed by the acceptance of the manufacturing unit by the general plant superintendent and the vice-president in charge of manufacture.

The preparation of the sales plan is then undertaken by the project supervisor in cooperation with the market research department, and submitted to the general sales manager (of the division of products into which the new product falls) and the vice-president in charge of sales. Approval is followed by the transition into sales operation under the supervision of the project supervisor. After this has been accomplished, the supervisor submits a final report to the manager of planning and development, and the file is closed.

In contrast to the cases cited in the two preceding sections, there are the following outstanding features. The authority of accepting or rejecting all ideas at the outset is vested in one department which initially consults with those in the organization who have information to offer. Then if the idea is accepted, it is turned over to one individual who controls all work on the project until it is absorbed in the regular schedules of the company. There is also a definite policy whereby all suggestions are investigated in a preliminary way before a definite schedule of development work is made up. Likewise there is a noticeable lack of the use of committees. Responsibility is well placed, and each person's duties are clearly defined. Attention is also directed to the presence of communication channels whereby contact can be made with anyone in the organization who might have information bearing on a given project.

In addition to this case there are other organizations operating along the same general lines, with variations as the cases may warrant. One of the companies goes so far as to include the sales development department in the research and development department. Indeed, every staff department relating in any way to the research function and the development of new products is thus incorporated.

There are also those companies similarly organized that have placed the responsibility for results on one man or a small group, whose function it is to "sell" ideas to the appropriate line organization rather than have them accepted through the approval of a group of officers of the company. In such cases the line departments concerned are consulted from time to time, but there is the possibility that friction will be developed if a mutual agreement cannot be reached.

Research in the Largest Type of Organization

Very large corporations are taken to mean those that act more or less as a holding company with a number of operating subsidiaries, or branch plants, employing upward of 50,000 men. Fig. 4 shows a partial chart of this general type of organization.

The close personal relationships that are found in the smaller companies cannot be here maintained, and consequently a greater degree of organization necessarily has to exist. Likewise it is practically impossible for any executive or group of executives to be actively in touch with all research and development work. The executive or committee in charge of the research function knows what is going on, but cannot handle the detail that is possible to the executive in the smaller company. This condition naturally leads to a greater delegation of authority.

In some cases there is a sharp distinction here between engineering, design, and research. The fact that these three should be closely related with each other, and then as a unit with sales and production is not questioned, but the problem of so doing is much more difficult. Often in these organizations the objectives of the research activities are much more varied and inclusive, and in some cases it is not necessary to investigate the markets in relation to technical research work because of the peculiar nature of the latter. The author has in mind one particular organization that carries on practically no market research in relation to the other research functions because the findings of the latter, when applied, usually change only an integral part of the product as a whole and do not warrant any detail sales consideration. Then, too, in organizations of this type the actual research work is sometimes of a more fundamental nature, which, although it might have a specific object in view, must be supplemented by engineering development work in an operating division in order to put the new development into usable and salable shape.

Attention is first called to the methods employed by a large electrical manufacturing concern, particularly in those branches with which the engineering department has the closest association—namely, the commercial and manufacturing departments and the research laboratory.

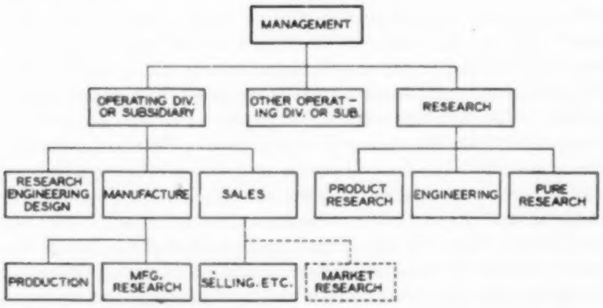

Fig. 4 Partial Chart of Largest Type of Organization
(Dotted lines indicate function may appear as indicated.)

The commercial department is headed by a vice-president and has the responsibility for the sales policy and the selling activities. The manufacturing activities are under the control of two vice-presidents. The engineering department is under the control of two vice-presidents and is responsible for all engineering work except that which affects one line of products and the activities of the research laboratory. One of these vice-presidents is in charge of the commercial engineering group and the other of the designing engineering group. The research laboratory is headed by a vice-president. This laboratory is equipped to assist the designing engineers in solving their problems, and also initiates many new developments of which advantage may be taken by the designing engineers. In addition to this central research laboratory, each branch maintains its own research laboratory, which is responsible to the vice-president in charge of the branch.

The designing engineers are responsible for the design of apparatus and the engineering supervision of its manufacture. Although in most cases they are not responsible for the methods used in manufacture or for following production, they see that the products are manufactured in accordance with the design as evolved. In some instances the manufacturing and designing responsibilities are combined in one individual who is given the title of managing engineer and who is jointly responsible through the works manager to the engineering and manufacturing vice-presidents.

The commercial engineer acts in the capacity of engineering advisor to the commercial or sales department and is engaged in applying the apparatus designed by the designing engineer to specific uses. The commercial engineer studies the requirements of the market from an engineering standpoint and determines upon the best and most economical method of meeting them. In some cases these requirements can be met by products already designed, but when this is not possible, the matter is referred to the appropriate designing engineer to make layouts and submit cost estimates covering the apparatus. There are three main commercial engineering departments, each associated with one of the main commercial departments, these divisions being made on the line of products handled. While the prime function of the commercial engineering departments is to make applications of apparatus, they often become interested in introducing improvements in the design of apparatus which they utilize.

In general, ideas relating to product development and changes in existing products are submitted to the commercial engineer in charge of the department into which this product naturally falls. This engineer investigates in a preliminary way the feasibility of the contemplated move, and if favorably impressed, refers it to one man for follow-up. Each division in the engineering department has a budget for the development work to be carried on for the coming year, and the engineer in charge is responsible for its proper disbursement. A market analysis by the appropriate division in the commercial department may be called for. After all such investigations, the project is sent to the designing department to have layouts prepared. If a project is approved by the engineering and designing departments in which it is being developed, it is sent to the works laboratory, where the manufacturing methods and processes are determined upon and a sample is made up. After leaving this department the product goes back to the designing department, where it is ordered into production in accordance with the demand.

Constant checks of progress on all current developments are made by standardizing committees. One of these committees, composed of a representative from the design, commercial engineering, and commercial departments, is appointed for each main line of products. In addition there is a general standardizing committee having jurisdiction over these individual committees.

The activities of the central research department do not form an essential part of this procedure. This department stands ready to assist any of the engineering or designing departments in the solution of their problems.

Particular attention is called to the function of the commercial engineering department and the part it plays in the relating of company products to the commercial or sales department. Here we have a large unit acting as a coordinator of the different development activities. Attention is likewise called to the close relation existing between design departments and production departments through which development activities can be closely related to line production.

In some cases the proper coordination of development activities can be brought about through a system of budgetary control, which, while giving a certain amount of freedom to the executives involved, holds them for results. This principle is illustrated by a company which is similar in general type of organization to the preceding case. This is a large corporation operating a number of subsidiaries manufacturing a wide and diversified line of products, both of an industrial and consumer nature. A central laboratory, in which all types of research are carried on, reports directly to the management. The problems are those submitted by one of the subsidiaries and those originating within the laboratory or coming from outside the corporation. Problems from the two latter sources are developed up to a certain point and then turned over to one of the subsidiaries for further development and subsequent manufacture. In considering the organization of one of the subsidiaries, there is a technical department (all research and development work except market research is carried on here) headed by a general manager, who reports to the president of the subsidiary. There is an operating division for each major line of products headed by a general manager reporting to the president. These operating divisions maintain their own sales and production departments.

In relation to research and development work, the budget system operates along the following general lines. The general manager of the technical department can spend a certain amount of money on any development work, but to get a larger appropriation after the development work has started, the executive committee of the subsidiary has to be notified. The executive committee likewise has a limit on the requests that it can approve, and all in excess of this must be approved by the executive committee of the corporation (parent company), which likewise has an upper limit, all in excess of which must be referred to the board of directors. From this it follows that, as a project grows in magnitude and importance, the scrutiny to which it is subjected is much more inclusive. In consequence, all factors having any influence on the project are properly investigated in the initial stage.

All development work is under the control of the technical director so far as dispatch, supervision, etc., are concerned, but projects have to be accepted by the general manager of the operating division concerned before adoption. This means that the technical department would have to consider the attitude of the operating division heads in order to insure the acceptance of the results. Throughout the development period these operating departments are in informal contact with the work being done by the technical department. The first formal discussion which involves them, however, takes place after all the development work has been completed and the matter is referred to a process committee. This process committee is composed of the technical superintendent from each plant (the operating divisions sometimes have several plants), the managers of the sales-service divisions, and one or more representatives from the technical department. This committee is an ideal medium whereby consideration is given to production troubles, plant difficulties as a whole, trade trends, process problems, customer reaction to the existing line of products, etc. The findings of this committee are reported in the form of recommendations to the individuals concerned, but they do not have to be adopted unless so desired by those interested. It should be added here that the sales-service departments are very active in making market tests and the like in conjunction with the development work carried on by the technical department.

Follow-up of progress on all research and development projects is accomplished through the medium of reports. Reports from the department heads in the technical department are submitted to the general manager of the department once a month (these department heads being in daily contact with the work done in their department), and the technical department reports once a month to the executive committee. All projects are considered as individual units, and the progress on each approved by the general manager of the department. Likewise all work done on any project in other departments is charged against the department that obtained the original appropriation.

A review of this case would seem to indicate that there are three factors that tend toward coordinating the various activities engaged in development work: The system of budgetary control which definitely places the responsibility for research expenditures and thereby plays its part in insuring sound conclusions based on careful consideration of all factors involved; the work of the process committee incorporating the point of view of research, sales, and production; and the organized application of executive judgment to specific projects.

Let us turn attention to the operation of a central laboratory of one of these larger corporations. This company is one in which the function of market research does not play so important a part in connection with research projects. The nature of the product is such that the projects are not concerned with the development of a new product, but with the improvement of integral parts of the existing product.

This company maintains a central research laboratory and many operating divisions. The research laboratory reports, through a technical committee, to the president of the corporation, and the operating divisions likewise report to the president. This technical committee is composed of all the chief engineers of the operating divisions, and the function of the committee is that of coordination between the operating divisions and the laboratories. There is a general research director who controls all research work done in the laboratories and coordinates all activities. The laboratories are divided into various sections in accordance with the service rendered, and these activities are directly controlled by a technical director who has charge of the technical work and a business director who has charge of the business activities. Then there is a control committee for advisory purposes, composed of the general director, the technical director, and the business director.

Problems requiring research are usually referred to the proper section head. Upon approval, the problem is sent to the technical director, the business director, and the general director. At this point the problem is thrashed out by all concerned, and the advice and opinions of a great many executives and engineers in the corporation are sought. If approved by the head of the research laboratories, the project then goes to the management of the corporation for final approval and the necessary appropriation. An appropriation is then set aside, a project number assigned, and the project sent back to the original section for the work to be done. If the project had originated further up the line or outside the laboratories (except in an operating division), the general director would turn it over to the section best equipped to handle it. Under the direct supervision of the section head, the work is carried forward until completion. In some cases it is necessary to have other sections perform a certain amount of work on a project, and under these circumstances the proper contacts are made through the technical director, and all expense is charged against the project number for which the original section is responsible. After all development work is completed, contact will be made with the operating division interested, and an attempt is made to "sell" the new development to it. The operating division does not hear of a project only upon completion and the subsequent attempt to "sell," for operating divisions are usually acquainted with the work of the laboratories through the technical committee. If the project is accepted, the research and engineering department of the operating division puts the new development into a shape whereby it can be used. Close contact is maintained between the product design department and the manufacturing department so as properly to consider the production point of view. Information concerning the markets is obtained from the sales committee (composed of the sales managers of the operating divisions and reporting to the president of the corporation) or from the sales department of the operating division, as the case may demand.

In addition to performing work on projects originating in the research laboratory, work is also done for the operating divisions on specific problems submitted by them. Under such circumstances all expense is charged against the operating division for which the work is being done.

The research projects in the central laboratory are followed up in this way. Each project is reported on periodically by the man doing the work. This report is approved by the section head and sent to the technical director, who sends it to the one whom he thinks should see it. The function of seeing that progress reports are sent to the right parties is in the hands of a separate section of the laboratories. The head of this section is notified to whom the reports are to be sent in the different operating divisions and elsewhere (here again it is seen how the various officials in the operating divisions are notified of development work in process in the laboratories). This system of reports has the necessary supporting authority to insure proper operation, in that all appropriations are made to cover a certain period (this is fixed regardless of the project), and if a project comes up for reappropriation, this request cannot pass unless the project has been reported on since the last appropriation. The responsibility for seeing that this is done is definitely fixed, because reports must clear through the technical director and all requests for reappropriation require the approval of this executive.

General Trends

While the specific object of this paper was to demonstrate how the different research activities could be coordinated with sales and production, it likewise brings out the fact that this industrial activity of coordination is in an embryonic stage. The direction of the development is clearly toward a greater cognizance of the problems of coordination, with more thoughtful attempts toward their solution. An increasing number of companies are accepting the research functions as vital to the perpetuation of their business. These new activities are usually first associated with production, and we find the technical research functions established in the manufacturing department—a decentralized form of organization.

As the research function grows in importance and the problem of coordination becomes paramount, we find the different activities being segregated into an independent department. This movement is usually initiated by removing the product research, pure research, and engineering functions into a separate department to give a partially centralized type of organization. This is later followed by the advent of the market and manufacturing research into this research and development department to give a completely centralized type of organization.

Then as the size of the individual companies increase, difficulties of coordination do likewise. This leads to a departure from the completely centralized organization and a trend toward the establishment of separate research, engineering, and pure research departments, each having a specific function to perform. Manufacturing research activities are returned to the manufacturing department, and market research to the sales department. In consequence we find a greater delegation of authority, a higher degree of organization, and an increase in importance of adequate systems of records of research work.

Conclusions

The following general conclusions may be presented:

1 In the development of a new product or a major change in an existing product, the following types of research have ordinarily to be performed: product research, manufacturing or process research, and market research. The relative emphasis to be placed on each will depend upon the peculiar needs of the business. They should be coordinated with one another and as a unit, with, sales and with production. Formal methods for such coordination are now in embryonic form in a limited number of American industries.

2 The specific product manufactured, while important, does not have as great an influence on the structure or form of coordination as is frequently attributed.

3 The technical research activities, in general, have been accepted as vital to industry and are the most widely used types. When the technical research activities are found in the manufacturing department, the relationship existing between them is usually close and the problem of coordination relatively simple. Pure research does not require coordination until the findings of the research are to be applied.

4 The use of organized market research is becoming accepted as an essential phase of present-day industry, but it frequently has not been recognized as a specific function, nor has it been as well organized or controlled as has technical research.

5 Coordinated research activities should be performed in a preplanned sequence based upon the extent of initial knowledge regarding the project and the precise relationships existing between the various necessary research activities. In many cases it has been found that all significant elements of the research problem were not given adequate weight when a project was under initial consideration.

6 The lack of proper coordination may result in:

(*a*) The spending of large sums of money in development work on a project which turns out later to be a failure owing to improper consideration of all phases in the initial investigation.

(*b*) The development of products which are not commercially sound from the point of view of either lack of markets, etc., or high selling price due to high manufacturing costs, etc.

(*c*) The waste of time and money on research projects which have no direct application to the business as a whole, either present or future.

(*d*) Product design developed without proper consideration of the manufacturing department.

(*e*) Failure to direct the activities of the different research functions into those channels from which the greatest benefits might be obtained.

(*f*) Danger of personnel difficulties arising out of apparent conflicts of authority.

(*g*) Progress delays on a given project due to the lack of cooperation on the part of the various departments concerned.

(*h*) Omission of periodic follow-up of research work to determine the advisability of continuance.

(*i*) Danger of not routing research projects, in relation to types of research to be performed, so as to eliminate impractical ideas in the early stages.

7 The factors influencing the structure or form of coordination are:

(*a*) The size of the company. (For example, small companies do not require such a high degree of organization.)

(*b*) The type of organization. (For example, highly functionalized organizations may have greater need for committees.)

(*c*) The personalities of the executives involved with research work. (For example, the extent of informal contact affects the degree of conference routine which is essential.)

(*d*) The attitude of the line executives toward research work. (For example, the importance of frequent contacts with progress of research varies inversely with cooperative attitude.)

(*e*) The types of research most used. (For example, the importance of coordination varies directly with number of research activities essential to adequate product development.)

(*f*) The specific object of the research activities demanding greatest emphasis. (For example, the relative importance of low unit cost or of high quality, or of wide sales appeal, etc., will determine the direction of coordinative emphasis.)

(*g*) The importance of research to the organization and to the perpetuation of business. (For example, synthetic products find in research perhaps their greatest insurance against competitive defeat.)

(*h*) Nature of the product. (For example, products whose form or characteristics may be radically varied by processing are particularly susceptible to benefit through coordinated research.)

(*i*) The nature of the markets. (For example, coordination with market research is particularly important when dealing with new or undeveloped markets.)

8 No best method of coordinating research, sales, and production applicable to all companies can be evolved, since the coordinating machinery should be devised to fit the organization and not vice versa. There are, however, certain general principles or rules of action which manufacturers have found helpful:

(*a*) The control of coordinated research and development requires the organization of personnel, methods, and facilities in no less degree than does production control, sales control, or financial control.

(*b*) The authority for the formal initiation of research and development work should be specifically assigned.

(*c*) Avenues of informal contact should be maintained between executives and sub-executives concerned with research, development, and allied line activities.

(*d*) Arrangements must be made whereby a single executive shall have authority to expedite any given research project to its completion through the necessary processes and departments.

(*e*) Prior to important research expenditures, a coordinated research project should have the benefit of the judgment of executives representing the major phases of the business. Such judgment may be gained through the organization of committees or conferences or through solicitation on the part of a single executive.

(*f*) After the approval of research appropriations, a coordinated research project should have, at periodical intervals, the benefit of executive judgment as to its continuing practicability and value. The activities of a single executive, committee, or conference have been found effective in making such judgment available.

(*g*) Periodical approval of coordinated research projects should be assigned to specific individuals or committees, and the "approval points" should be definitely fixed. Where different types of research work are carried on in sequence, the approval of progress of each type should be delegated to subordinates rather than the executive or committee giving the original approval. In those cases where the different types of research are carried on concurrently, the responsibility of approving progress should be vested in the executive or committee giving the original approval.

(*h*) The presence of budgetary control in the organization will be found to be of material assistance to any coordinated research project. When budgetary control is not in general use, its principles should be applied, as far as possible, in the departments affected by this coordination.

(*i*) In the larger companies the activities of an entire department may sometimes afford an effective means of coordinating the sales and product research functions. This usually takes the form of a study by this department of markets from an engineering point of view and an interpretation of these market requirements for the product design departments.

(*j*) As in production or sales control, a coordinated research project requires the establishment of a definite system of follow-up or inspection of progress.

(*k*) Where possible, the originator of any research project should be required to make an initial investigation relating to manufacturing cost, value to the company, effect on other products, expected cost of development, expected sales potential, etc. In cases where the collection of these data requires important expenditures, the project should have the approval of the executive or committee in charge of the research and development function.

(*l*) Coordinated research work is as susceptible to the benefits of planning and scheduling as is any other function of the business. The preplanning of an individual research project, however, is affected by (1) the types of research to be performed, (2) the extent of initial knowledge, and (3) the degree of centralization of the research functions.

(*m*) A fundamental in the successful conduct of coordinated research work is the definite placement upon individuals of responsibility for results.

(*n*) As a coordinative influence, as well as a research device, small-scale production and market tests are particularly valuable and should be undertaken as soon as development work has sufficiently progressed.

(*o*) Where the centralized type of research organization is in use, special care should be taken that the research activities be not too far removed from their related line activities, if the valuable constructive suggestions from line officials are to be encouraged.

(*p*) The informal placement of too much reliance in one executive as a source of either technical or commercial information of a research nature is unwise in the light of possible changes in personnel.

(*q*) The official ultimately determining the coordinative policies of the research and development function should be a man of broad business vision with balanced interest in sales and production problems.

Discussion

Charles M. Mills.[4] This paper gives a clear-cut analysis of the research problem, and points out succinctly the up-to-date progress of general research in various types of organizations. It has been exceedingly interesting to see the development in this paper between line and staff administration in various types of industries and organizations. One reads the paper feeling that there is no single or ideal set-up for the proper coordination between these three great activities of business and that each must be fitted into the particular individual staff. Behind the mere facts that are presented in the paper lie intimate histories of corporate life. Undoubtedly some of the more particular types of management are due, not to any lack of knowledge of the proper type of standard organization, but to differences in the personal equation and in the quality and type of personnel in the executive group. Thus one cannot say exactly whether completely decentralized, partially centralized, or centralized organizations are ideal.

The emphasis on the lack of market research is by no means overemphasized. It is astounding to find the lack of attention in some of the larger corporations given to the proper analysis of their markets. Too frequently, as is pointed out, the interpretation of market conditions is through sales executives and salesmen who are engaged in line administration or actual selling in the field. Such executives cannot have visualized the basic problems of markets. They are too near to see the objectives to which the efforts of the company should be directed. It is practically impossible for them to rightly interpret the facts of the situation without coloration and partiality.

Another point that the author very properly emphasizes is the lack of attention given to the patent situation. Not a few of us know of circumstances in various companies where new types of products have actually been devised and even manufactured without clearance as to patents. Line executives too often ignore the advice and counsel that may be contributed by the legal dedepartment.

It is easy to see in the author's analysis of the first large company, under "decentralized research," the distinct cross in functions between line and staff. It is exceedingly hard for the average line executive, not only to control, but to appreciate the work of staff groups under him. In the second place the planning of research is invested in a committee. The writer is inclined to think that the author has been generous in his word about committees when he says, "A great deal can be said both for and against the committee system of management. The effectiveness of a committee will depend to a large extent upon whether it is for control or advisory purposes." If one goes behind the scenes very far, he certainly will learn that unless there is an unusually high caliber group of executives who have forgotten personal jealousies, the committee system in regard to research is extremely cumbersome and irritating rather than an efficient factor in the activities of the company.

---

[4] Assistant Director, Twentieth Century Fund, Inc., New York, N. Y.

It is hard to see from the outside how partially centralized research functions can be fully successful. The writer would be glad to hear the author enlarge upon this type of organization. Perhaps the writer is a bit prejudiced toward completely centralized research, based largely upon his experience. As the author rightly sums up, there are two great advantages—authority is invested in one department which clears with other heads in the organization who must be properly consulted, and in the second place there is a lack of committees. The paper presents a good synopsis of the growth of research in business and its coordination both with sales and production.

W. L. Waters.[5] The paper indicates that there is no standard practice in regard to the organization of research and development activities and that every concern must work out its own system. This is in accord with the general opinion on the subject.

Market and patent surveys are of course required, but they are not necessarily final, because six months after a new product has been placed on the market, some new basic development may render the product quite obsolete; or a patent, the application for which has been in the Patent Office for five years, may be issued, which covers some of the essential features of the product.

Much the most important elements in any research or development organization are the personnel at the head of it and the morale of the department. If these are of the highest grade, details of the organization, etc. become only of minor importance.

Walter E. Lee.[6] Listening to presentation of these papers, the writer is inclined to believe that what is really being considered is the coordination of *development work* to production and sales, rather than research as it is generally understood and accepted, for often there is also involved, especially in the case of the manufacturer of industrial units, the matter of engineering and product design.

The term "research" hardly embraces this necessary phase in the development of a new product or improvement of an existing product. On the other hand, "development" is a sufficiently broad term to embrace pure research, product research, manufacturing research, patent research, and market research.

The type of development organization will vary with the type of corporate organization, depending on the location of its manufacturing units, the extent of its marketing territory, and the nature of research undertaken. In one case, as in small concerns, a decentralized type of research, undertaken by each department, may be more effective than a completely centralized research department acting as a staff function and most effective in large organizations having wide-flung operations.

While research organizations may have a part of their efforts directed toward pure research regarding the physical and chemical nature or structure of raw and finished products and their characteristics relating to desirable service performance, nevertheless the majority of the problems recommended for research generally comes from the field through the sales department.

Not only does the sales department produce the revenue which makes possible all other activities of an organization, but it is also the ears and eyes of the whole organization, having a constant touch on the pulse of the consuming public and knowing the change in their tastes, requirements, and demands. Moreover, the sales department knows when it is losing ground because existing products need improvements or because it sees opportunities and markets if only products were available to fulfil them.

While a research project can arise either within the research organization itself or be suggested by manufacturing or sales, the project will generally fall into one of the following classifications:

1 Pure research into physical and chemical nature of composition of raw products or finished products
2 Development of new products for an existing need in an established market, not now suitably supplied by existing products
3 Development of new products for an existing need in a market not yet established and which need is not fulfilled by any existing product
4 Development of synthetic products having better characteristics than existing products manufactured from raw supplies
5 Improvement of existing products to improve quality or to change form or structure to lower production in cost
6 Development of experimental products, new uses for which are afterward to be found
7 Development of new products to replace competitive products now being furnished by a different type of noncompetitive industry
8 Development of standards and specification formulas
9 Change in type of product to meet new consumer demand or service needs.
10 Meeting the demands of the sales organization for a new or more suitable product to meet the field demands of the user or consumer
11 Market research into:
  a Location of possible markets for product outlets
  b Requirements of each type of user or industry in any given market
  c Trend in consumers' requirements to anticipate future demand for products to meet more severe duty or severe conditions
  d Development of new uses for existing products
  e Substitution of existing products in markets now supplied by a non-competitive industry
  f Competitive sales methods and practices and prices structure
  g Determination of volume of potential business by market and product and reasonable quota which can be expected of each sales unit.

In times such as exist during the present business depression, research projects are generally approved only when the object is likely to produce tangible results which can be commercialized so as to give the greatest sales dollar return for each research laboratory dollar spent.

Once an object has been approved, much time and expense can be saved and the pitfalls of other previous investigators avoided by a full literature survey on the subject. Likewise, the loss of many months of intensive work through patent conflict may be avoided by a parallel patent research undertaken at the same time when the literature survey is made. After these two preliminaries have been completed, the complete research program may then be drawn, approved, and executed. Cooperative programs between research laboratories of the manufacturer and the industrial user are also very advantageous.

[5] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[6] Assistant Director, Research Laboratories, Standard Oil Development Company, Linden, N. J.

Usually the largest advertising agencies handling the accounts of large or national manufacturers perform, as a service to their clients, market forecasts as to territory season or period, product or grade, type of outlet, size of town, class of buyer, sales method and quota, and generally act as a marketing counselor.

However, this can hardly equal a full-time, 100 per cent market research within the organization itself, gathering and interpreting facts for the advice and guidance of management to predict future demand and effect of trends in market change on existing products and revenue. The writer understands that among the 200 largest organizations in this country, but seven of them have a regularly organized group to undertake and prosecute this important phase of business administration.

B. Townshend.[7] The papers by Mr. Bausch and Mr. Wilder represent careful thought on one of the fundamental problems of modern industry. Mr. Bausch's paper is a detailed description of a particular case and is valuable as a record of something which works well in a certain environment. Mr. Wilder's paper is an analysis by the author of different systems and a classification of these based on what it was possible to learn by an outside observer.

All too often systems are not sufficiently definite and classified to communicate them to another so thoroughly that he can reach accurate conclusions on their merits. In one case cited at least, with which the writer is connected, the organization of research is undergoing change in a constant effort to increase its effective power and usefulness.

In a new company starting under intelligent technical direction, the organization and control of research and other technical activities should be simple. The more general case, with which most of us are concerned, is the grafting of research in the modern sense into organizations already developed. Every manufacturing concern has done a certain amount of technical development work, usually scattered and uncontrolled, whether such work was called "research" or not. The problem is to collect such past activity, round it out and fortify it where necessary, and place it under definite management. Technically, this department must best serve the needs of the particular organization into which it is introduced, and practically it must be adjusted to peculiar conditions of habit and personalities.

Before starting any discussion of the place of research in modern industrial organizations, the meaning of the term must be defined, since it is one of the most abused words in the language. Mr. Bausch appears to have technical development (in this case of optical devices) particularly in mind, while Mr. Wilder's apparent definition appears far broader. Under "research" can be placed any or all of the following activities according to taste: Investigations in the sciences underlying the technical field of the organization, development of materials, development of processes, engineering of processes, testing of materials, control of production quality, investigation of economic conditions and markets, and general technical service to other departments and to customers. Nearly all of the foregoing activities could well be under a single direction, but it would be a "vice-president in charge of engineering and development," and "research" would be a department whose functions would be restricted to scientific investigations, and development of materials and processes, with only such testing of materials as was implied in intelligent material development. Engineering of processes, general testing of materials, control of quality, and general technical service could well be placed in an "engineering, development, and control department" and would have to work in close contact and harmony with production and sales. Economic and "marketability" research should be placed in the sales division.

The question of committee management of certain functions has been brought up by Mr. Wilder, and he cites one case with which the writer is familiar where this is supposed to be in usage. It is less true now than when the information for the paper was obtained. It is true that committees are cumbersome and inefficient. A committee generally functions as a brake, not a motor—it can stop most anything and start almost nothing. A committee is only as strong as its leader, and those committees which are efficient are really only specially appointed departments under the management of the chairman.

Obviously in the foregoing the needs of a large organization has been kept in mind. With only 200 corporations now controlling 40 per cent of the non-financial assets of this country, it is natural to restrict oneself to consideration of large units in discussing general principles for future application.

E. C. Rack.[8] Mr. Wilder has given a most interesting and comprehensive presentation descriptive of the mechanism employed by management in the coordination of the four functional divisions of industrial organization.

The organization with which the writer is connected has only in the past three years become intensively active in centralizing research as an independent function. Results of this segregation, as measured by accomplishments to date, have generally borne out those conclusions summarized by the author. It is not felt that a more detailed exposition of the operation of the research, engineering and development activities of Johns-Manville need be attempted at this time, especially in view of the fact that an outline of our methods of coordination and control, although not specifically cited by the author, are given as an example in his paper.

Convictions regarding details which must be considered by management are generally obtained as a result of experience. For this reason the writer feels that more studies of research coordination with resulting data should be reported. Contributions of this nature will undoubtedly be valuable data for study by management. It is also felt that various phases of the research function and its control as practiced, and the experience gained by industrial organizations, will be of value. As an example, with the rapid development of research new managerial methods are constantly being tried. It is desirable and necessary that management have some form of recognized judgment for approving progress. This calls for a measure with which to compare operational effectiveness, both as regards general accomplishments and those accomplishments of subdivisions under various commodity or product classification. Such an exposition is briefly given in the paper by Mr. Bausch.

The writer further feels that more descriptive outlines of the set-up and experiences of the various sectional divisions of research work would also be of much interest for round-table discussion and further study; such as for example, a detailed outline, together with an explanation of how those sections function to the best advantage which act as seekers and finders of ideas and developments which are fostered by individuals who may not be connected directly with that organization or branch of enterprise concerned. The period is past when secret processes were the order of things. When results of research are utilized and protected, data are very generally distributed for the benefit of the industry as a whole. The same policy can well be adopted by management. Results and experience of operation of research organizations when published will be received and acclaimed with as much interest as are the results of research in pure science and engineering.

[7] Manager, Research Laboratories, Johns-Manville Corp., Manville, N. J.

[8] Consulting Engineer, Sales Engineering Department, Johns-Manville Corp., New York, N. Y. Mem. A.S.M.E.

Other divisions of this Society act most efficiently as permanent clearing houses for efforts and data accumulated as a result of research work. This division can do much in the encouragement of a further discussion of the principles of management in the field of scientific research, and in this way the fundamentals of this particular branch of management will be coordinated into a specialized set of principles or laws which regulate the scientific functions of finance, sales, and manufacturing management.

L. A. Hawkins.[9] As Mr. Bausch says, the words "research" and "engineering" are sometimes used to mean much the same thing. This seems a pity, for in industrial laboratories and engineering departments there are two distinct kinds of activity which need two different words to name them. The search for new scientific knowledge is a different thing from the application of scientific knowledge in developing new or improved processes or product. The former may well be described as research; the latter, as engineering development.

A developmental project may require research before it can be successfully initiated, or in its course may reveal unknowns which need research for their explication. The research and development may be performed by the same personnel, but the two activities are different in their natures, and aptitude for one does not necessarily imply aptitude for the other. That is one of the reasons why, in a large organization, it is advantageous to have distinct engineering and research departments, in spite of the obvious advantage of closely linking activities so directly complementary in their objectives.

Now, while engineering development should be closely coordinated with production and sales, that is not wholly true of research. Production problems may call for research in their solutions, or market research may reveal the need of scientific research to determine whether a desirable development is possible or practicable, but neither production nor market studies can disprove in advance the wisdom of undertaking a given research project, since the very nature of research makes it impossible to predict its results or their applications. The only criterion is whether the project presents a promising path to new knowledge in the field of interest. Wisdom in applying that criterion is an essential qualification for success in directing research.

Mr. Wilder says, "Pure research does not require coordination until the findings of the research are to be applied." If the term "pure research" be taken to mean, as it is thought the author intended, researches other than those definitely directed toward meeting specific needs of production or sales, then his sentence is a concise equivalent of the preceding paragraph.

Ben Nash.[10] When coordinating the various factors of a product-development project, modern competitive conditions require that greater consideration be given to the appearance of the product. The appearance or visual aspect of a new product should consist of:

1 A visual exterior which adequately expresses the function, benefit, and value of the product

2 A practical visual conception so organic, simple and aesthetic as to:

a Indicate an advanced product

b Secure the greatest share of consumer preference at the time of purchase

c Continue to invite a lasting regard.

The reasons for the increasing importance of the visual aspect of a product are:

1 The necessity of meeting current trends

2 The necessity of expressing values and benefits

3 The necessity of attracting markets.

The trends indicate:

a That the pioneering functional era is now augmented by an era of good appearance.

As long as our products remained in the pioneering utilitarian era, during which each new product invention or development merely served a utilitarian need, consideration of the product's visual aspect was incidental. If a new product which functioned effectively possessed a visual crudity, this visual crudity went unnoticed because the product's ability to function was of major importance. As long as there was a ready non-competitive market for inventive talents along functional lines, visual aspects could be ignored. But now, two conditions have arisen which demand that visual aspects receive their share of attention too. There has been an increasing education in style and good taste throughout the country, and competition has learned how profitable it is to respond to the desire for products in better taste. Within our own time we have seen the automobile, the radio, and the electrical appliances change from mere assemblages of functional parts into attractive articles, which invite possession. By reducing the emphasis on their mechanisms and increasing the attention given to their complete design unity and beauty factors, the marketability of these products has been greatly enhanced. While the search for exterior design simplicity in mechanical products was going on, a new product possessing simplicity of tone design appeared upon the scene and pointed the way to new possibilities. The aeroplane, through force of circumstances, had to be simple in its design form to function successfully. As a result, we make this product without gadgets, protusions, layers of attached parts, nuts or bolts to deter its functioning or to spoil its smooth design silhouette or distinctive design character. Design simplicity was necessary in an aeroplane to enable it to fly. Design simplicity is just as essential to other products to make them sell more readily.

b That consumers are measuring values through appearances.

Present conditions are proving that consumer buying is strongly influenced by appearances. The new method of open-counter merchandising of products which possess self-selling qualities is but one evidence of this trend. The increase in the purchase of attractive novelty merchandise in this immediate era of curtailed buying of staples is another evidence of the importance of the value of product appearance.

c That products must bear a more harmonious relation to their surroundings. The consumer is interested in the harmonious ensemble idea in the home.

The educational programs carried on by magazine publishers and by the style service departments of manufacturers have caused the consumer to look for and choose products which fit into the ensemble idea. Many staple products have been given a new visual treatment or have been grouped in ensemble combination with related products in order to attract this market trend. Products which formerly sold upon their functional merits alone have now been developed to fit into the visual ensemble.

---

[9] Executive Engineer, General Electric Company, Schenectady, N. Y.

[10] Products Development Company, New York, N. Y.

d That new living conditions, smaller living quarters, and more hand-to-mouth buying require compactness of product design to attract consumers.

More compact organization of functioning parts is showing itself in new products designed to fit more exactly into the new type living quarters. Products designed to meet these modern conditions require a new design simplicity through the force of these new circumstances.

e That new architectural treatments, new building materials, and modern color treatments require harmoniously appearing products.

Both old and new materials are being used to furnish products which fit into the home or office. Color, fittingly and adroitly applied to products, is being used to conform to consumers' desires. Consumers continue to want products to work well, but they also want them to look well and to fit appropriately into their surroundings.

f That the increasing number of purchases of mechanical appliances by housewives requires product design which reduces the mechanical and laborious-looking features.

The assemblage of mechanical parts which bespeak mechanism to the housewife is not as desirable as the necessary appointments to her daily tasks. Design unity of assembled parts, less evidence of nuts and bolts, and an aesthetic organization of materials will better secure the housewife's preference.

g That there is an increasing interest in products which will perform with the least amount of maintenance effort.

Products with less places to catch the dirt, with smoother, plainer surfaces, with enclosed parts and a minimum of protrusions furnish a visual expression of easy maintenance to the consumer. A recent consumer investigation of a mechanical product clearly indicated one outstanding consumer desire, "a product which was easy to keep clean." Another product research program indicated that one essential of the visual aspect of the product was "easy maintenance." In both of these cases these requirements were made a major specification in the product development project.

h That competitive conditions require a product to be competitively adequate in appearance as well as to be adequate functionally.

A product which functions with competitive superiority may find itself giving ground to a competitor which appears superior; for by appearing superior it furnishes a sales resistance to its more adequate competitor. What a disappointment it is to the engineer who knows the technical differences between the two products, to see the consumer influenced by appearances. There is but one certain way to meet this condition, and that is to have the visual aspect of the product wholly in keeping with its mechanical excellence. A mechanical disadvantage can often be transformed into a visual selling advantage through the adroit use of exterior design styling. The visual character of the product should seek to express or feature the attributes which particularly appeal to the consumer. As an engineer you may know that a mechanical part is the big feature, while the consumer may be influenced to buy because of a particular result. Therefore, you should feature the result and not the mechanical detail.

i That the exterior of a product must help express the unseen inherent values.

The exterior shell or dress of a product can glorify its contents so as to express its unseen worth, through design, color, a touch of embellishment, and greater appropriateness to the consumer's present-day desires. Products whose values are not visually apparent cannot express these values.

j That effective visual treatment can endow a product with exclusive features. These features can aid in securing the full benefit of sales promotion effort.

Many products which enjoy an exclusive competitive advantage accomplish this through visual characteristics. The resulting distinctiveness separates them and lifts them above comparable competition and gives the full benefit of the advertising to these features.

k That the exterior of a product can secure a more lasting good will through a continued high regard.

A product which is conceived in organic simplicity and which possesses aesthetic qualities will always be good to look upon. The more beautifully it is designed, the greater and more lasting regard it will receive. No one tires of something which is well designed. Those whose products require human attention in the fulfilment of their performance will find that a better-looking machine will perform better because it will receive greater respect and better treatment than one which is less attractive.

To attract markets:

l The visual aspect can create obsolescence. It can indicate a product advance and can reopen saturated markets.

The use of this designing policy in the automobile industry indicates the value of its application in other fields. New arrangements of functional parts or new exterior design or the use of new materials can serve to express advanced products to reattract lethargic markets.

m It can aid in attracting wider markets.

A product can find its usefulness extended into new places when made more attractive or aesthetically fitting to a wider range of surroundings. Products whose present function does not require them to be seen or to possess visual attractiveness may unfold new places for usefulness and wider markets if made visually attractive. One example of this treatment is the attractively designed furnace which has replaced the old coal furnace and transformed dirty cellars into game rooms. This opportunity is open to many other products.

A well-designed product pays from the moment it is seen by the consumer on through its life by earning and retaining a high regard.

AUTHOR'S CLOSURE

The author again wishes to emphasize a point brought out by Mr. Mills when he stated, "One reads this paper feeling that there is no single or ideal set-up for proper coordination between these three great activities of business and that each must be fitted into the particular individual staff." This is a consideration of utmost importance and should constantly be in the minds of executives undertaking the solution of this problem of coordination.

The practicability of the partially and completely centralized types of organization was questioned. Here again one is confronted with the nature and size of the enterprise and the type of personnel as the limiting factors. The outstanding advantages of the completely centralized type are (*a*) the lessening need for committees, (*b*) the definite placing of responsibility, (*c*) speeding up of the work, and (*d*) a complete segregation of line and staff work, both from the actual operation and the control points of view. An obvious disadvantage is the danger of removing these staff functions too far from their related line activities and thereby widening the breach between them. Partially centralized research organizations generally have only the technical research (except manufacturing research) in a separate department. This is usually the first step toward the completely centralized type. It is taken primarily because of the increasing importance of the research function and the broadening of its scope to include a multitude of problems. As this work grows it becomes too much for a line executive to control, as there is a direct cross between the line and staff functions. While the partially centralized type has certain of the advantages offered by the completely centralized type, it has the additional advantage of closely relating the manufacturing and market research to the production and sales departments, respectively. However, there is a danger that these two research functions will be too far removed from the remainder of the research activities.

The author heartily agrees with Mr. Mills's statement about committees and would like to add that when a committee does operate efficiently it is usually dominated by one man, in addition to having a personnel of high caliber. Unfortunately space restrictions prevented a more detailed treatment of this phase of the subject.

Mr. Waters brings out a very good point in his statement to the effect that market and patent surveys are not necessarily final. This substantiates the fact that a program of constant revaluation of research projects in the light of changing business conditions and newly discovered facts should be maintained.

Mr. Lee's criticism of the use of the term "research" can best be answered by defining the different types of research as the author used them. This will also answer one of Mr. Townshend's criticisms. Pure research is taken to mean that which has to do with scientific research of a general nature, research into fundamental scientific principles with no specific commercial objective in view—this type is sometimes known as "blue sky research." Product research has to do with the development of new products and new uses for existing products (on a basis of technical investigation), changes in existing products, and search for and development of raw materials. Very closely related to product research, and sometimes included in product research itself, are the engineering and design functions. In many cases these two functions comprise all the product research which is undertaken in a given organization. Again, product research may consist of research of a pure or fundamental nature on a specific problem, this being followed by engineering and design in the natural sequence of putting the product into salable form. Manufacturing or process research is taken to mean the development of manufacturing methods and processes, both in regard to more efficient operation and reduction of manufacturing costs, in relation to the manufacture of existing products, and to the manufacture of new products. Control research has to do with the control of the quality of raw materials, stock in process, and the finished product. This is more or less a routine inspection operation and has not been considered in this paper. Market research is concerned with finding out whether there is a market for a given product, what type of market exists and where it is, what quantities it can absorb, the number of competitors in relation to a given product, the buying powers of different markets, distribution facilities, etc.

Mr. Lee also points out that the majority of research problems come into an organization through the sales department. In the light of this it would appear very essential to properly coordinate this phase of the business with research and production, so that through these departments the problems presented could best be translated into factors of commercial and technical value.

The definition of pure research, as given, will answer the question brought out by Mr. Hawkins in his last paragraph.

Mr. Nash's discussion brings out very clearly the necessity of market consideration in product development and shows how important should be the relationship between the technical and marketing functions in American industry.

MAN-54-5

Dividend Programs Related to Depreciation

By E. G. Field,[1] Atlanta, Ga.

Figures are presented to show the working out of five selected dividend programs and to demonstrate that depreciation funds can be and often are misused as a result of the dividend program chosen. Several related subjects also are discussed, such as historical statements for interpretation of results, possibility of a current investment to current liability ratio, dividends that return parts of the original investment, and depreciation funds spent by management.

Among the factors contributing to the decline of the textile industry in New England, there has been included the lack of adequate provision for depreciation. This reason may be stated in two ways: first, because of the general failure to provide for depreciation, and second, as indicating the general lack of complete policies and programs directed to the perpetuation of the manufacturers. This same defect may be noted in the administration of Southern cotton mills and in certain other industries, wherever the value of the plant investment represents a large proportion of the assets.

It is commonly admitted that there was a lack of regular recognition of depreciation as an element of cost prior to the introduction of the Federal income tax. Some mills did not provide for any depreciation, under the assumption that the appreciation would exceed the depreciation. More often, the importance of providing for replacements had been experienced, and it had become customary to charge depreciation during good years and to omit depreciation in years of poor earnings. Thus depreciation came to be used as a means to level earnings in a more uniform relation to the dividend program. But in the long run this method did not prove satisfactory in that sufficient depreciation was not charged.

During the last 15 years there have been few failures to include depreciation as a deduction in figuring net income for Federal and state tax purposes. In fact, depreciation has become so well established that several associations have promulgated uniform rates. Depreciation is an acknowledgment of the depletion of original value, but the reserve for depreciation is intended to provide for replacement. This feature has been ignored or overlooked in the failure of management to keep available the funds so intended for the replacement of worn-out or obsolete properties. Thus the industry has continued the error of failure to provide for its future. In the omission it has encouraged abuses that have had far-reaching effects in undermining the financial position of the industry.

The depreciation reserves have taken on further significance in the late years of declining profit margins. A review of mill financial statements, issued for fiscal years ended in 1929, was printed in "Comparing Balance Sheets," in the August, 1930, number of *Cotton*, where it was stated: "Part of the difficulties within the textile industry can be traced to inadequate financing being desperately continued by loans. In turn this shortage in capitalization may have resulted from improper dividend policies, etc."

Among the significant facts about the depreciation reserve, as indicated in the tabulations in that article, were these: (1) The industry may have a depreciation reserve equivalent to one-half of the combined common stocks and surpluses, and (2) the depreciation reserve may be almost 50 per cent larger than the net current capital available for carrying on the businesses. Therefore the depreciation reserve does become of importance in the financial structure of any business requiring a large investment in plant facilities.

In considering ways for the funds represented by the depreciation reserves to be applied to other purposes, it was noticeable that the more prevalent cases included the diversion of funds in doing these things: (1) to reduce current liabilities, (2) to buy in the company's bonds, (3) to provide property additions, and (4) to pay cash dividends. In a discussion on "Depreciation Reserves," in the November, 1930, issue of *Factory and Industrial Management*, the last three diversion cases were illustrated and a method of identification was offered for detecting depreciation dividends.

As stated in that discussion: "Seldom have directors fully considered the results that may arise from following some dividend plans. This example has been cited because of the way in which the textile industry has been affected by controlling stockholders' greed for earnings, directors' lack of dividend policy, and administrative unintentional mismanagement."

The diversion of depreciation funds through the paying of cash dividends is of interest because of the common belief that any cash can be used to distribute surplus. This may arise from the usual legal requirements that dividends be paid from earnings. Nevertheless it is possible that dividends improperly paid in cash may impair the credit, and it is a warning signal to those who have loaned funds to the company. On the other hand, dividends paid from the depreciation funds and not so marked may have been in reality a return to the stockholder of a part of his original investment. Thus the amount of dividend may have been misleading, and it might have resulted in the taxpayer having paid unnecessary surtaxes. There are times when dividends should not be paid in cash, but may be paid by distributing stock.

To illustrate the effect of different dividend policies upon the depreciation funds and the company's plans for its continuation in the manufacturing business, five dividend programs will be reviewed.

In the statements to illustrate this discussion it will be noticeable that the conventional order of the items in the balance sheet has been reversed. This was done purposely to keep attention upon the net plant and the surplus.

---

[1] Cost consultant and industrial engineer, Wm. H. James & Associates. Mem. A.S.M.E. The author was graduated from the Rhode Island State College, Kingston, R. I., in 1916 with the degree of B.S. in Mechanical Engineering. His practical experience has included textiles, power plants, machine shops, and woodworking. He received his industrial training under H. L. Gantt, while engaged with the management problems of several prominent companies. In 1923 he joined the system staff of a large accounting firm. Since 1928 he has been in his present connection.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

As a starting point, it is assumed that the balance sheet on April 30, 1930, when the plant was put in operation, disclosed the following uses and sources of funds, in dollars:

Plant at cost	1,000,000
Current assets	1,000,000
Total assets	2,000,000
Surplus	200,000
Capital stock	800,000
Bonds	500,000
Current liabilities	500,000
Total liabilities	2,000,000

In order to reduce the variations to a relatively few items so that one may more readily compare the cases to be discussed, certain features will be taken alike in all five dividend programs. These conditions include:

(1) The plant will be increased by a 60 per cent addition

(2) Assuming that the current assets will be necessary in an amount equivalent to or more than the investment in gross plant, as at the start, and also continuing the use of current liabilities at one-half of the necessary current assets, the current liabilities will be increased proportional to the change in the plant investment

(3) An arbitrary earning program proportional to the plant size will be selected

(4) Bonds will be retired on a definite schedule

(5) The reserve for depreciation will be increased by annual amounts at a fixed percentage of gross plant, except that the depreciation charges will be discontinued when a definite portion of the plant cost becomes fully depreciated.

For use in showing the points to be emphasized, each program is demonstrated. The examples continue the use of hypothetical and somewhat extreme balance sheets at the close of consecutive years.

Accompanying each set of these statements, there will be found a cumulative solution arranged to locate the changes that have taken place since the start of the program.

Program 1. In this case the dividends paid in cash have equaled the net earnings, except when funds had to be retained in anticipation of or to pay for property extensions. The position statements show, in dollars:

As on April 30	1931	1932	1933	1934	1935
Gross plant at cost	1,000,000	1,000,000	1,000,000	1,600,000	1,600,000
Depreciation reserve	200,000	400,000	600,000	900,000	1,100,000
Net plant	800,000	600,000	400,000	700,000	500,000
Current assets	1,000,000	1,000,000	1,300,000	1,600,000	1,600,000
Total assets	1,800,000	1,600,000	1,700,000	2,300,000	2,100,000
Surplus	200,000	200,000	400,000	700,000	500,000
Capital stock	800,000	800,000	800,000	800,000	800,000
Bonds	300,000	100,000	......	......	......
Current liabilities	500,000	500,000	500,000	800,000	800,000
Total liabilities	1,800,000	1,600,000	1,700,000	2,300,000	2,100,000

To observe what has taken place to the date of each balance sheet, a historical statement is now furnished:

Cumulative to April 30	1931	1932	1933	1934	1935
Additions to plant at cost	......	......	......	600,000	600,000
Necessary increase in current assets	......	......	......	600,000	600,000
Bonds retired	200,000	400,000	500,000	500,000	500,000
Cash dividends paid	300,000	600,000	700,000	880,000	1,560,000
Distributed	500,000	1,000,000	1,200,000	2,580,000	3,260,000
Increase in surplus	......	......	200,000	500,000	300,000
Dividends in cash	300,000	600,000	700,000	880,000	1,560,000
Net earnings	300,000	600,000	900,000	1,380,000	1,860,000
Necessary increase in current liabilities	......	......	......	300,000	300,000
Depreciation funds diverted	200,000	400,000	300,000	900,000	1,100,000
Provided	500,000	1,000,000	1,200,000	2,580,000	3,260,000

As a result of this dividend program, four features are noticeable: (1) The surplus was not increased as the bonds were retired; (2) the only year in which a part of the depreciation reserve was available occurred in the third year when earnings were retained in anticipation of other uses; (3) in general the depreciation policy failed to provide for any replacements, although the accounting formality had been gone through and such a charge recorded in the books of account; (4) in paying these high dividends on top of the additions to plant and working capital, the management has entirely ignored the limitations of the net earnings after depreciation.

(In working out the five programs, the depreciation reserve has been carried on the asset side of the statement and treated as a deduction from gross plant. This method has been generally adopted and is to be recommended, since it prevents the corresponding inflation of the total assets.)

Program 2. This dividend plan starts out by limiting the cash dividend to about two-thirds of the earnings so as to build up a surplus for some future use. The balance sheets are as follows:

As on April 30	1931	1932	1933	1934	1935
Gross plant	1,000,000	1,000,000	1,000,000	1,600,000	1,600,000
Depreciation reserve	200,000	400,000	600,000	900,000	1,100,000
Net plant	800,000	600,000	400,000	700,000	500,000
Current assets	1,100,000	1,200,000	1,300,000	1,600,000	1,700,000
Total assets	1,900,000	1,800,000	1,700,000	2,300,000	2,200,000
Surplus	300,000	400,000	400,000	700,000	600,000
Capital stock	800,000	800,000	800,000	800,000	800,000
Bonds	300,000	100,000	......	......	......
Current liabilities	500,000	500,000	500,000	800,000	800,000
Total liabilities	1,900,000	1,800,000	1,700,000	2,300,000	2,200,000

What has really taken place is shown by this historical statement:

Cumulative to April 30	1931	1932	1933	1934	1935
Additions to plant at cost	......	......	......	600,000	600,000
Necessary increase in current assets	......	......	......	600,000	600,000
Bonds retired	200,000	400,000	500,000	500,000	500,000
Cash dividends paid	200,000	400,000	700,000	880,000	1,460,000
Distributed	400,000	800,000	1,200,000	2,580,000	3,160,000
Increase in surplus	100,000	200,000	200,000	500,000	400,000
Dividends in cash	200,000	400,000	700,000	880,000	1,460,000
Net earnings	300,000	600,000	900,000	1,380,000	1,860,000
Necessary increase in current liabilities	......	......	......	300,000	300,000
Depreciation funds diverted	100,000	200,000	300,000	900,000	1,000,000
Provided	400,000	800,000	1,200,000	2,580,000	3,160,000

In this instance four results are outstanding: (1) The surplus was increased by a part of the amount paid out for the bonds bought in; (2) about one-half of the depreciation reserve was available until the plant was extended, at which time this reserve was fully diverted; (3) while the intention in regard to depreciation was better than in Program 1, the final result was almost as bad a failure to provide for replacements; (4) it is quite apparent that the management has tried to spend the same earnings for both expansion and dividends.

Program 3. Here a good start was made by limiting dividends in order to pay off the bonds, but no provision was made for the sudden expansion. The annual reports show:

As on April 30	1931	1932	1933	1934	1935
Gross plant	1,000,000	1,000,000	1,000,000	1,600,000	1,600,000
Depreciation reserve	200,000	400,000	600,000	900,000	1,100,000
Net plant	800,000	600,000	400,000	700,000	500,000
Current assets	1,200,000	1,400,000	1,600,000	1,900,000	2,100,000
Total assets	2,000,000	2,000,000	2,000,000	2,600,000	2,600,000
Surplus	400,000	600,000	700,000	1,000,000	1,000 000
Capital stock	800,000	800,000	800,000	800,000	800,000
Bonds	300,000	100,000	......	......	......
Current liabilities	500,000	500,000	500,000	800,000	800,000
Total liabilities	2,000,000	2,000,000	2,000,000	2,600,000	2,600,000

The facts about what has been done are given historically:

Cumulative to April 30.	1931	1932	1933	1934	1935
Additions to plant at cost	.....	.....	.....	600,000	600,000
Necessary increase in current assets	.....	.....	.....	600,000	600,000
Bonds retired	200,000	400,000	500,000	500,000	500,000
Cash dividends paid	100,000	200,000	400,000	580,000	1,060,000
Distributed	300,000	600,000	900,000	2,280,000	2,760,000
Increase in surplus	200,000	400,000	500,000	800,000	800,000
Dividends in cash	100,000	200,000	400,000	580,000	1,060,000
Net earnings	300,000	600,000	900,000	1,380,000	1,860,000
Necessary increase in current liabilities	.....	.....	.....	300,000	300,000
Depreciation funds diverted	.....	.....	.....	600,000	600,000
Provided	300,000	600,000	900,000	2,280,000	2,760,000

In consequence of this program, four points may be observed: (1) The surplus has increased in proportion to the bonds retired; (2) the depreciation reserve was kept available until the sudden expansion, for which no provision had been made, and at that time the original depreciation policy was canceled; (3) to the extent that less cash dividends have been paid out, the financial position is better than in the previous programs, although it is apparent that both the expansion and the cash dividends could not all be paid out of the same earnings; (4) the relatively constant total assets, including the jump for property additions, are indicative of the intention to fully maintain the property.

Program 4. Starting with a definite plan for expanding the business, no earnings were distributed to the stockholders until the plant additions with necessary increase in working capital had both been provided. On this program the annual positions were reported:

As on April 30	1931	1932	1933	1934	1935
Gross plant	1,000,000	1,000,000	1,000,000	1,600,000	1,600,000
Depreciation reserve	200,000	400,000	600,000	900,000	1,100,000
Net plant	800,000	600,000	400,000	700,000	500,000
Current assets	1,300,000	1,600,000	2,000,000	2,480,000	2,700,000
Total assets	2,100,000	2,200,000	2,400,000	3,180,000	3,200,000
Surplus	500,000	800,000	1,100,000	1,580,000	1,600,000
Capital stock	800,000	800,000	800,000	800,000	800,000
Bonds	300,000	100,000	......	......	......
Current liabilities	500,000	500,000	500,000	800,000	800,000
Total liabilities	2,100,000	2,200,000	2,400,000	3,180,000	3,200,000

And the history followed these steps:

Cumulative to April 30.	1931	1932	1933	1934	1935
Additions to plant at cost	.....	.....	.....	600,000	600,000
Necessary increase in current assets	.....	.....	.....	600,000	600,000
Bonds retired	200,000	400,000	500,000	500,000	500,000
Cash dividends paid	.....	.....	.....	......	460,000
Reserved for plant extension	100,000	200,000	400,000	......	......
Distributed	300,000	600,000	900,000	1,700,000	2,160,000
Increase in surplus	300,000	600,000	900,000	1,380,000	1,400,000
Dividends in cash	.....	.....	.....	......	460,000
Net earnings	300,000	600,000	900,000	1,380,000	1,860,000
Necessary increase in current liabilities	.....	.....	.....	300,000	300,000
Depreciation funds diverted	.....	.....	.....	20,000	......
Provided	300,000	600,000	900,000	1,700,000	2,160,000

As it was intended to accomplish certain purposes, it will be of interest now to observe what took place. Four items are most noticeable: (1) The surplus grew by the annual earnings, except in the last period, when a cash dividend was paid; (2) the reserves for depreciation were fully maintained for replacements, except in the fourth period, when a very small part was temporarily diverted; (3) the earnings were retained for the plant extensions without attempt also to pay them out in cash dividends; (4) it is noteworthy that the increases in total assets properly preceded or accompanied the expansion of the business.

Program 5. Finally a plan is reviewed that combines the good points of the last three arrangements. The balance sheets are presented as follows:

As on April 30	1931	1932	1933	1934	1935
Gross plant	1,000,000	1,000,000	1,000,000	1,600,000	1,600,000
Depreciation reserve	200,000	400,000	600,000	900,000	1,100,000
Net plant	800,000	600,000	400,000	700,000	500,000
Current assets	1,300,000	1,600,000	2,000,000	2,480,000	2,700,000
Total assets	2,100,000	2,200,000	2,400,000	3,180,000	3,200,000
Surplus	400,000	600,000	700,000	700,000	700,000
Capital stock	900,000	1,000,000	1,200,000	1,680,000	1,700,000
Bonds	300,000	100,000	......	......	......
Current liabilities	500,000	500,000	500,000	800,000	800,000
Total liabilities	2,100,000	2,200,000	2,400,000	3.180,000	3,200,000

The accompanying historical statement follows:

Cumulative to April 30.	1931	1932	1933	1934	1935
Additions to plant at cost	.....	.....	.....	600,000	600,000
Necessary increase in current assets	.....	.....	.....	600,000	600,000
Bonds retired	200,000	400,000	500,000	500,000	500,000
Cash dividends paid	.....	.....	.....	......	460,000
Reserved for plant extensions	100,000	200,000	400,000	......	......
Distributed	300,000	600,000	900,000	1,700,000	2,160,000
Increase in surplus	200,000	400,000	500,000	500,000	500,000
Dividends in cash	.....	.....	.....	......	460,000
Dividends in stock	100,000	200,000	400,000	880,000	900,000
Net earnings	300,000	600,000	900,000	1,380,000	1,860,000
Necessary increase in current liabilities	.....	.....	.....	300,000	300,000
Depreciation funds diverted	.....	.....	.....	20,000	......
Provided	300,000	600,000	900,000	1,700,000	2,160,000

The important considerations are four in number, thus: (1) The surplus has been increased by the amount of bonds retired; (2) the depreciation funds have been kept available except for one small borrowing; (3) the earnings retained for plant extension have been turned over to the stockholders by means of stock dividends, while further earnings can be paid in cash; (4) the increase in total assets accompanies the planned growth of the business attended by adequate financing.

Following the brief study of these programs it may be set down that a dividend policy is fundamentally wrong when it later may require the reduction or omission of future dividends in order to raise the funds necessary for replacements. Perhaps the dividends can be continued by selling stock to the unsuspecting public in order to release the replacement funds, but this will correspondingly cut down the amount of dividend to the old stockholders. Moreover, it is not convenient to sell stocks or bonds at certain times, and especially when the physical properties are well consumed and the industry is in the doldrums. No bank is going to knowingly make short-term loans for machinery replacements, and many commission sales agents are going to learn that they should not make advances for release of depreciation reserves.

Stock dividends offer a fair and equitable distribution to the stockholders in that these dividends acknowledge the extension of the facilities, permit the retention of depreciation funds, and give the stockholders an opportunity to continue their proportion of the investment or to sell their stock dividend and accept profits in lieu of the extra shares.

When a balance sheet is placed before an executive, banker, or stockholder, how is he going to sense the indications of inability to make replacements that must come eventually and even now may be responsible for the high costs that leave little or no profits? As the current assets include the cash, inventories, marketable securities, etc., that should apply in part to the depreciation reserve, the status of the working assets exclusive of the depreciation fund may be noted. At the close of the last period just reviewed, the working assets as a result of the five different policies show (losses are in italic figures):

Program	1	2	3	4 and 5
Current assets	1,600,000	1,700,000	2,100,000	2,700,000
Depreciation funds	1,100,000	1,100,000	1,100,000	1,100,000
Current investment	500,000	600,000	1,000,000	1,600,000
Current liabilities	800,000	800,000	800,000	800,000
Current working investment	*300,000*	*200,000*	200,000	800,000
Current working capital	800,000	900,000	1,300,000	1,900,000
Ratio of current assets to current liabilities	2.000	2.125	2.625	3.375
Ratio of current investment to current liabilities	0.625	0.750	1.250	2.000

From this tabulation it should be apparent that the usual current-asset–current-liability ratio requires considerable interpretation at all times. While the accountant may have stressed the importance of this ratio, the experienced banker has learned that the desirable risk is not foretold by any such computation. The current-asset–current-liability ratio is affected by the depreciation reserve, and also it should be observed for the relation of the current assets to the total assets.

In the last illustration, it is to be noted that this company started out with a current-asset–current-liability ratio of 2 to 1, and as a result of the several dividend programs, this ratio at the close of the fifth year would be 2 or better. Such a 2 to 1 ratio might indicate that the customary credit terms may be continued to the company for merchandise shipped to them in the usual way, as long as the company discounts or remits promptly.

But the banker and the investor should be more interested in the relative maintenance of the current-investment–current-liability ratio as indicative of sound financial policies supported by ability to make replacements, and especially to take advantage of improved manufacturing processes or the opportunities that may attend changes to more profitable lines or specialties.

Returning to the last illustration, it may be observed that this company started out with a current-investment–current-liability ratio of 2 to 1 and that this condition was continued at the close of the fifth year only in the cases of dividend programs 4 and 5. In the other programs large proportionate departures were shown, going as low as 5 to 8 (or 0.625) in program 1. And this was going on while the current asset ratio continued as high as 2!

Whether the annual depreciation charge is sufficient and the total depreciation reserve is proportional to the consumption of the assets plus reasonable allowance for obsolescence cannot be established directly by reference to the financial statements of any single company. But the ability to spend the replacement funds, set aside by the creation of the depreciation reserve, is indicated in the balance sheet, and it may be further determined by examination of the past history of the company. This ability, in combination with records of annual replacements made, is convincing proof that the company has officers who are looking forward into the future and planning to continue in active business.

Because the historical interpretation of financial statements can develop these significant facts, it also contributes to the study of stock values. This is not to be construed as an attempt to foretell market prices, but rather as a secondary step in judging the desirability of future ownership in a specific company.

It is a well-known fact that there is no relation between so-called book value and market value. Future dividend prospects help set the market prices. Should the future earnings be required for replacements, future dividends become improbable.

When a historical statement is available, an illuminating study of indicated value may be made. This is demonstrated by an observation of the final results from the five dividend program (losses are in italics), as follows:

Program	1	2	3	4	5
Net earnings	1,860,000	1,860,000	1,860,000	1,860,000	1,860,000
Distributed in dividends	1,560,000	1,460,000	1,060,000	460,000	1,360,000
Increase in surplus account	300,000	400,000	800,000	1,400,000	500,000
Depreciation diverted	1,100,000	1,000,000	600,000	......	......
Enhancement or *shrinkage*	*800,000*	*600,000*	200,000	1,400,000	500,000
Original surplus	200,000	200,000	200,000	200,000	200,000
Indicated value or *lack* of book surplus	*600,000*	*400,000*	400,000	1,600,000	700,000
Capital stock	800,000	800,000	800,000	800,000	1,700,000
Indicated value of net worth	200,000	400,000	1,200,000	2,400,000	2,400,000
Indicated net worth relative to original capital stock, per cent.	25	50	150	300	300
Actual book value	1,300,000	1,400,000	1,800,000	2,400,000	2,400,000

Attention is directed to the difference between the indicated net worth and the book value. This difference represents the amount of additional money that must be put back into the business in order to restore the full values. For instance, to restore the cost of the original plant facilities it will be necessary to obtain funds equivalent to the depreciation reserve diverted. If new purchasers should take over the shares they will have to expect to raise the additional funds if they intend to continue all of the business. These funds might be borrowed temporarily or by mortgage, but they will eventually have to be put in by the stockholders who may have (1) additional stock sold to them to pay for the plant addition and thus release the depreciation reserve for replacements, or (2) the future dividends must cut down until the future earnings will supply the replacements.

In the first instance, it will be apparent that the possible sale value of the stock should be below the book value by the additional amount which the stockholders must put in to restore the original cost value. The market value as usually applied to investments is dependent upon the future earning ability, since those earnings should control the dividend possibilities. It is common to see the earnings of the last five years averaged to outline the future possibilities. But do not pay any such price without further consideration! The deficit from depreciation diverted should be deducted to establish what should be paid for the stock, as was done to arrive at the indicated net worth.

In the second instance, it will be observed that the shareholders must expect the dividend rate to be cut or maybe suspended until the future earnings will repay the depreciation funds so necessary to restore the plant facilities. This point cannot be overemphasized. It explains how the big dividends of one generation may have been advance payments out of future earnings and why the second generation must go without dividends. The future earnings have been discounted to the extent that future dividends have been anticipated. Accordingly, that discounting has been accomplished by reducing the present or indicated value of the net worth. Thus, a part of the past dividends must have reduced the real investment, which is not shown by the book value.

This point is also of importance to the bondholder and banker, for it increases the risk, and in case of default it may be expected to necessitate the bondholder and banker putting in restorative cash running into large amounts that were never contemplated at the time of making the original loans. It often takes large sums of money to rehabilitate old properties that might better have been left alone.

Referring to the last tabulation, it will be clear that the first program would have given the stockholder the largest immediate return and would have left the least real or indicated value to the stock. The fifth program would have given the same cash dividend as in program 4, plus a sizable block of stock that might have been sold for quick cash return or held for the increased investment value. The first three programs give the stockholder fictitious dividends that are in reality repayments of the original investment.

As provided in the Federal Income Tax Regulations, certain companies using natural resources, such as coal mines, oil wells, timber cutting, etc., experiencing depletion, inform their stockholders concerning the portions of the dividend that were paid from earnings and by investment return. No such relief is definitely specified for the stockholders in a manufacturing company who personally may have paid a tax on cash dividends that used funds from the depreciation reserve and therefore also were a return of the investment. In Regulations 74 (1928), section 115, article 626, provision is made for "distributions from depletion or depreciation reserves." The last sentence in that article states, "No distribution, however, can be made from such a reserve until all the earnings or profits of the corporation have first been distributed." In the examples of the dividend programs 1, 2, and 3, part of the earnings was left in surplus because of the plant additions made out of earnings. But the shareholders did pay a tax on the return of that part of the investment distributed through the dividends using cash from the depreciation reserve. Whether the income tax provision is correct or is not, need not be argued here. The point to be made is that improper dividend policies may be expensive to the taxpayer who must consider surtaxes.

All investors should give more attention to guard against improper dividends that will attract unjustified competition which cannot be repelled after the financial position has become greatly weakened. The individual mills in the textile industry are responsible for the large and often unwarranted cash dividends which prompted the building of new plants that greatly extended the available capacity, and thus have brought competitive unprofitable sales.

This explanation may help account for some of the repetitive cycles of business activity, especially the sequence of good profits, expansion with cash dividends, and idle plants with lack of earnings. It certainly does explain why many stock and bond estates, formerly very attractive, have in another period deteriorated quite rapidly.

Some people may be of the opinion that too much emphasis has been given to the misuse of depreciation funds. Foremost among their arguments may be mentioned the exceptional companies that have been very profitable and apparently have never found it necessary to give much thought to the form of dividend paid. These exceptions on closer examination often may furnish conclusive evidence of the importance of the depreciation funds.

For example, an examination of the foremost automobile companies will show the frequent large expenditures of cash in providing the most economical facilities to produce new models. Here the depreciation funds are in actual use as intended, so cannot be used to distort dividend considerations.

The leaders in other lines frequently are maintaining their progressive positions because of their willingness to spend depreciation funds for more economical processing. In some instances a rule-of-thumb plan has been adopted. This may provide for an average replacement each five years equivalent to the average depreciation charge so as to keep the book value at a figure approximately one-half depreciated, but with facilities thoroughly modern. This practical solution uses the depreciation funds before that money can be misapplied. Therefore, the success of these companies has been assisted by the good management that has acted before the depreciation funds have been allowed to accumulate and become a source of trouble to unsuspecting directors.

This point brings out the value of more consideration being given to the use of depreciation funds. The banker and investor should inquire more into the expenditures from those funds. The management should be expected to average certain rates of replacements, and any slighting of this provision can be accepted as evidence of lack of sound policies. The engineer watching for signs of healthy management will insist upon more detailed reports about the depreciation reserve and especially the history of all depreciation expenditures.

The better relations between engineers and bankers makes it possible for the engineer to bring forth advance proofs that may be of great benefit. This is especially true where the engineer can show the necessity for sufficient original capital to provide all necessary funds essential to properly rehabilitate old properties into conditions of practical economic use. Worn-out properties should not be bought and returned to competition unless they are adequately refinanced to permit complete modernization within a reasonable time. Thus, many of the troubles that follow lack of sufficient own capital can be avoided.

In an unusually clear discussion of business ills, Fred W. Shibley, Vice-President, Bankers Trust Company, commented upon depreciation in his article, "Look to Your Working Capital," appearing in the May, 1931, issue of *Nation's Business*. In his presentation of the lessons taught in this last depression, he says:

> One fact has been driven into the minds of the commercial bankers who lend money and of the manufacturing corporations which look to banking credit for additional working capital. That is how seldom the item "depreciation," annually charged to expense, has been soundly treated. This item should be regarded as a true reserve set up in the form of cash or its equivalent to provide not only for depreciation, but also for obsolescence of plant and machinery. Such a reserve should be conserved as a sacred fund to be employed for no purpose except the replacement of plant and equipment, the addition of new and improved machinery, and, in an emergency, as working capital under an implied obligation that restitution shall be made of such working capital from profits in subsequent years or from the sale of capital securities.
>
> In this machine age depreciation and obsolescence cannot be ignored. Maintenance and repairs are well enough in their place, but the current pace of improvements in mechanical processes is too swift for them. A plant maintained in a high degree of efficiency may become obsolete in comparatively few years. It is necessary, therefore, that the manufacturers should reserve depreciation as a cash asset, not available for dividend requirements, a use to which it has been prostituted too frequently in recent years, particularly when payment of dividends was required to maintain the market value of corporate securities.

CONCLUSION

Dividend programs are related to depreciation. The figures that were presented to show the working out of five selected dividend programs have demonstrated that the depreciation funds can be and too often are misused as a result of the dividend program chosen. In those instances, the intention of the depreciation reserve is accordingly destroyed.

Following the demonstration of this relation between dividend and depreciation and its consequence, discussion has been given to the following related, special features:

Historical statements for interpretation of results
Dividend programs wrong if provision has not been made for replacements
When stock dividends rather than cash
Lack of significance in current-asset-current-liability ratios

Possibility of current-investment–current-liability ratio
Ability to make replacements indicates plans for continuity
Indicated net worth relative to original capital stock
Dividends that return parts of the original investment
Improper dividends promote unprofitable competition
Management should spend depreciation funds.

It is proper to suggest that more attention upon the retention of depreciation funds as intended by that reserve would help to prevent extreme business depressions such as have been experienced. Should the state laws relative to the payment of dividends be further defined to make the directors liable for dividends distributed by misuse of depreciation funds, a strong influence would be exerted in restraint of unwarranted plant expansion. It is hoped that such restraints will be developed as protection, both to the general purchaser of investment issues and to the great number of trusting workers who have so much suffering thrust upon them during the periods of long business depressions.

In the textile industry, late years have shown remarkable improvement in machinery and processing arrangements. Individual investors may advisably examine the depreciation policies and quietly withdraw from participation in those companies that are not now taking the necessary mechanical steps to lower their operating costs.

In all industries where the investment in plant values is proportionately high, it is important that the dividend program shall not be contingent upon the lack of a complete depreciation policy.

Discussion

Ernest F. DuBrul.[2] The paper gives a clear analysis of the effect of various policies in connection with the payment of dividends. Entirely too little attention generally is paid by management to the question of the handling of depreciation accounting and depreciation-reserve funds. It is thought that the author should have made it a little clearer that when he refers to a depreciation reserve he means a depreciation-reserve fund. The item called depreciation reserve is frequently used in balance sheets merely as a bookkeeping entry against which there is no actual cash or securities fund. Only by using the word fund can the meaning be made clear. The author shows how an analysis of the figures will disclose what has happened to the accounting entry.

Mr. Shibley, as quoted by the author, wants the depreciation reserve conserved as "a sacred fund to be employed for no purpose except the replacement of plant and equipment, the addition of new and improved machinery, and, in an emergency, as working capital under an implied obligation that restitution shall be made of such working capital from profits in subsequent years or from the sale of capital securities."

It is noted that Mr. Shibley himself tolerates a temporary emergency diversion of the sacred depreciation-reserve funds into working capital. To do so gives the "sacred obligation" a very weak hold on the conscience of the management. The difficulty is that so-called emergencies usually become chronic conditions. When a departure from a sound standard is made in the case of emergency, it is usually exceedingly difficult to bring the minds of directors back to the standard practice after the emergency has passed.

While the author has rendered a real service in calling attention to these conditions and showing a practical method of analysis, his paper unfortunately does not go deep enough, because his presentation is true only if one blindly accepts the accounting fallacy which assumes stability in the purchasing power of the money unit. The cold, inescapable facts are that the dollar varies in purchasing power, and therefore the actual cost of acquisition on which the author's analysis is based is of very limited use from a managerial point of view. Therefore the method of analysis needs to be amplified and clarified. In other words, the dollar measurements must be adjusted to the actual purchasing power. Unfortunately, few accountants have as yet seen the need of calibrating the dollar marks on their books to the actual current facts of purchasing power of the dollars which those dollar marks represent.

Every condition cited in the paper showing a dollar deficiency of the depreciation reserve fund is accentuated to whatever extent there has been an increase over original cost in the prices of the property which must replace property that is wearing out or becoming obsolete. Traditional accounting takes no responsibility for disclosing this cold economic fact. There was an enormous rise in prices from the low prices of 1896 to the high prices of 1920. This rise in price enormously accentuated every condition of incorrect, fallacious, and useless depreciation accounting that is set out in the paper.

Then, quite to the contrary, we have had a falling price level since 1920. This fall destroys the validity of the author's analysis in the other direction. If a plant had been built at the peak of prices of 1920, its depreciation accounting, based on the author's method, might appear very bad. Still it might have presented no financial difficulties to the company, because it may not cost as many dollars in 1931 to replace an equivalent amount of productivity which was purchased in 1920. Traditional accounting simply does not tell management these economic facts which management and owners ought to know.

A large trouble with discussions of depreciation lies in the fact that accountants are actually thinking of their book entries, although they talk as though they were thinking of the physical property. The author falls into this error of confused thought. On the fourth page of the paper he says, "To restore the cost of the original plant facilities it will be necessary," etc. Again he says, "The possible sale value of the stock should be below the book value by the additional amount which the stockholders must put in to restore the original cost value." But the inescapable managerial fact is that the thing which must be restored is the equivalent productivity *regardless* of the original cost value of the property.

The depreciation fund automatically diverted by the change in purchasing power of the dollar should be deducted to establish what should be paid for the stock if the costs of property have risen since the date of their acquisition, and on the contrary there may in fact be no real deficit from a diverted depreciation which would be shown by the author's formula, if prices of property have in the meantime fallen to such a degree as to make replacements cost less than the calculated diversion.

The writer fully agrees with the author's statement of the principle that "a dividend policy is fundamentally wrong when it later may require the reduction or omission of future dividends in order to raise the funds necessary for replacements." His own statement is perfectly true *regardless* of the original cost of acquisition of the asset. But when his accounting is based on the erroneous assumption of the stability of the purchasing power of the dollar, he vitiates the application of this perfectly sound principle which he enunciates.

Our accountants, cost consultants, industrial engineers, management consultants, financiers, bankers, and others deal with physical property which is represented by dollar symbols on books of account. We must bring more of these people to think of the preservation of the substance of the asset rather than the balancing of the accounting symbols representing that substance. All of these factors should carefully study depreciation principles such as are set out by the author, but expressed in dollar symbols calibrated to the purchasing power of the dollar.

---

[2] Management Engineer, Cincinnati, Ohio. Assoc. A.S.M.E.

What should be done, of course, is the actual valuation of all balance-sheet items at current replacement values, the taking of depreciation and the setting up of depreciation-reserve funds based on current replacement value, revaluation of all balance-sheet items as often as important changes in purchasing power of the dollar justify the revaluation, and a setting up of enough adjustment accounts which will indicate the difference between the original cost and current values of not only the properties but of the depreciation sums set aside to take care of the replacement of those properties.

The usual cry is that this is entirely too complicated a procedure. But complex problems cannot be solved by simple procedures, and this problem of preserving the substance of the asset is a complex problem which kindergarten methods of accounting cannot possibly solve.

Nevertheless, it also may be pointed out that methods in actual use which attain the very objectives that the writer has set out are not excessively difficult, in spite of the cry to the contrary, so that the cry of excessive complexity is merely a confession of ignorance or worse.

Judging by the slow progress that traditional accounting practice has made in the way of giving management true pictures of the real facts of business, it will be many years before management can expect to get the true facts from the ordinary accountant. So we ought to be very grateful for any minor improvements that may come along, even though based on the inadequate facts presented by ordinary accounting.

Some improvement of that sort is possible by the use of the author's formula. Much advance would be made if these methods were carried out by accountants and managers who now violate the principles that he lays down. Half a loaf is better than no bread at all, so we should be glad to see management generally adopt the author's method of analysis. Even though it is defective, it is far ahead of anything that is usually done, and replacement programs might be improved somewhat compared to what they are.

The writer takes exception to the paragraph on the third page which says, "Stock dividends offer a fair and equitable distribution to the stockholders in that these dividends acknowledge an extension of the facilities, permit the retention of depreciation funds, and give the stockholders an opportunity to continue their proportion of the investment or to sell their stock dividend and accept profits in lieu of the extra shares."

Here again mere dollar marks on the accountant's books are taken as meaning something, whereas they have no meaning at all. The author's statement would apply only if par values on stocks meant anything, and we know that they mean nothing at all. The statement would not be applicable in the case of a company with no-par stock. Whether the company has par stock or no-par stock, the distribution of stock dividends is merely a distribution of pieces of paper evidencing some fractions of ownership. So there is no validity to the author's conclusions in connection with stock dividends on that account. It is granted that the stock dividends would balance certain columns of figures, according to the author's formula, but such balancing would not automatically do what he says. It is simply a part of the formalism of traditional accounting which confuses the issue instead of throwing any light upon it.

AUTHOR'S CLOSURE

Most of the discussion has proposed additional ideas. At the outset the author can admit the omissions cited because it was of course necessary to place a limit on the length of this paper.

Mr. H. F. Coes, in his oral discussion, emphasized the necessity that depreciation fully include both deterioration and obsolescence, and stressed the importance of depreciation (a rental charge for use of equipment) as an element of cost. In reply to his inquiry about the use of the proposed current-investment–current-liability ratio, the author will explain that this contribution has been suggested for its ready indication of past dividends and financial policies that may directly lead to an unsatisfactory financial condition.

He also helped to stress the importance of distinguishing between the depreciation reserve (an allowance for depreciation accrued) and the depreciation funds (the dollars provided to make replacements). This point was very well taken, for it is essential that these two features of depreciation be kept clearly in mind when considering the accounting for property. In the paper, the illustrations were used to keep track of the disposition of the depreciation funds that should be retained to accompany the depreciation reserve. Failure in this particular damages the financial situation and leads to economic troubles. Many of these failures have in the past been brought about by questionable dividend policies that exhausted the depreciation funds. Until management fully recognizes these consequences and acts to prevent this form of waste, the financial situation is relatively but little better than in the old days before depreciation was considered.

Mr. DuBrul has added the economic theory of fluctuating dollar values and presented it in his usual enthusiastic manner. Much could be said on both sides of this question. While we recognize this feature, it is well also to remember that it is not the only variable. In many lines of business the changes of customer desires, the competition of other products, the improvement in methods, etc. make plants partially unprofitable and have much more effect upon the plant values to going concerns than does that of change in the purchasing power of isolated dollars. Admittedly, one variable can be identified, but that does not detract greatly from the risk of doing business, which in the last analysis must include all the uncontrolled variables.

Mr. DuBrul exposes the theory he so ably presents, by announcing "the inescapable managerial fact is that the thing which must be restored is the equivalent productivity *regardless* of the original cost," etc. The periods of rising dollar values have been accompanied by remarkable improvements in the relative productivity. In many instances the rate of output from new machines has contributed to lower costs through reducing the number of the machines or the floor space required. This point was well taken by Mr. Coes, who so aptly remarked that "replacements are not *in kind*, but are by improvements." The variable dollar value cannot fairly be applied in fact finding unless the variable productivity, plant desirability, and other factors also be considered. It is not essential to include such variables in the customary financial statements, at least not before the present form of report is much better understood and used more effectively.

Finally, it is apparent that we are all striving for the reduction of economic ills, and it is generally agreed that the depreciation funds should be retained available for the replacements which must be provided in accordance with the accrued depreciation set out in the depreciation reserve. That this move is in the proper direction was stated by Mr. DuBrul: "Some improvement of that sort is possible by the use of the author's formula. Much advance would be made if these methods were carried out by accountants and managers who now violate the principles that he lays down."

Automatic Internal Grinder

By H. L. BLOOD,[1] WORCESTER, MASS.

Internal grinding, originally a toolroom operation, has been demanded for such a large number of parts that it has become necessary to develop machines that would grind the holes at the lowest possible cost. This development has culminated in the automatic internal-grinding machine which positively determines the size of the hole and which requires no gaging on the part of the operator, who merely puts the work into the chuck and starts the cycle of operations. The improvements on the machines and their adaptation for special grinding jobs are described.

INTERNAL GRINDING was originally a toolroom operation, but the demand for large numbers of parts having accurately finished holes made it necessary to develop machines that would grind the holes at the lowest possible cost. The culmination of years of development in internal grinding is the automatic machine which positively determines the size of the hole being ground and which requires no effort on the part of the operator except to put work into the chuck and start the cycle of operations. In order to understand and appreciate the various features of the automatic internal grinder the steps by which it was developed should be reviewed.

The first type of machine used for internal grinding was a universal grinder, Fig. 1, which was designed for external and face as well as for internal grinding. The spindle and wheel for internal grinding may be seen at x.

This machine was followed by one designed especially for internal work (Fig. 2). The workhead, which rotated the work, was carried on a reciprocating table, and a high-speed grinding spindle was mounted on a cross-slide supported from the back. This was a bench machine and was adapted for grinding only small holes up to a maximum of $^1/_4$ in. diameter.

An internal grinder for holes larger than $^1/_4$ in. was brought out in 1906 (Fig. 3). Its capacity was for holes of $^1/_2$ to $8^1/_2$ in. in diameter and up to 11 in. long. When it was introduced, one of the leading machine-tool builders expressed the opinion that there would be a very small market for such a machine adapted only for internal grinding. He did not foresee the general use of hardened gears, rolls, bushing, and anti-friction bearings and the need for accurate holes in softer materials that have made internal grinding indispensable. Neither could he foresee the developments that have made the modern internal grinder an economical producer.

A basic improvement in internal grinders was made by utilizing a hydraulic cylinder to reciprocate the wheel, in place of the gears and clutches previously employed. The hydraulic system, Fig. 4, is worthy of note because of its simplicity. It consists of a gear pump, with a relief valve, and a combined throttle and reverse valve which admits oil first into one end of a cylinder and then into the other. This system was incorporated in an early machine, with the addition of a bypass valve opened by a cam bar on the table. When the operator lifts the table dog and the wheel beings to move away from the work, the bypass valve opens, allowing oil to bypass the throttle and run the table out at high speed to the rest position. After the operator unloads the chuck and puts in a new piece, he throws over the reverse valve, causing the table to run in at high speed. Just before the wheel reaches the work the bypass valve closes and the wheel reciprocates at the proper speed for roughing, as governed by the setting of the throttle valve.

When the hole is nearly to size, the operator lifts a latch, which allows the table to run out far enough to permit the diamond to drop into position for truing the wheel, and after being trued the wheel returns into the work for finish grinding. For truing the wheel, the operator reduces the speed by means of the throttle, a slow, uniform speed being necessary to allow the diamond to true the wheel properly instead of merely cutting a thread on it. Still another speed is used for finishing. From this it will be seen that the hydraulic system permits the use of the most economical speed for each part of the cycle, greatly increasing the productive possibilities of the machine. It eliminates gears and clutches, is smooth and quiet in operation, and is extremely reliable and durable, because the moving parts are few and run in oil under light loads. The hydraulic system also provides forced lubrication for the table ways and forms a foundation for the automatic features which will be described.

The same hydraulic system is also used on rotary surface grinders (Fig. 5) and in internal grinders of the planetary type, commonly known as cylinder grinders (Fig. 6). Cylinder grinders are well adapted for grinding pieces which cannot be rotated to advantage, such as large cylinders and locomotive connecting rods. The work is supported on an auxiliary table which can be adjusted horizontally and vertically to bring the work into the proper relation with the spindle, the vertical adjustment being obtained by means of a wedge member upon which the auxiliary table rests. The grinding spindle is carried in two eccentrics, one inside the other, which revolve together and carry the wheel in a circular path. Relative adjustment of the two eccentrics can be made while the machine is running, to increase the radius of operation and to enlarge the hole until the desired size is secured.

As the development of internal grinders progressed, other improvements were added, such as high-speed ball-bearing workheads and wheelheads, automatic starting of the workhead when the wheel approaches the work, automatic stopping of the workhead as the wheel runs out, and automatic starting and stopping of the flow of coolant at the proper time, but the greatest problem in internal grinding remained.

---

[1] The Heald Machine Company. Mem. A.S.M.E. Mr. Blood is a graduate of Cornell University (1913, M.E.). From 1913 to 1923 he was with the Niles-Bement-Pond Company at their Pond and Pratt & Whitney plants, engaged in shop, inspection, development, sales engineering and design work, and had charge of the design of many types of machine tools. From 1923 to 1929 he was with the Western Electric Company, becoming chief of the Machine Design Division. This organization designed the large variety of cabling, insulating, and assembling machines, special machine tools, and automatic machinery used by the company. He was also in charge of a number of cost-reduction development projects. Mr. Blood has been with his present company since 1929.

Presented at a Joint Meeting of the Metropolitan and Plainfield Sections of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., March 19, 1931, sponsored by the Machine Shop Practice Division.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

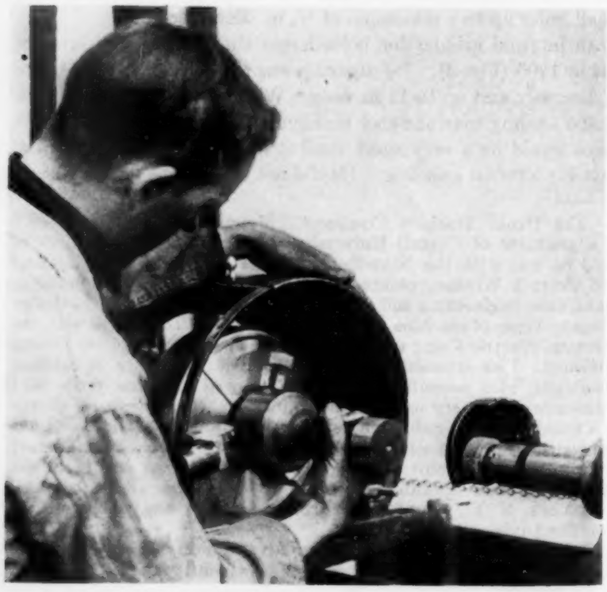

FIG. 7 INTERNAL GRINDING MACHINE WITHOUT AUTOMATIC SIZING
(With flexible idler drive and automatic wheel guard. Wheel guard gives protection to the operator when plugging the work.)

In the machines so far described it was necessary to run the wheel out of the work and try with a plug gage to see whether the hole was to size (Fig. 7). Internal grinding was a guessing contest in which the operator would guess that the hole was nearly to size, run the wheel out, try the plug, grind some more, guess that the hole was about right, run out and try again, until proper size was reached. In order to make a close guess it is necessary to estimate the effect of many variables, such as the amount of stock to be removed, which may vary widely from piece to piece, the amount of wheel wear, the condition or sharpness of the wheel, and the spring of the wheel spindle. An experienced demonstrator could make a fair showing in spite of this handicap, but training operators to obtain a reasonable production was a different matter, and at best the percentage of scrap was high, which added materially to the cost of the product. These difficulties are now becoming still more serious because the demand for closer tolerances is increasing.

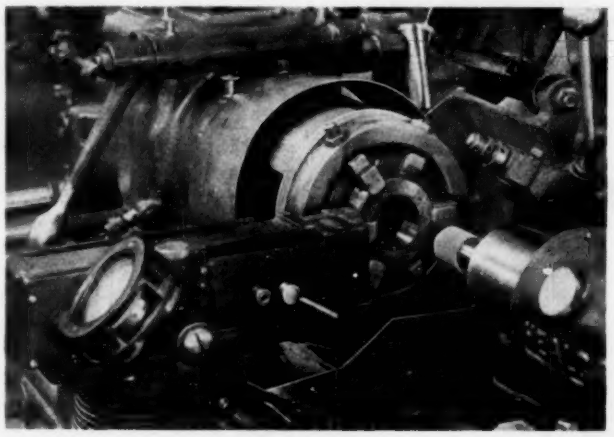

FIG. 8 DIAL INDICATOR WITH DIAMOND-POINTED FINGER BEARING AGAINST THE WORK
(This device does away with hand gaging.)

Three methods have been developed by which holes can be brought to size without the necessity for hand gaging. The first method is to arrange a dial indicator with a diamond-pointed finger bearing against the inside of the hole (Fig. 8). The indicator swings away from the work automatically as the table goes to the rest position so that the work may be unloaded and loaded quickly. By reading the indicator the operator can follow the change in size, true the wheel at the proper time, and stop the machine when finish size has been reached.

The dial indicator is not satisfactory, except for large work, because the indicator finger occupies part of the hole, making it necessary to use a comparatively small wheel and wheel spindle. The spring of a small spindle prevents the use of a fast feed and reduces the accuracy of the hole. The operator must give the indicator close attention and make a large number of motions to control the machine. He must increase the stroke of the machine for truing, reduce the table speed, pull down the diamond, reverse the table, change the table speed again for finishing, run the wheel away from the work when finish size is reached, compensate for wheel wear by turning a knob on the handwheel, and change the speed again for roughing the next piece. The motions which the operator must make not only take time, but their repetition at short intervals requires considerable physical exertion, resulting in fatigue and consequent loss in production. When the operator merely loads an automatic machine, the slow manual motions are eliminated, and it is easy for him to keep up indefinitely with the pace set by the machine. For these reasons machines of the dial-indicator type and those which require hand gaging are being superseded to a large extent by automatic machines, several types of which will be described.

Automatic sizing was first accomplished by adding two electric contacts to the dial indicator, making it an "electric indicator" (Fig. 9). The two contacts are connected to two magnets which lift the table dogs at the proper time and also open an oil valve, causing the diamond to swing down into position for truing the wheel. As the diamond swings down it moves a valve which reduces the table speed for truing, and as the diamond swings up again it moves the valve to give the desired speed for finishing. The cycle of operations is shown diagrammatically in Fig. 10. When the hole has been roughed out and approaches finish size, the first contact is made, the diamond swings down, the wheel runs out past the diamond at truing speed, and immediately re-enters the hole at finishing speed and with reduced feed. When the hole is to size, the second contact is made, and the wheel runs out to the rest position at high speed.

The electric indicator is used mainly on large work such as airplane cylinders. It is not adapted for holes having splines or keyways, or for smaller work, where it is important to keep the wheel and wheel spindle as large as possible.

Automatic interruption of the grinding cycle for truing, as just described, has proved indispensable for many jobs and economical for most jobs, because it keeps the wheel sharp, clean, and straight, making it cut rapidly and produce smooth work, practically overcoming the tendency to grind bell-mouthed holes. Automatic truing for every piece takes a very short time, and is highly desirable, even when tolerances are coarse and a smooth finish is not required, because of the increased production obtained. It might be thought that truing the wheel for every piece ground would increase the consumption of wheels. As a matter of fact, it often reduces wheel consumption because it permits the use of a comparatively hard wheel which breaks down slowly. Usually there is an increase in wheel consumption, which, however, is small compared with the advantages gained.

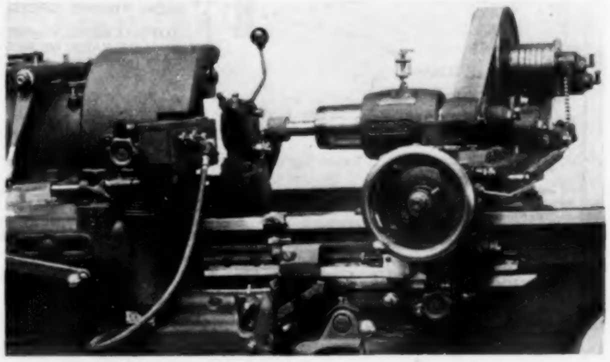

FIG. 9 AUTOMATIC SIZING, WITH TWO ELECTRIC CONTACTS ADDED TO THE DIAL INDICATOR

Automatic interruption and truing just prior to finishing the work forms the basis for another method of automatic sizing.

It has been seen that holes of a definite size cannot be produced by merely feeding the wheel a certain distance into the work, because the wheel wears down while roughing out the hole, and the amount of wheel wear depends upon several variables. However, after the work has been rough-ground to nearly the desired size, the wheel may be trued, bringing its working face into a definite location, and then fed into the work a short distance beyond this location. The desired size can be duplicated in this manner within very close limits. The wheel wear after truing is slight, because only a small amount of metal is removed, and remains practically constant from piece to piece, so that it does not interfere with duplication of size.

This method of sizing, generally known as the Size-Matic principle, is embodied in the machine shown in Fig. 11. The cycle of operations is the same as in Fig. 10, but the two contacts, instead of being in the indicator, are operated by a cam on the cross-feed handwheel. In order to have the handwheel come to the same position for each piece so that the contact will be made at the proper point, a device is incorporated which automatically advances the cross-slide at each cycle without moving the handwheel. In other words, it compensates for the wear of the wheel.

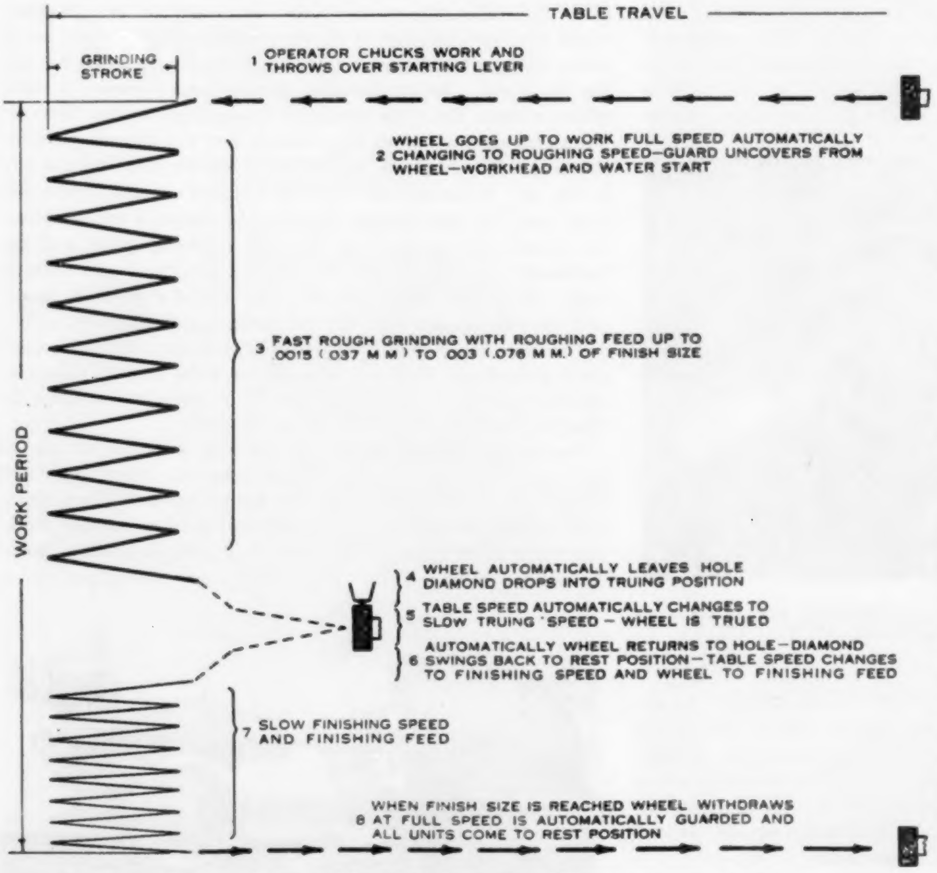

TABLE TRAVEL
GRINDING STROKE
1 OPERATOR CHUCKS WORK AND THROWS OVER STARTING LEVER
2 WHEEL GOES UP TO WORK FULL SPEED AUTOMATICALLY CHANGING TO ROUGHING SPEED—GUARD UNCOVERS FROM WHEEL—WORKHEAD AND WATER START
3 FAST ROUGH GRINDING WITH ROUGHING FEED UP TO .0015 (.037 M M) TO .003 (.076 M M.) OF FINISH SIZE
WORK PERIOD
4 WHEEL AUTOMATICALLY LEAVES HOLE DIAMOND DROPS INTO TRUING POSITION
5 TABLE SPEED AUTOMATICALLY CHANGES TO SLOW TRUING SPEED – WHEEL IS TRUED
6 AUTOMATICALLY WHEEL RETURNS TO HOLE—DIAMOND SWINGS BACK TO REST POSITION—TABLE SPEED CHANGES TO FINISHING SPEED AND WHEEL TO FINISHING FEED
7 SLOW FINISHING SPEED AND FINISHING FEED
8 WHEN FINISH SIZE IS REACHED WHEEL WITHDRAWS AT FULL SPEED IS AUTOMATICALLY GUARDED AND ALL UNITS COME TO REST POSITION

Fig. 10 Cycle of Grinding Operations With Automatic Sizing

In developing a machine to operate on the Size-Matic principle numerous refinements were necessary in the workhead, cross-slide, and diamond unit. The cross-slide must move a little as 0.0001 in. at a time and follow the motion of the feed screw accurately, and the diamond must be adjusted easily by very small amounts. The diamond is therefore mounted in two sets of preloaded ball bearings, one set being used when the diamond is swung into and out of position, while the other set is mounted eccentrically so that the diamond may be moved as little as 0.00005 in. by simply turning a graduated knob at the top of the unit, making a change of 0.0001 in. in the size of the holes being ground.

There are several reasons for the use of a swinging diamond instead of a fixed diamond. A diamond held in a fixed location necessitates a longer and more flexible wheel spindle in order to reach past the diamond, resulting in a loss in production. The swinging diamond overcomes this objection, is more accessible, and has the further advantage that the adjustments are more easily made, including the means for rotating the diamond to present a new truing surface.

Still another method of automatic sizing is to hold a plug gage against the back of the work by spring pressure, so that it will enter the hole as soon as the latter is to size and stop the machine. The essential parts may be seen in Fig. 12.

In practice it is usually desirable to use two gages *A*. These are mounted at the end of a rod *D*, which extends through the spindle of the workhead and holds the gages against the back of the work by spring pressure. The rod and the gage rotate with the work. As the wheel approaches the gages, the table pushes rod *F*, moving rod *D* and the gages out of the way of the wheel. When the work approaches finish size, the first gage, which is the smaller of the two, enters and allows adjusting screw *H* to make a contact which starts the truing cycle. The wheel then makes a few more passes at the proper speed and feed for finishing, and when the hole is to size, the second gage enters, allowing screw *G* to make a contact which causes the wheel to run out at high speed and which stops the machine. This is known as the Gage-Matic principle.

The method is not adapted for grinding blind or taper holes, but is ideal for ordinary straight open work. The work is not only produced automatically, but is inspected by the same machine and manual inspection is eliminated except for checking an occasional piece. A high rate of production can be maintained and scrap is practically eliminated regardless of variations in wheel wear, hardness of the work, amount of stock to be removed,

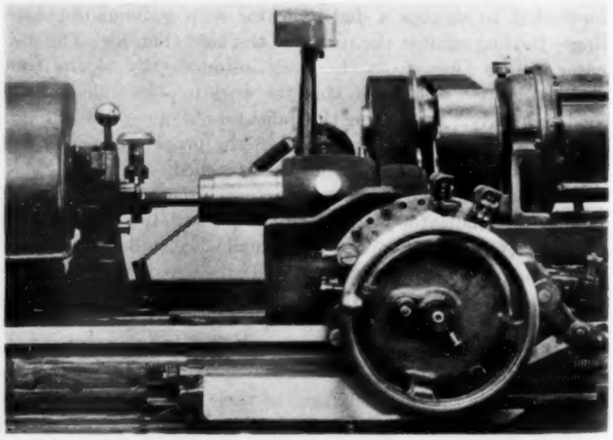

Fig. 11 Automatic Sizing, With Two Electric Contacts Operated by a Cam on the Cross-Feed Handwheel

and inattention or lack of skill on the part of the operator.

These machines, although automatic, can be used economically on small lots, as they require no more operations for setting up than plain machines. In the following comparison it is assumed that each machine is provided with a suitable chuck and wheelhead:

To set up plain internal	To set up Gage-Matic
(1) Set dogs for table stroke	(1) Set dogs for table stroke
(2) Set cross-slide feed	(2) Set cross-slide feed
(3) Grind hole to hand plug	(3) Mount and set gage
(4) Set cross-slide stop	(4) Set cross-slide cam
(5) Set diamond to true wheel	(5) Set diamond to true wheel

A number of interesting special features have been developed in connection with these machines; for instance, attachments for facing and internal grinding at the same setting, for chamfering, and for grinding pieces having two concentric holes of different diameters; a "backing-off" attachment for separating the wheel and work automatically before withdrawing the wheel, to obtain an improved finish; a short-stroke device for work requiring a short, rapid oscillation of the wheel, and "sparking out" devices which allow the wheel to make any desired number of passes after the feed has been stopped, giving extreme accuracy and especially smooth finish in connection with any of the automatic sizing methods which have been described.

Workhead bearings have now been improved to such an extent that when a "sparking out" device is used holes can be ground on a production basis with an average out-of-roundness of only 0.00005 in. (commonly known as "half a tenth"). It is now much easier to grind a hole to this degree of accuracy than to measure the error.

Recent developments in wheelheads have greatly increased the life of their ball bearings, in spite of the extremely high speeds at which they are run to secure the greatest efficiency in grinding. The usual speeds are:

Diameter of spindle, in.	Speed of wheelhead, r.p.m.
$1\,/_4$ to 1	10,300
$^3/_4$	15,000
$^9/_{16}$	19,500
$^7/_{16}$ and less	25,000

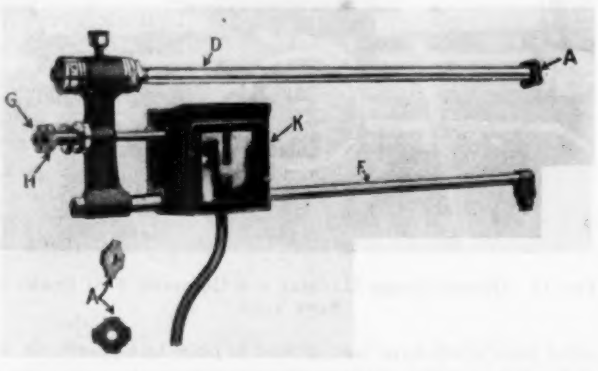

FIG. 12 AUTOMATIC SIZING, WITH PLUG GAGE OPERATED BY SPRING PRESSURE

It is not always appreciated that quick-acting means for holding the work are of more value in internal grinding than in many other operations because of the shortness of the machine cycle. A typical example illustrates this, as follows:

	Slow chuck	Quick-operating chuck
Grinding time, sec.	30	30
Chucking time	15	3
Total time (average), sec.	45	33
Production per year of 2000 hours, pieces	160,000	218,000
Increase in production, per cent	..	36
Cost of machine and chuck	\$5300.00	\$5500.00
Interest and depreciation at 16 per cent	\$ 848.00	\$ 880.00
Labor and other elements of burden at \$3000 a year	3000.00	3000.00
Total cost per year	\$3848.00	\$3880.00
Total cost per piece	0.0245	0.0177
Saving per piece		0.0068
Savings per year (218,000 pieces)		\$1482.40

Thus an investment of \$200 (the difference in cost between a slow- and a quick-acting chuck) brings a yearly return of 741 per cent. This is only an average return and is based upon conservative figures.

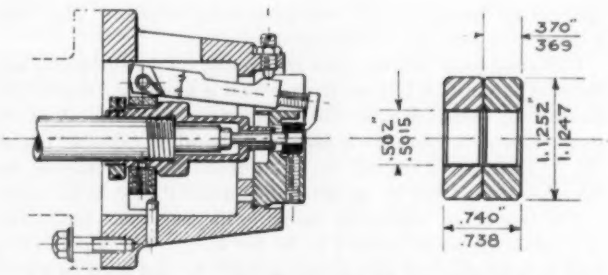

FIG. 13 CHUCK WHICH HOLDS THE WORK LATERALLY

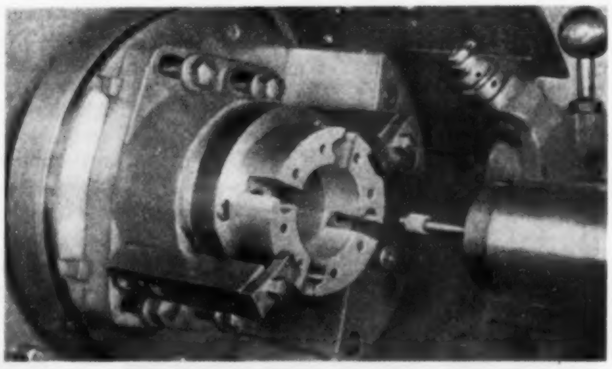

FIG. 14 GRINDING HOLES IN DIE HEAD

The following examples of typical work, chucks, and production times show what may be expected from modern internal grinders:

Parts such as valve-lifter rolls can be ground two at a time in a simple chuck which holds the work laterally (Fig. 13). Surrounding the gage is an ejector tube which pushes the finished work into a chute as the chuck opens. While the machine is grinding, the operator, having no other duties, slips two rough pieces on a hand plug, which makes it possible to load them into the chuck without loss of time. These hardened-steel rollers have 0.006 to 0.008 in. of stock to be removed, and a production of 200 an hour is maintained, although the total tolerance is 0.0005 in. on the diameter, 0.0005 in. for roundness, and 0.0001 in. for taper.

An example of a tool job where accuracy and finish are the important factors is shown in Fig. 14. The job, a die head, consists of grinding four holes which break out into slots for a part of their length. The diameters of the holes are held to a tolerance of 0.0002 in. They must be parallel to each other, and the chordal distances must have practically no error. This work is done on a plain or non-automatic machine.

Universal joint bearing pins are ground on an automatic machine at the rate of 170 per hour, which is more than double the production obtained with non-automatic equipment. A short-stroke reverse mechanism is used, and the wheel takes a "plunge cut." From 0.010 to 0.017 in. of hardened steel is removed, the tolerance being 0.001 in. on the diameter and 0.0005 in. for taper.

The use of an automatic machine increased the production of drill-chuck bodies from 6 to 60 per hour. The taper hole is held to a tolerance of plus or minus 0.001 in. and must be a good fit on a taper plug. These bodies come in several sizes, which are accommodated by simply changing adapter rings.

Cold heading dies were formerly lapped in 1 to 2 hours apiece, but are now ground in 10 to 35 min., depending upon the size. Grinding permits the use of much harder dies and gives a straighter and rounder hole with a finer finish and no bell mouth, which results in greatly increased life of the dies and improves the quality of the bolts. Chuck jaws are changed to accommodate different sizes. The holes are small in proportion to their length, and the dies are therefore ground half-way through, using as short a spindle as possible, and then turned end for end and the other half of the hole ground. The holes are held to a tolerance of 0.001 in., and the fact that it is possible to get them straight in this way shows the degree of accuracy obtained with this type of chuck.

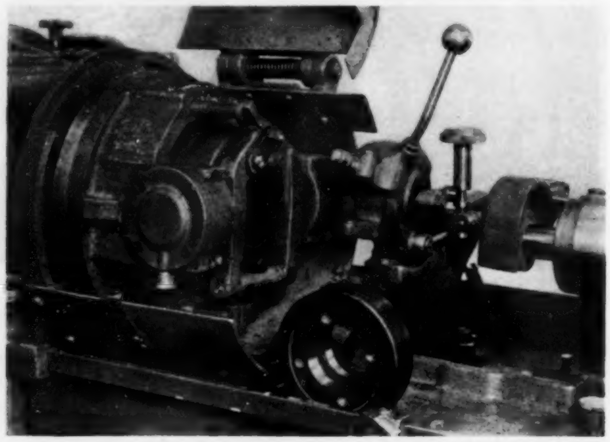

Fig. 15 Indexing Fixture for Grinding Both Ends of Steam-Shovel-Scoop Roll

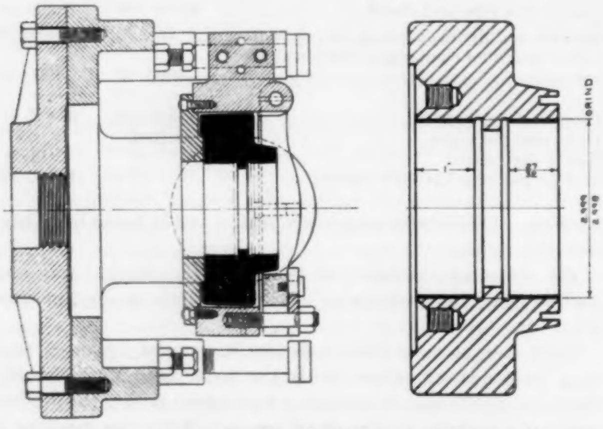

Fig. 16 Diagram of Set-Up and Work as Shown in Fig. 15

On hydraulic brake cylinders, an unusually good finish is required to prevent wear of the rubber piston. Such a finish is obtained with a production of 40 pieces per hour, although the work is long and 0.012 to 0.015 in. of stock is removed from the diameter by an unusually slim spindle, $^7/_8$ in. in diameter and 5 in. long. The tolerance for taper is 0.0005 in. The work is of cast iron and is ground dry, the dust being exhausted through the rear of the chuck. The work is loaded through the side of the chuck, conically centered and held by end pressure.

Figs. 15 and 16 show a steam-shovel-scoop roll. This job illustrates the growing use of hardened steel parts ground to close limits, even in rough machinery. The ground surfaces form seats for roller bearings and are held to a total tolerance of 0.001 in. The rolls must be ground from both sides without rechucking, to insure perfect alignment of the holes. This is accomplished with a trunnion fixture at the rate of 30 complete rolls per hour.

A large variety of sizes of shackle-bolt bushings can be handled by simply adjusting the jaws. From 0.008 to 0.012 in. on the diameter is removed from these hardened-steel parts. Holes 1 in. in diameter by $1^3/_4$ in. long are ground at an average of 165 an hour. Holes $1^1/_4$ in. in diameter by 2 in. long are finished almost as rapidly, with a tolerance of 0.001 in. on the diameter and 0.0003 in. for taper.

Spur and helical gears may be quickly and accurately chucked by means of pins held in a spring cage. The cage allows the pins to be slipped over the gear and to center themselves between the teeth. The gear, with pins and cage, is slipped between plain collet jaws which have been ground in place to a true circle, locating the gear accurately by the pitch line. In some cases a larger number of pins are used, or the pins are enlarged in the center, to minimize the effect of distortion of the teeth.

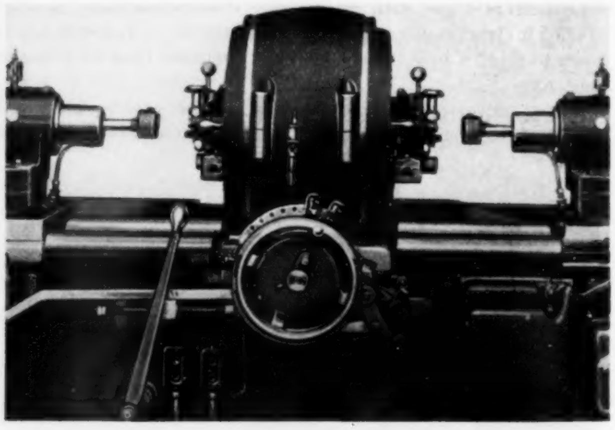

Fig. 17 Double-Ended Machine for Grinding Two Holes at Same Time

Double gears are held by means of two sets of jaws and two sets of pins. One set of pins is loosely held against the rear jaws while the other set of pins is held in a cage. The pressure on the two sets of jaws is equalized by a coil spring in the chuck. The production is 45 to 55 an hour, with a tolerance of 0.001 in.

The method of chucking cluster gears is similar to that for double gears, but a double-ended or duplex machine, Fig. 17, is used to grind the two holes at the same time and in perfect alignment. This machine operates on the Size-Matic principle and grinds gears of the size shown at the rate of 26 per hour. On some similar work the operator runs both a duplex internal and a rotary surface grinder, facing both ends of the gears while the duplex is grinding the holes. The practice of having an operator run two machines is becoming more common and is carried out quite extensively in some shops. In some cases where the operator runs only one machine he performs a secondary operation, such as burring or filing, while the machine is working.

Work of the nature of airplane cylinders, including all long tubes, is best held in a hollow workhead similar to that used on the duplex machine. Otherwise the work overhangs a long distance beyond the spindle, and the necessary rigidity cannot be obtained. The ball bearings used in these workheads are interesting because of their unusual size, the outside diameter being as large as $21^1/_2$ in. in some cases. Airplane cylinders are loaded from the rear of the workhead. Average production is four per hour, and in some cases is very much higher, although a high finish is required, the tolerances for out-of-roundness and taper are very close, and a large amount of metal is removed.

Still larger work, such as railway gears, roller-bearing races and cylinders, is handled in a heavy-duty machine which weighs 18,000 lb. and is driven by motors totaling 31 hp. These large machines are also made with hollow workheads for certain work.

Bevel gears are located from the pitch line by holding against an internal spur gear. On a bevel gear requiring a hole 0.755 in. in diameter and $^{13}/_{16}$ in. through the gear, the remarkable production of 254 pieces an hour is maintained, one piece every 14 sec.

Two automatic machines turn out the work to a tolerance of 0.001 in. as fast as an operator can load them, working between them.

The grinding of drive-shaft flanges and hubs is a good example of a chuck with adapters to accommodate a variety of work. Automatic equipment increased the production from 15 to 50 pieces per hour.

Grinding motor stators results in a uniform air gap, which is highly desirable, and makes it possible to allow comparatively wide tolerances in punching the laminations. The grinding is done dry, and the dust is exhausted through the back of the chuck. The production is 50 or 60 per hour.

For hardened-steel chain blocks, such as are used in coal-mining machinery, the work is centered by a taper plug which enters the rough bore and then recedes, leaving a uniform amount of stock to be removed from all sides of the hole. The work is reversed for grinding the second hole. Fully 50 complete blocks are ground per hour.

Universal-joint yokes are held between hollow cones having teeth which interlock with the splines. This method of holding practically eliminates the scrap which was formerly produced when the parts were held by the outside diameter, which is not always true with the splines. One operator running two machines produces 40 pieces per hour.

Cast-iron drive-shaft housings are typical of a large number of parts which are internally ground to form a good seat for ball and roller bearings. A short, rugged wheel spindle is used on this job, for grinding the hole and facing the shoulder. Facing is accomplished by allowing the table to come up to a cam stop, against which it is held by the hydraulic cylinder while the cam is turned by hand, feeding the wheel against the shoulder. One operator runs two machines, performing two operations on each, and produces 30 parts per hour. The holes are more than 3 in. in diameter by $1^1/_2$ in. deep.

The term "automatic" in connection with internal grinders has been so loosely used as to be confusing. Screw machines are commonly provided with devices for feeding work into the chuck and are then known as automatic machines. Milling machines and internal grinders, on the other hand, are not built with standard loading devices, and are called automatic when the operator has merely to load them and start the cycle of operations, the machine performing all other functions and finishing the work to the required size.

Internal grinders with hopper feeds have been developed and are in successful operation, but these are special machines.

It is obviously incorrect to call an internal grinder automatic unless it sizes the work automatically.

Performance of Cutting Fluids

Progress Report No. 3 of the Subcommittee on Cutting Fluids of the A.S.M.E. Special Research Committee on Cutting of Metals

By O. W. BOSTON,[1] ANN ARBOR, and C. J. OXFORD,[2] DETROIT, MICH.

This paper presents the results of a series of experiments to determine the influence of eleven different cutting fluids on the power required to plane and drill an annealed S.A.E. 3150 steel.

This investigation was conducted as a project of the Subcommittee on Cutting Fluids of the A.S.M.E. Special Research Committee on the Cutting of Metals, by the Department of Engineering Research of the University of Michigan, with funds provided by Engineering Foundation. The object was to secure definite performance data for certain limited conditions as a preliminary step to a comprehensive study of cutting fluids.

The force required to cut metal by planing for a single tool shape was determined for a variety of feeds and depths of cut. A formula for the planing force is developed as a function of the cutting fluid, the depth of cut, and the feed as $P = CD^{0.95}f^{0.79}$.

The torque, thrust, and power required to drill the S.A.E. 3150 steel are determined for a variety of drill diameters and feeds for each of the eleven cutting fluids. Formulas for each of these factors are developed as a function of the cutting fluid, the feed, and the drill diameter. Torque $T = Cf^{0.78}d^{1.8}$ thrust $B = Kf^{0.87}\left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$. The results show clearly the relative advantages from a power standpoint of the various oils studied, and the constants C and K provide for the influence of the cutting fluid used. All data are presented graphically.

An attempt is made to correlate various physical and chemical properties of the cutting fluids with the results of their cutting performance. It appears that cooling is the primary requisite of a cutting fluid rather than lubrication.

THIS paper is a report covering an investigation of cutting fluids. An attempt was made to determine the characteristics of each oil as determined by its influence on the cutting action of a tool. These characteristics are then correlated with the various properties of the oils.

Because of the limited funds provided for this investigation, only one material was cut. Eleven different cutting fluids, including dry cutting, were selected as representing the many types in commercial use. The cutting tests were confined to the determination of force or power values when drilling and planing.

O. W. Boston

C. J. Oxford

THE MATERIAL CUT

An S.A.E. 3150 steel was selected as the one most favorable for these tests. This high-carbon chrome-nickel steel was annealed to provide uniformity between various bars and between different locations in the same bar. About two tons of this material, 2 in. × 6 in. in section, were purchased, with 40 pieces each 14 in. long for drilling and 30 pieces each 24 in. long for planing. The material had a chemical analysis as follows:

Carbon	0.50	Phosphorus	0.022
Manganese	0.68	Chromium	0.62
Sulphur	0.023	Nickel	1.16

It was furnished in the annealed condition giving approximate physical properties as follows:

Elastic limit	66,140 lb. per sq. in.
Ultimate strength	114,200 lb. per sq. in.
Per cent elongation in 2 in.	26
Per cent reduction in area	53

The Brinell hardness was 170 on a smooth surface 1/2 in. beneath the skin.

THE CUTTING FLUIDS

The cutting fluids selected for these tests consisted of the following (they are listed with their properties in Table 1):

1 Dry cutting.

2 An aqueous solution consisting of distilled water to which was added 1 1/2 per cent borax by weight. Actual analysis of

[1] Professor, College of Engineering, University of Michigan; Mem. A.S.M.E. Professor Boston was graduated from the University of Michigan Engineering College in 1913, received a master's degree in 1917, and the degree of mechanical engineer in 1926. After graduation he was engaged at the university as instructor in engineering mechanics and mechanical engineering for four years. In October, 1917, he was commissioned in the U. S. Navy and assigned to duty in the Bureau of Ordnance on design and manufacture of submarine mines used in the North Sea blockade. From 1919 to 1921 he was engaged in industrial engineering work for the Cleveland Tractor Co., in Cleveland, as assistant to the vice-president and works manager. In the fall of 1921, he returned to the University of Michigan, where he is now professor of shop practice and director of the department of engineering shop. He is author of many papers dealing with the subject of metal cutting and is serving as A.S.M.E. representative on the Tool Steel Committee of the American Society for Testing Materials.

[2] Chairman, Subcommittee on Cutting Fluids; Chief Engineer, National Twist Drill & Tool Co., Detroit, Mich.; Assoc-Mem. A.S.M.E. Mr. Oxford was born in Norway and came to the United States in 1909. After two years in the engineering department at the University of Michigan, he served as tool draftsman with the Packard Motor Car Co., Dodge Brothers, and Nordyke & Marmon until 1916, when he became designing engineer for the Wilt Twist Drill Company. The following year he became associated with the National Twist Drill & Tool Co.

Contributed by the Machine Shop Practice Division and presented at the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers.

a sample used in the drilling tests showed 1.19 per cent borax by weight.

3 A soluble oil consisting of one part oil to fifty parts distilled water. Actual analysis of a sample used in the drilling tests showed 2.3 per cent of soluble oil and a viscosity of 31 Saybolt seconds at 100 deg. fahr.

4 A soluble oil consisting of one part oil to ten parts water. Actual analysis of a sample used in the drilling tests showed 8.37 per cent of soluble oil and a viscosity of 32 Saybolt seconds at 100 deg. fahr.

5 A No. 1 lard oil commonly used for machine-shop work. This oil was pressed from inedible hog fat. An analysis of a sample from the drum of oil after being used intermittently for three weeks in the planer tests showed 12.23 per cent oleic acid and 24.3 milligrams of potassium hydroxide per gram of oil. A later analysis of a sample used for a longer period in the drilling tests showed 13.6 per cent free fatty acid and 86.4 per cent fat. The lard oil viscosity was 200 Saybolt seconds at 100 deg. fahr.

6 A light mineral oil having a final viscosity of 110 Saybolt seconds at 100 deg. fahr. This oil is a distillate from a naphthenic Texas crude oil and is refined sufficiently to render it reasonably stable. Subsequent analysis of a sample used in the drilling tests showed the oil to have some properties of both paraffin and asphaltic and so is listed as mixed in Table 1.

7 A mineral oil having a final viscosity of 210 Saybolt seconds at 100 deg. fahr. This mineral oil is the same type as No. 6.

8 A mineral-lard oil consisting of 90 per cent mineral oil and 10 per cent No. 1 lard oil, having a final viscosity of 100 Saybolt seconds at 100 deg. fahr. The mineral oil is a fully refined neutral or paraffin oil.

9 A 95 per cent mineral oil plus 5 per cent double-distilled oleic acid, having a final viscosity of 100 Saybolt seconds at 100 deg. fahr. The mineral oil is the same as that used in No. 8. Analysis of a sample used for several weeks in the drilling tests showed 4.90 per cent oleic acid.

10 A sulphurized straight mineral oil having a final viscosity of 100 Saybolt seconds at 100 deg. fahr. This was reported by the manufacturer to contain 4 per cent sulphur. Subsequent analysis of a sample used for several weeks in the drilling tests showed 4.38 per cent sulphur as given in Table 1. An asphaltic-base oil was used.

11 One part of sulphurized lard oil blended with five parts of mineral oil, having a final viscosity of 100 Saybolt seconds at 100 deg. fahr. The manufacturer reported that the oil contained 1.6 per cent sulphur. The subsequent analysis showed the sulphur content to be 2.34 per cent. This blend contains a considerably higher percentage of sulphurized lard oil than is customarily used as a cutting oil. It was felt desirable for these tests, however. Sulphurization greatly increases the viscosity of the lard oil. Rather than use a mineral oil of too low a flash to get the required final viscosity, a lower sulphur content of the lard oil was used.

Table 1 summarizes the properties of these oils. A drum of each oil was furnished by the manufacturer and reported to have the viscosities given above. Table 1 shows the viscosities as determined from later tests. They differ very little from the former. A drum of each of the cutting fluids 2, 3, and 4 were prepared, using distilled water.

Five gallons of each cutting fluid were taken from the drum for use in the drilling tests. The remainder was used in the planer tests. Every precaution was taken to avoid the mixing of one oil with another at the time of changing oils.

In Table 1 two values are given for power, flash, and color for some of the oils. The first values were given by the manufacturer when the oils were submitted, and the second values are the results of subsequent tests.

The specific heats C at temperatures of 100, 210, and 430 deg. fahr. were computed for oils 5 to 11, inclusive, using the generally accepted formula $C = (t + 670)\ (2.10 - d)/2030$, in which t is the temperature of the oil in deg. fahr. and d is its specific gravity at 60 deg. fahr. (Table 1). This formula has been proved to be reliable within the temperature range 50–430 deg. fahr., so long as the product is a liquid. The error is less than 2.5 per cent for a specific-gravity range of 0.75 to 1.0. The specific-heat values are tabulated in Table 1.

Again for the determination of thermal conductivity for the various oils 5 to 11, inclusive, the formula developed by the Bureau of Standards (Bureau of Standards Miscellaneous Publication No. 9) was used as follows: $k = (0.813/d)\ [1 - 0.0003\ (t - 32)]$, in which k is the thermal conductivity of the oil in B.t.u. per hour per square foot per inch per deg. fahr., d the specific gravity of the oil at 60 deg. fahr. (Table 1), and t the temperature of the oil in deg. fahr. The values of thermal conductivity for the various oils at 100, 210, and 430 deg. fahr. are given in Table 1.

A general discussion of the characteristics of the oils is given near the end of the paper. Temperature-viscosity curves are shown in Fig. 46. The scale used is such as to give straight lines for each of the temperature-viscosity curves. The circles indicate actual experimental determinations. Other characteristics of the cutting fluids tabulated in Table 1 are plotted in Figs. 48, 49, and 50.

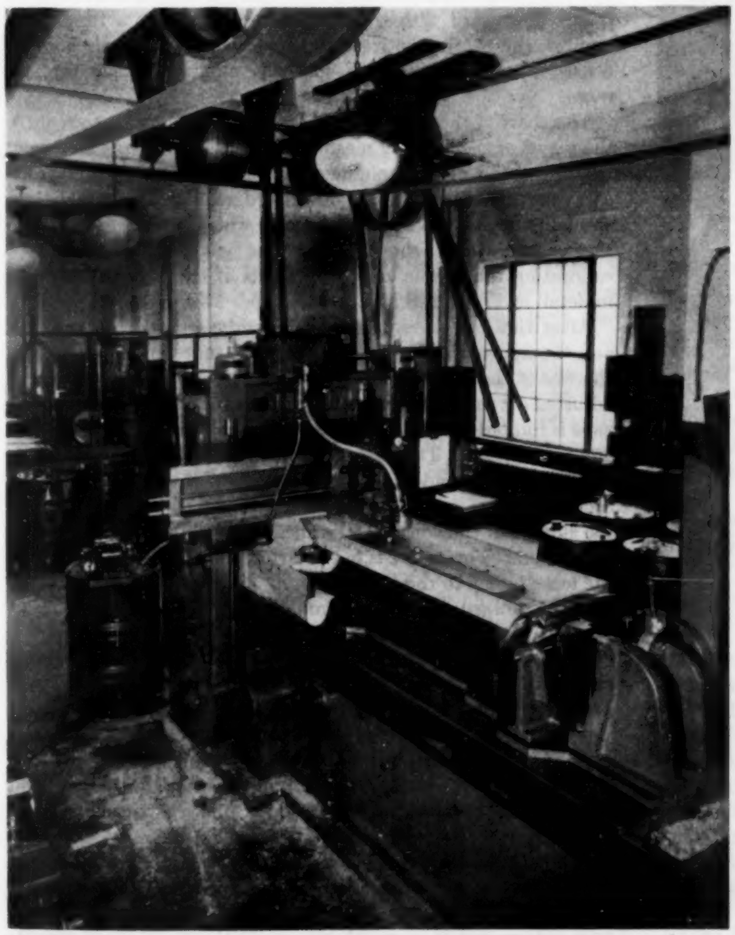

Fig. 1 Planer and Accessories Used in Tests

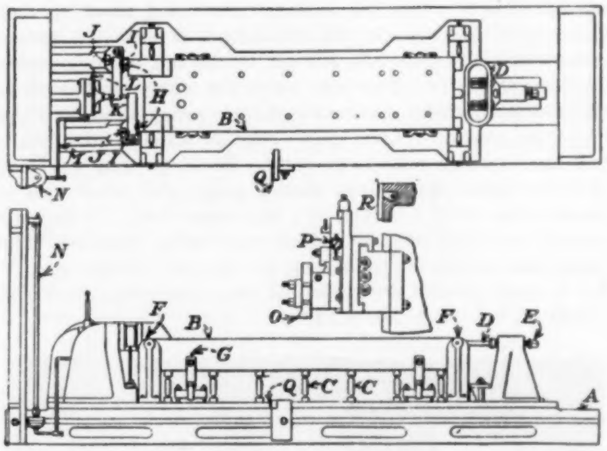

Fig. 2 Line Diagram of Planer Dynamometer

THE PLANER—ACCESSORIES AND TOOLS

Fig. 1 shows the planer and accessories used in determining the power to cut the S.A.E. 3150 steel under like cutting conditions for each of the eleven cutting fluids. On the bed of this 30-in. × 36-in. × 8-ft. planer was mounted a dynamometer, the line diagram of which is shown in Fig. 2. On the bed of the dynamometer table is mounted a large galvanized-iron pan in the bottom of which the test piece being cut is securely fastened. The various cutting fluids in drums are shown about the planer. The drum containing the coolant to be used is brought to the planer and placed as shown at the left. A portable motor-pump unit is placed on the drum so that, during the test, the oil is pumped to a reservoir shown on the top of the planer housing. This reservoir has three drain pipes, one, an overflow pipe leaving the reservoir on the rear side near the top, draining back to the drum. At all times liquid flows through this overflow pipe, insuring relatively constant head. The coolant flows from the reservoir through the flexible tube and is discharged at low velocity but in large quantities directly on the tool face. The coolant flows from the tank through a drain pipe at the left into a trough and thence to the drum. Various fine-mesh screens are placed in the returning pipes to make sure that no chips or foreign solid matter are returned to the drum. The third drain pipe from the reservoir emerges from the bottom of the reservoir and is used only for draining when the set-up is changed from one coolant to another. During this process all tanks and pipes are thoroughly cleansed with water and then wiped dry. Considering the large quantity of the cutting fluid being circulated, any smaller quantity of one oil remaining in the system, it is believed, is not detrimental to the next oil used.

Power was supplied to the planer from a 15-hp. motor driving through a reversing variable-speed transmission to the standard countershaft above the planer. The cutting speed was maintained at 20 ft. per min. in all tests, except where speeds were purposely varied for specific purposes.

Referring to Fig. 2 the dynamometer consists essentially of a cast-iron bed B, weighing about 1300 lb., mounted on seven 14-in.-long horizontal floating pins shown in the plan view supported by the brackets *F*. The bed is kept from being lifted by four knife edges shown at *G*. An initial load of 2000 lb., tending to force the bed to the left, was put on the bed by compressing the loop spring *D*. This load keeps the whole mechanism in compression, thereby eliminating chatter during a cut, and also keeps the mercury-column gage under an initial load which is indicated as a zero point on the scale. The loop spring was made of $^3/_4$-in. square spring steel having major and minor axes to center of bar of $11^1/_2$ in. and $4^3/_4$ in., respectively. It had previously been calibrated on a Universal testing machine. This spring also served for calibrating the mercury-column gage *N*. For a more detailed description of this equipment, see Trans. A.S.M.E., Vol. 48 (1926), p. 749.

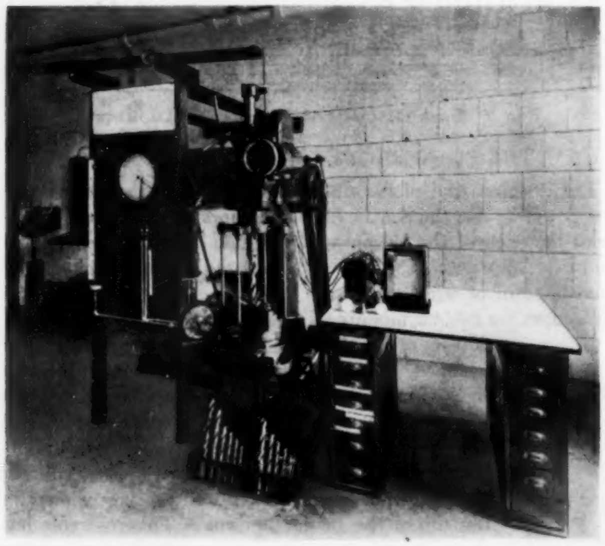

FIG. 3 DRILL PRESS AND EQUIPMENT USED IN TESTS

The Planer Cutting Tools. Tools were ground on each end of twenty $^3/_8$ in. × $^3/_4$ in. × 5 in. long high-speed-steel tool bits. The tool had a shape as follows: an 8-deg. front-rake angle; a 14-deg. side-rake angle; a 6-deg. front and side-clearance angle; a 6-deg. end-horizontal-clearance angle; and a 90-deg. plan-cutting angle with the work. The nose was ground to a $^1/_{32}$-in. radius. After being ground, all tools were honed smooth on all ground surfaces so that they would retain their geometric shape and condition throughout a series of tests. The tools were changed frequently, so that all test values are based on sharp tools. Inasmuch as only the power to cut the metal was determined as a function of the cutting fluid, no data were accumulated regarding tool-life values.

THE DRILL PRESS SET-UP AND DRILLS

The testing equipment for determining the influence of the cutting fluids in drilling is shown in Fig. 3. This equipment was devised so that torque and thrust as developed at the drill point could be determined, as well as the input power developed by the motor. The testing equipment, consisting of a drill press, a drill dynamometer with gages, and the recording wattmeter, is shown in Fig. 3. The drill press was a No. 2 manufacturing-type Colburn press, which was driven by a 5-hp., 220-volt, 3-phase, 60-cycle motor attached to the rear of the column. The motor drove the tight and loose pulley through a short belt. A gear pump was provided for raising the coolant from the tank at the side of the column to the drill. As in the case of planing, the cutting fluid was supplied to the drill in as large a quantity as possible. It was dumped at a low velocity upon the drill just above the work.

The drill dynamometer was of such a design that the torque and thrust could be measured independently. The pressure developed by the drill was exerted directly on a plate resting on a rubber diaphragm, just above the dynamometer base. Water underneath this rubber diaphragm was subjected to compression, due to the thrust of the drill, and the hydrostatic pressure was transmitted to one pen of the gage through the $^1/_8$-in. pipe. The plate resting on the rubber diaphragm which carried the thrust load was made to form the lower race of a large ball bearing consisting of sixty-four $^1/_2$-in. balls, so that the table of the dynamometer was free to rotate except for the arm extending to the left, which had a bearing against a piston resting on a second and smaller rubber diaphragm. This arm was 1 ft. long, measured from the center of the dynamometer, which latter corresponded with the center line of the drill spindle. The pressure on this small rubber diaphragm or torque diaphragm subjected the water back of the rubber to compression. This pressure was transmitted through a $^1/_8$-in. pipe, leading both to the mercury-column base and the second pen of the gage. The mercury column had a scale which had units larger (more sensitive) than those of the gage, but which did not have the range permitted by the gage. To prevent tilting of the dynamometer table on the thrust rubber diaphragm, a spider fitted around the spindle housing was attached to the table of the dynamometer by four vertical rods. To eliminate friction and to permit the spider to rotate freely with the table as the torque was applied or to be forced downward with the dynamometer table as a thrust was applied, the bearing between the spider and the spindle housing consisted of twenty-four $^1/_2$-in. balls mounted in appropriate races.

The chart of the recording gage was made to rotate, to register the travel of the drill, by means of a fine wire which passed from the upper end of the spindle over pulleys to a position vertically above the gage, thence downward, making one turn about a special pulley on the shaft of the gage which carried the chart to the counterweight shown below the gage. The method of calibrating the torque and thrust pens of the gage is described in detail in Trans. A.S.M.E., 1930, paper MSP-52-2.

After the drill press has been properly set up with the drill and the appropriate speed and feed, the material is adjusted in the vise of the dynamometer. The mercury-column gage is next adjusted for zero reading. At this point the chart of the pressure gage is rotated so as to draw the base or zero lines for the torque and thrust pens. This insures having the same torque zero reading in all tests, and the exact torque and thrust base lines for each individual test. The drill is brought to within $^3/_8$ in. of the surface of the work to be drilled, after which the feed clutch is engaged. The motor is next started and the belt shifted from the loose pulley to the tight pulley. The drill is thereby rotated and fed toward the work through the $^3/_8$-in. travel, without cutting. During this time the wattmeter is recording the power developed by the motor in driving the machine with all speed and feed gears engaged, but not cutting. This permits the wattmeter to record the tare power, and later, when the drill is cutting, to record the gross power. The tare deducted from the gross gives the net input power, which corresponds to the power output at the drill point except for the additional frictional load on the gears and bearings of the machine due to the cutting load.

Celluloid scales prepared from the calibration are used to measure the torque and thrust values from the chart. During the drilling, the actual rotating speed of the spindle is measured with a cutmeter in order that proper allowance may be made for belt slippage, reduced speed of the motor, etc.

The Drills Used

The drills used in these experiments were selected as being representative of the drills corresponding with standard specifications for taper-shank, high-speed-steel twist drills. They were selected in sizes $^1/_2$, $^3/_4$, 1, and 1 $^1/_4$ in. in diameter and correspond to the R drills described in the previously mentioned paper (MSP-52-2). The drills were ground in an SPK Blau drill grinder in such a manner that each could be ground and reground without changing the various drill-point angles. All drills had a point included angle of 121 deg., a helix angle of 30 deg., and a clearance angle near the periphery of about 5 deg. and adjacent to the chisel edge of about 13 deg. Other dimensions of the drills used are as shown in Table 2. This table also shows the feed in inches per revolution for each drill diameter in the commercial tests, as well as the actual cutting speed in r.p.m. and feet per minute.

TABLE 2 DRILLS USED IN TESTS, WITH MEASUREMENTS

Drill		Web thickness at point, in.	Helix angle, deg.	Point angle, deg.	Chisel-edge angle, deg.	Clearance at periphery, deg.	Commercial		
Diam., in.	No.						R.p.m.[1]	Ft. per min.	Feed, in. per rev.
$^1/_2$	R	0.0825	29	121	129	5–20	449	58.8	0.009
$^3/_4$	R	0.1055	31	121	134	5	300	59.0	0.012
1	R	0.147	31	121	136	5	231	60.5	0.013
1$^1/_4$	R	0.182	30	121	138	5	174	57.1	0.015
1	O.H.	0.1377	32	121		5	230	60.0	0.013
1	44	0.142	33	121		5	231	60.5	0.013

[1] This r.p.m. to give as nearly as possible 60 ft. per min.

Two additional 1-in.-diameter drills were used for special tests in which the speed, feed, and quantity of oil were varied separately. One of these 1-in.-diameter drills, indicated as O.H. in Table 2, was an oil-hole drill provided for the purpose of studying the influence of the quantity of oil supplied to the drill point as discussed below. The second 1-in.-diameter drill No. 44 was used in special tests as described below. The measurements of both drills are given in Table 2.

THE RESULTS OF THE DRILLING TESTS

Before running the commercial drilling tests to determine the torque, thrust, and power required to drill under different conditions with each of the oils, some preliminary tests were thought desirable.

Influence of Dulling During Use

The condition of the cutting edge and of the point of a drill naturally changes while cutting. In order to determine definitely just what this change was and its influence on the test results, some so-called dulling tests were run. Fig. 4 shows the results for determining the dulling effect on the torque for each of the R drills used when operated at their commercial feeds and speeds. The speed was as near as possible to 60 ft. per min. When cutting dry this speed was excessive. The chips were blued, and there was evidence of the generation of excessive heat.

Fig. 4 shows that the torque for the $^1/_2$-in.-diameter R drill operating at 0.009 in. feed and at 449 r.p.m. in the S.A.E. 3150 steel averages 14 ft-lb. for the first hole of 1$^1/_2$ in. depth; 14$^1/_2$ ft-lb. for the second 1$^1/_2$ in. of depth; and 15 ft-lb. at the end of the next 3 in. of depth, or at a total depth drilled of 6 in. Further drilling showed only a slight increase to a maximum value of 15$^1/_2$ ft-lb. for a total depth drilled of 36 in. It is seen that the maximum rate of increase of torque due to dulling is during the first 6 to 9 in. of metal drilled.

A similar dulling curve for the $^3/_4$-in.-diameter R drill operating at 0.012 in. feed and at 300 r.p.m. is shown. This shows that the torque for the newly sharpened drill is only 33 ft-lb. At the end of the fourth hole, the torque is 47 ft-lb., after which it remains practically constant. Similar curves are shown for the 1-in.-diameter drill operating at 0.013 in. feed and at 231 r.p.m., and the 1$^1/_4$-in.-diameter drill operating at 0.015 in. feed and 175 r.p.m. It is seen that the smaller diameter drills become dull more gradually than the larger diameter drills. At a total depth of 6 in. drilled, the keen cutting edge of the newly sharpened drill is apparently removed and fairly uniform conditions maintain beyond this depth. The per cent increase in torque from that of the first 1$^1/_2$-in. depth to that at the end of the 6-in. depth is approximately 8, 11, 6 $^1/_2$, and 8 for the $^1/_2$-, $^3/_4$-, 1-, and 1$^1/_4$-in.-diameter drills, respectively. Undoubtedly the smaller rate of feed accounts for the slower dulling of the smaller drills.

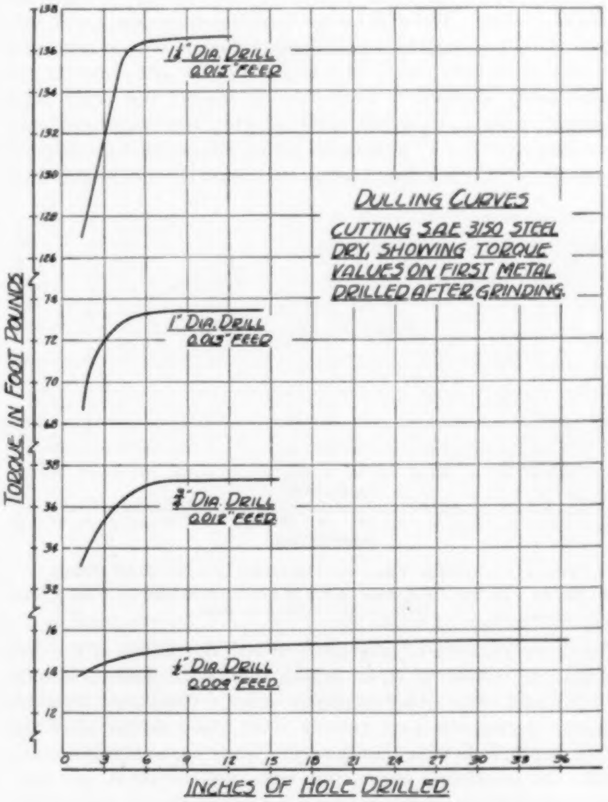

Fig. 4 Dulling Curves

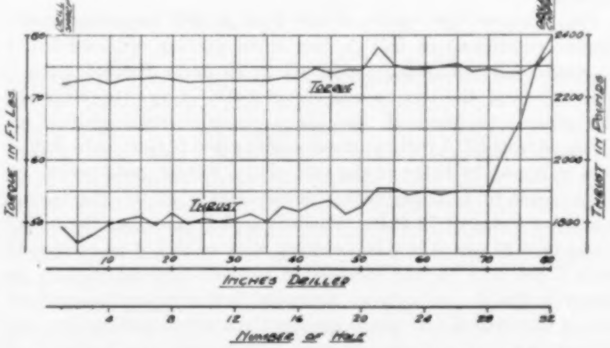

Fig. 5 Dry Dulling Tests in Drilling S.A.E. 3150 Steel
(1-in. drill, No. 44; feed, 0.013 in.; 231 r.p.m. Each hole 2$^1/_2$ in. deep.)

A similar test was run with the 1-in.-diameter drill No. 44

with a feed of 0.013 in. per revolution and a speed of 231 r.p.m. in drilling dry the annealed S.A.E. 3150 steel. Each hole was drilled to a depth of $2^1/_2$ in. The values of the drill torque and thrust are shown in Fig. 5. The value of the torque for the first hole $2^1/_2$ in. deep is 72.4 ft-lb., which agrees fairly well with the value of 72 ft-lb. for the 1-in.-diameter drill of Fig. 4 at a depth of 3 in. The drill torque increases very slowly with additional drilling, until at a total depth drilled of 55 in. it measures a value of 75 ft-lb., or a total increase of 3.3 per cent. It remains fairly constant or even falls off beyond this point until the drill chipped at a depth of 80 in., when the torque suddenly increased to 80 ft-lb. This again would indicate that the original keen edge, due to grinding, is removed during the first hole drilled.

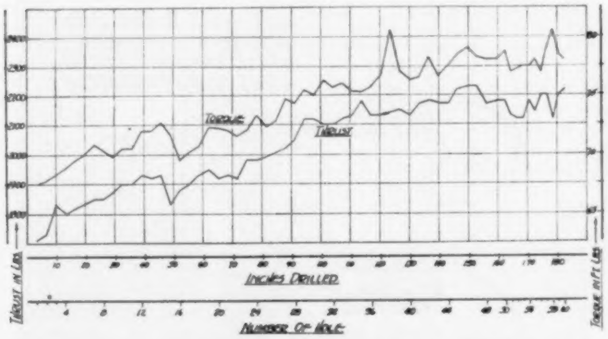

FIG. 6 DULLING TEST IN DRILLING S.A.E. 3150 STEEL
(Oil No. 4; 1-in. drill "R;" feed, 0.013 in.; 231 r.p.m. Holes 1–50, $3^1/_4$ in. deep; holes 51–60, 2 in. deep.)

The thrust values gradually increase with the dulling of the drill so that, at the end of 70 in. drilled, there is an increase of only 6.3 per cent, or a rather negligible value. The thrust increases rapidly during the next two or three holes drilled after the 70-in. depth, indicating that the drill already has suddenly become dull. As mentioned above, this high speed of 60 ft. per min. when cutting dry is excessive, and it is interesting to see that the dulling does not influence the torque and thrust to a greater extent.

Fig. 6 shows the results of the 1-in. R drill operating under similar conditions of Fig. 5, but when cutting with oil No. 4 (a soluble oil containing 1 part oil to 10 parts distilled water). The values of the torque and thrust both are erratic, although the general tendency of the torque curve shows a gradual increase of from $67^1/_2$ ft-lb. at the end of the first $3^1/_4$-in. hole drilled to a value of 79 ft-lb. at the end of the 180-in. penetration, or an increase of 14.6 per cent. After drilling 75 in., the torque reaches a value of 72 ft-lb., which is an increase over the initial value of 6.25 per cent when cutting with oil No. 4 as compared with 2 per cent for the increase in torque when cutting dry as shown in Fig. 5. It is shown, however, that when cutting with oil No. 4 the drill life is much greater than when cutting dry, although the torque increases more rapidly and to a higher final value. At the end of the 180 in. drilled in Fig. 6, the drill still was in a satisfactory condition for further drilling. The thrust curve in Fig. 6 practically parallels the torque curve, which seems to agree fairly well with the relation shown in Fig. 5.

As a result of these dulling tests, after grinding each drill, two or three holes were drilled before using the drill for test purposes, in order to remove the original keenness of the ground edge. In some subsequent tests where it was desirable to have the drill retain its condition during several tests, the cutting edge was honed. It was felt that this honing produced a condition of the cutting edge which remained more nearly constant for a considerable length of time.

TESTS TO CONFIRM TORQUE AND THRUST FORMULAS

An equation for torque as a function of variable feed and drill diameter was reported in a paper, "Power Required to Drill Cast Iron and Steel," Trans. A.S.M.E., 1930, MSP-52-2, and reported on further in a paper before the Society of Automotive Engineers at its annual meeting in Detroit on January 20 (*Journal S.A.E.*, Vol. 28, No. 3, p. 378). These equations were determined from tests on a wide variety of steels by using a soluble cutting oil one part oil to 16 parts water.

It was felt desirable to confirm these equations for torque and thrust, so some tests were run on the annealed S.A.E. 3150 steel, using a number of the cutting fluids under consideration. The results of the tests using oil No. 3 (a soluble oil consisting of one part oil to 50 parts water) are shown in Fig. 7. The variable-feed tests were run with the 1-in.-diameter R drill, whereas the variable-diameter tests were run with a constant feed of 0.009 in. per revolution. The torque values at the 0.009-in. feed for various drill diameters are shown to be practically a straight line, the slope of which is 1.8. This value represents the tangent of the angle included between the horizontal and the line. The torque values for various feeds for the 1-in.-diameter drill also indicate a rather satisfactory straight line, the slope of which is 0.78. These values then would indicate that the equation for torque is

$$T = Cf^{0.78}d^{1.8}$$

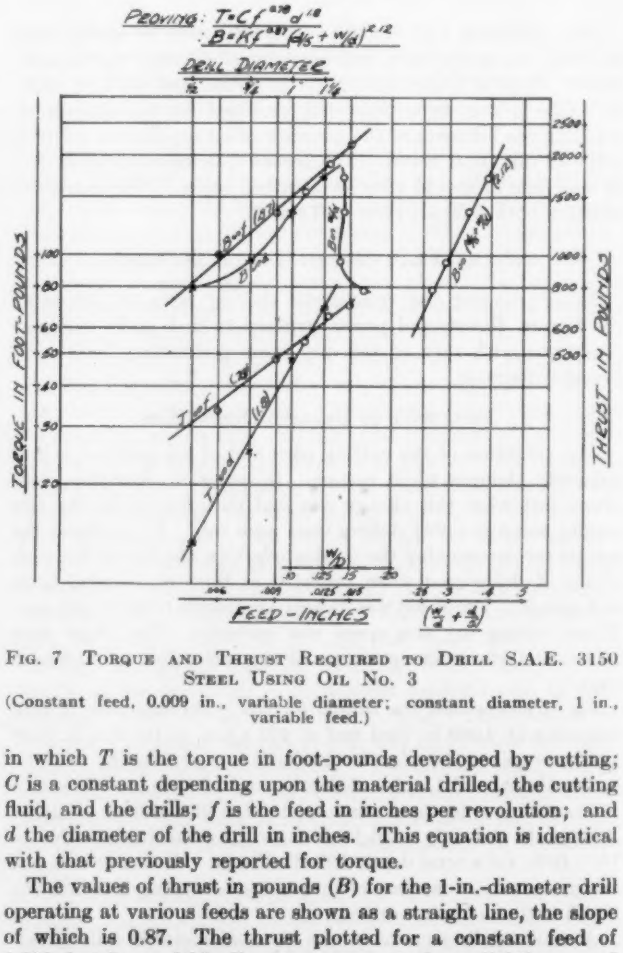

FIG. 7 TORQUE AND THRUST REQUIRED TO DRILL S.A.E. 3150 STEEL USING OIL NO. 3
(Constant feed, 0.009 in., variable diameter; constant diameter, 1 in., variable feed.)

in which T is the torque in foot-pounds developed by cutting; C is a constant depending upon the material drilled, the cutting fluid, and the drills; f is the feed in inches per revolution; and d the diameter of the drill in inches. This equation is identical with that previously reported for torque.

The values of thrust in pounds (B) for the 1-in.-diameter drill operating at various feeds are shown as a straight line, the slope of which is 0.87. The thrust plotted for a constant feed of 0.009, but for variable diameter appears to be a slightly curved line. For the drills when new, this line was more nearly straight.

After being ground several times the web thickness increased, causing the thrust to increase for each drill size, but in proportion to the increase in web thickness. Another almost vertical curve is shown representing the thrust for various values of w/d, where w is the web thickness at the point. Further to the right a straight line is obtained indicating the thrust B as a function of $[(d/5) + (w/d)]$. The slope of this line is 2.12. This indicates then that an equation for thrust is a function of the feed ($f^{0.87}$) and the value of $[(d/5) + (w/d)]^{2.12}$, resulting in the equation

$$B = K f^{0.87} \left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

The equation previously reported for thrust was more simple, as

$$B = K f^{0.78}\, d$$

and gives values considered fairly satisfactory for commercial use. In view of the nature of the present investigation, the first formula, which is more complicated, is being used in this paper, inasmuch as it is considered more accurate.

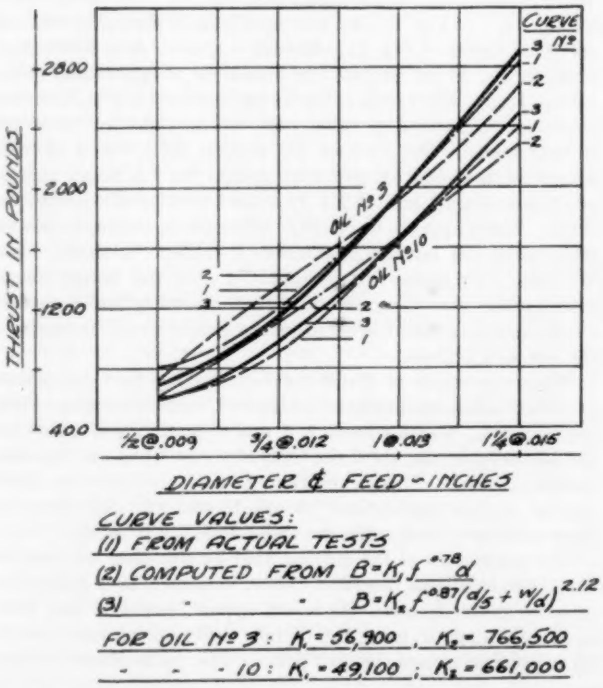

Fig. 8 Comparison of Actual and Computed Values of Thrust of Commercial Tests

A set of data similar to those for oil No. 3 shown in Fig. 7 was also obtained for oils Nos. 5 (lard oil), 6 (light mineral oil), 8 (10 per cent lard in mineral oil), and 10 (4 per cent sulphurized mineral oil). Values quite similar to those represented by the confirmed formula were obtained for oils Nos. 6, 8, and 10. Oil No. 5 (lard oil) gave an exponent of d in the torque formula of 2.3 instead of 1.8. It also gave an exponent of f of 0.92, which was the highest of all. Taking an average of the results of the tests for variable feed and variable diameter for the five oils, the following equations would result:

$$T = Cf^{0.84}d^{1.9}$$

$$B = K f^{0.84} \left(\frac{d}{5} + \frac{w}{d}\right)^{2.56}$$

It is felt that additional information of this nature, as well as confirming information, should be obtained. The limited funds available do not permit this detailed investigation, so that in the remainder of this paper the following formulas will be used:

$$T = Cf^{0.78}d^{1.8}$$

$$B = K f^{0.87} \left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

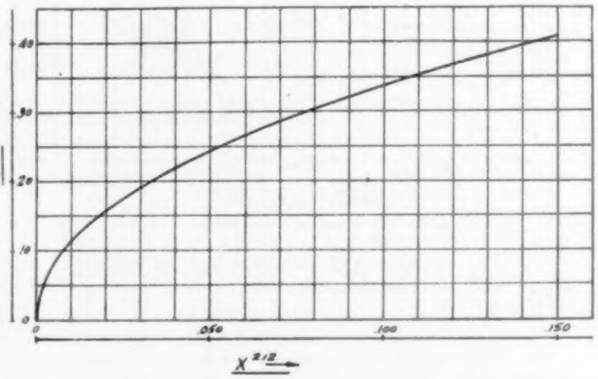

Fig. 9 Curves Showing Values of $X^{2.12}$ Which Are to Be Used in the Equation: $B = Kf^{0.87}(d/5 + w/d)^{2.12}$, Where $X = (d/5 + w/d)$

Fig. 8 has been prepared to show graphically the values of thrust in drilling the S.A.E. 3150 steel under the commercial test conditions, that is, when each drill diameter was operated at its respective commercial feed. The actual test values are plotted as curve 1 for oils Nos. 3 and 10. Curve 2 represents the values of thrust computed from the formula

$$B = K_1 f^{0.78} d,$$

while curve 3 represents the thrust values computed from the equation

$$B = K_2 f^{0.87} \left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

It is seen that for each oil the thrust values from the actual tests for the 1-in.-diameter drill, at 0.013 in. feed, correspond very closely with the values computed from the equations for curves 2 and 3. The same is generally true for the ½-in. drill at 0.009 in. feed. The greatest discrepancy occurs for the ¾-in. drill operating at 0.012 in. feed, for which the values of thrust computed by the equation for curve 3 agree quite satisfactorily with the actual test value, but the values computed from the equation for curve 2 are high.

In order that computations for torque and thrust can be made easily, values of the various feeds, diameters, etc. to required exponents are given in Table 5. Various values of $[(d/5) + (w/d)]^{2.12}$ may be determined from Fig. 9, in which X represents the value $[(d/5) + (w/d)]$ plotted as ordinates, and the values of $X^{2.12}$ are plotted as abscissas.

Influence of Quantity of Cutting Fluid

The commercial drilling tests as described below were all run with the coolant or cutting fluid dumped on the drill just above the work. A large volume of oil was supplied at a low velocity. In order, however, to obtain some idea as to the influence of other methods of applying the oil, a series of tests were run in which the oil was applied in various quantities and by different methods.

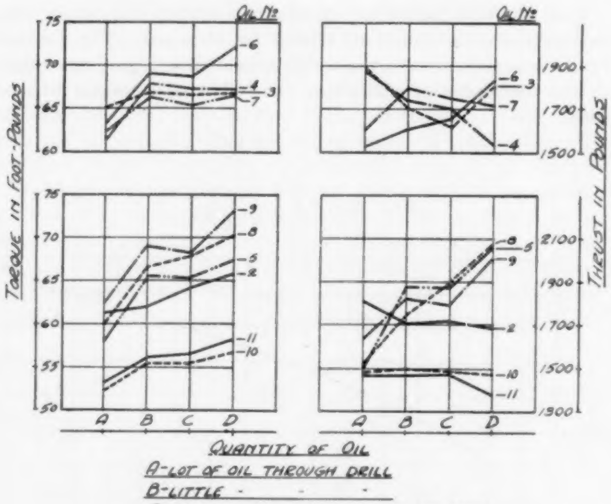

FIG. 10 INFLUENCE OF QUANTITY OF CUTTING FLUID ON TORQUE AND THRUST IN DRILLING S.A.E. 3150 STEEL
(1-in. oil-hole drill at 230 r.p.m. and 0.013 in. feed.)

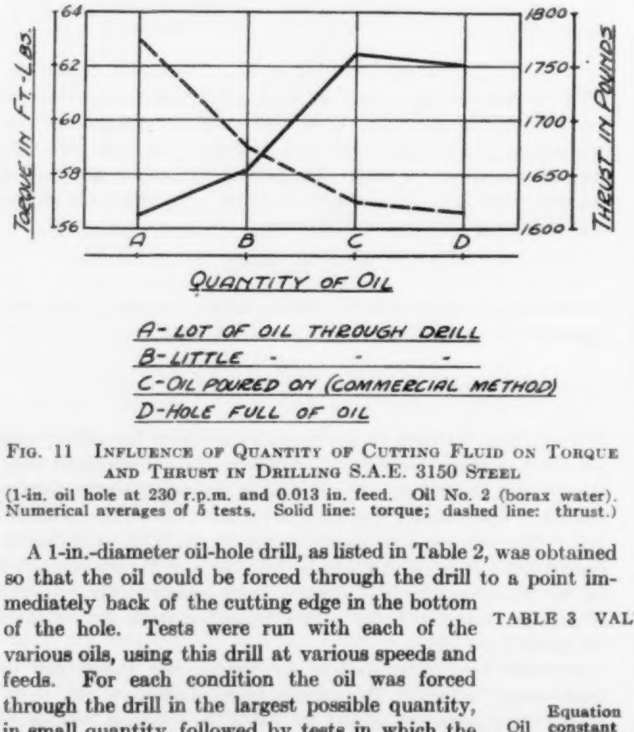

FIG. 11 INFLUENCE OF QUANTITY OF CUTTING FLUID ON TORQUE AND THRUST IN DRILLING S.A.E. 3150 STEEL
(1-in. oil hole at 230 r.p.m. and 0.013 in. feed. Oil No. 2 (borax water). Numerical averages of 5 tests. Solid line: torque; dashed line: thrust.)

A 1-in.-diameter oil-hole drill, as listed in Table 2, was obtained so that the oil could be forced through the drill to a point immediately back of the cutting edge in the bottom of the hole. Tests were run with each of the various oils, using this drill at various speeds and feeds. For each condition the oil was forced through the drill in the largest possible quantity, in small quantity, followed by tests in which the oil was dumped on the work above the drill, and finally by discontinuing the addition of oil, allowing the drill to continue cutting only with the hole full of oil. In this last condition, drilling could not be continued for long because the oil was carried out of the hole with the chips, and it steamed away rapidly because of the intense heat developed.

The average values of torque and thrust for five tests under each condition of oil application are shown plotted in Fig. 11. Cutting fluid No. 2, consisting of $1^1/_2$ per cent by weight of borax in water, was used with the 1-in.-diameter oil-hole drill operating at 230 r.p.m., and at a feed of 0.013 in. per revolution. S.A.E. 3150 steel was being cut. The results show that the lowest torque is developed when the oil is supplied in the greatest quantity at the drill point. The value of the torque for this condition is 56.5 ft-lb. The torque is increased to 58.2 ft-lb. when only a little of the cutting fluid is forced through the drill. The average torque increases to 62.5 when the oil is dumped on, and drops off slightly to 62 ft-lb. when no oil is added but when the hole is full when the cut starts. The thrust, on the other hand, starts at a maximum of 1775 lb. when the cutting fluid is applied in greatest quantity, drops to 1675 lb. when only a little is forced through the drill, and drops still further to 1625 lb. when dumped on. Only a slight further decrease is noted for the thrust when drilling with the hole full and no additional cutting fluid added.

The results of torque and thrust for a single test under each condition of cutting-fluid application, using each of the cutting fluids, are shown in Fig. 10. The curve of torque for cutting fluid No. 2 is quite similar to, but slightly higher than, the curve for torque shown in Fig. 11. That the curve for torque of Fig. 10 is higher than that of Fig. 11 is probably due to the fact that the drill was duller for the values given in Fig. 10. The thrust curve for oil, No. 2 of Fig. 10, also corresponds quite favorably with the curve for thrust of Fig. 11, although a greater drop in thrust is noted in Fig. 11 for the last two conditions of application of the cutting fluid. The values of the torque as shown in Fig. 10 show a tendency to increase in value from left to right for all of the cutting fluids. The increase for cutting fluid No. 3 (1-to-50 soluble oil) is least of all, with cutting fluid No. 7 (a heavy mineral oil) a close second, and oil No. 4 (a one-to-ten soluble oil) a close third. There appears to be little difference in torque values for these three oils for the conditions of "little," "dumped," and "in hole." It seems rather surprising that the lowest torque should occur when the greatest amount of cutting fluid is applied. Under this condition the temperature is more nearly normal and the viscosity highest.

When the values of thrust for each cutting fluid are plotted over the various conditions of application, rather confusing results are obtained. Cutting fluids 2, 3, and 4, consisting of water and the two soluble oils, show the highest thrust when an abundant amount is used. There appears to be little difference in thrust for the various applications for oils 10 and 11. All other oils show a tendency to increase the thrust from left to right.

The application of the cutting fluid by dumping was used in the commercial test described below, inasmuch as it appears to be more generally used. It would appear, however, that there is an advantage in using the oil-hole drill and forcing as much oil as possible to cool the drill point. The values shown in Figs.

TABLE 3 VALUES OF TORQUE REQUIRED TO DRILL S.A.E. 3150 STEEL, USING VARIOUS CUTTING OILS

(Arranged according to increasing value of factor.)

[1] Numerical average of test values.
[2] Computed from equation $T = C f^{0.78} d^{1.8}$ and corresponding to curve values in Fig. 12.
[3] Average of 37 tests.
[4] Average of 22 tests.
[5] Average of 15 tests.
[6] Average of 18 tests.
All other test values average of 6 tests.

10 and 11 are the results of only a short investigation and are not intended as final. Further work along this line, employing higher pressures, might prove advantageous.

THE COMMERCIAL DRILLING TESTS

The commercial drilling tests were carried out with each of the cutting fluids as follows:

A 1/2-in.-diameter drill rotating at 449 r.p.m. with a feed of 0.009 in.

A 3/4-in.-diameter drill rotating at 300 r.p.m. with a feed of 0.012 in.

A 1-in.-diameter drill rotating at 231 r.p.m. with a feed of 0.013 in.

A 1 1/4-in.-diameter drill rotating at 174 r.p.m. with a feed of 0.015 in.

TORQUE VALUES

After running a number of tests with all drills in each oil but in different orders, the values for torque were averaged numerically as shown in Table 3. Similarly, numerical averages of thrust are shown in Table 5. Gross power input and net power input are shown in Tables 6 and 7, respectively.

The numerical averages for torque were plotted on log-log paper as shown in Fig. 12. The ordinates equal the average torque in foot-pounds from the drilling experiments, while the abscissas equal $L = f^{0.78} d^{1.8}$ as taken from the equation developed for torque as a function of feed and drill diameter, namely, $T = Cf^{0.78} d^{1.8}$. Straight lines were obtained by connecting the points for a given cutting fluid as shown. All lines seem to be nearly parallel. That for cutting fluid No. 11 (sulphurized lard oil) has a slightly greater slope than the others, although it does not seem to diverge sufficiently from the others to warrant a separate equation.

The values of the torque required for drilling the S.A.E. 3150 steel, using the various cutting fluids as indicated by the straight-line log-log curves, Fig. 12, are tabulated for each drill diameter and feed in Table 3 in the column headed "computed." They represent the values computed from the formula $T = Cf^{0.78} d^{1.8}$, and correspond with values taken from the torque lines on the log-log scale given in Fig. 12. These values differ but slightly from the numerical averages given in the same table. This table affords a favorable opportunity to compare the numerical averages as determined from the test with the computed or smoothed-out values as read from the curves.

The highest line for torque given in Fig. 12 is for oil No. 9, a 5 per cent oleic acid and 95 per cent mineral oil, and the lowest is for oil No. 10, which is a 4 per cent sulphurized mineral oil. This indicates that oil No. 9 causes the highest torque when drilling and oil No. 10 the lowest. The other oils cause torque values in between as indicated.

Substituting a value of the torque for a given feed and diameter for cutting fluid No. 1, the constant C is determined as 2178, as shown in Table 3. Similarly, substituting values of torque for the other cutting fluids, constants for the torque equation for each oil are computed as listed in the second column of Table 3. With cutting fluid No. 1 taken as unity, factors indicating the ratio of the constant for each oil to the constant for oil No. 1 are computed and tabulated in the third column of Table 3. The oils are arranged so that the one having the lowest constant, and consequently the lowest factor, is listed at the top. The other

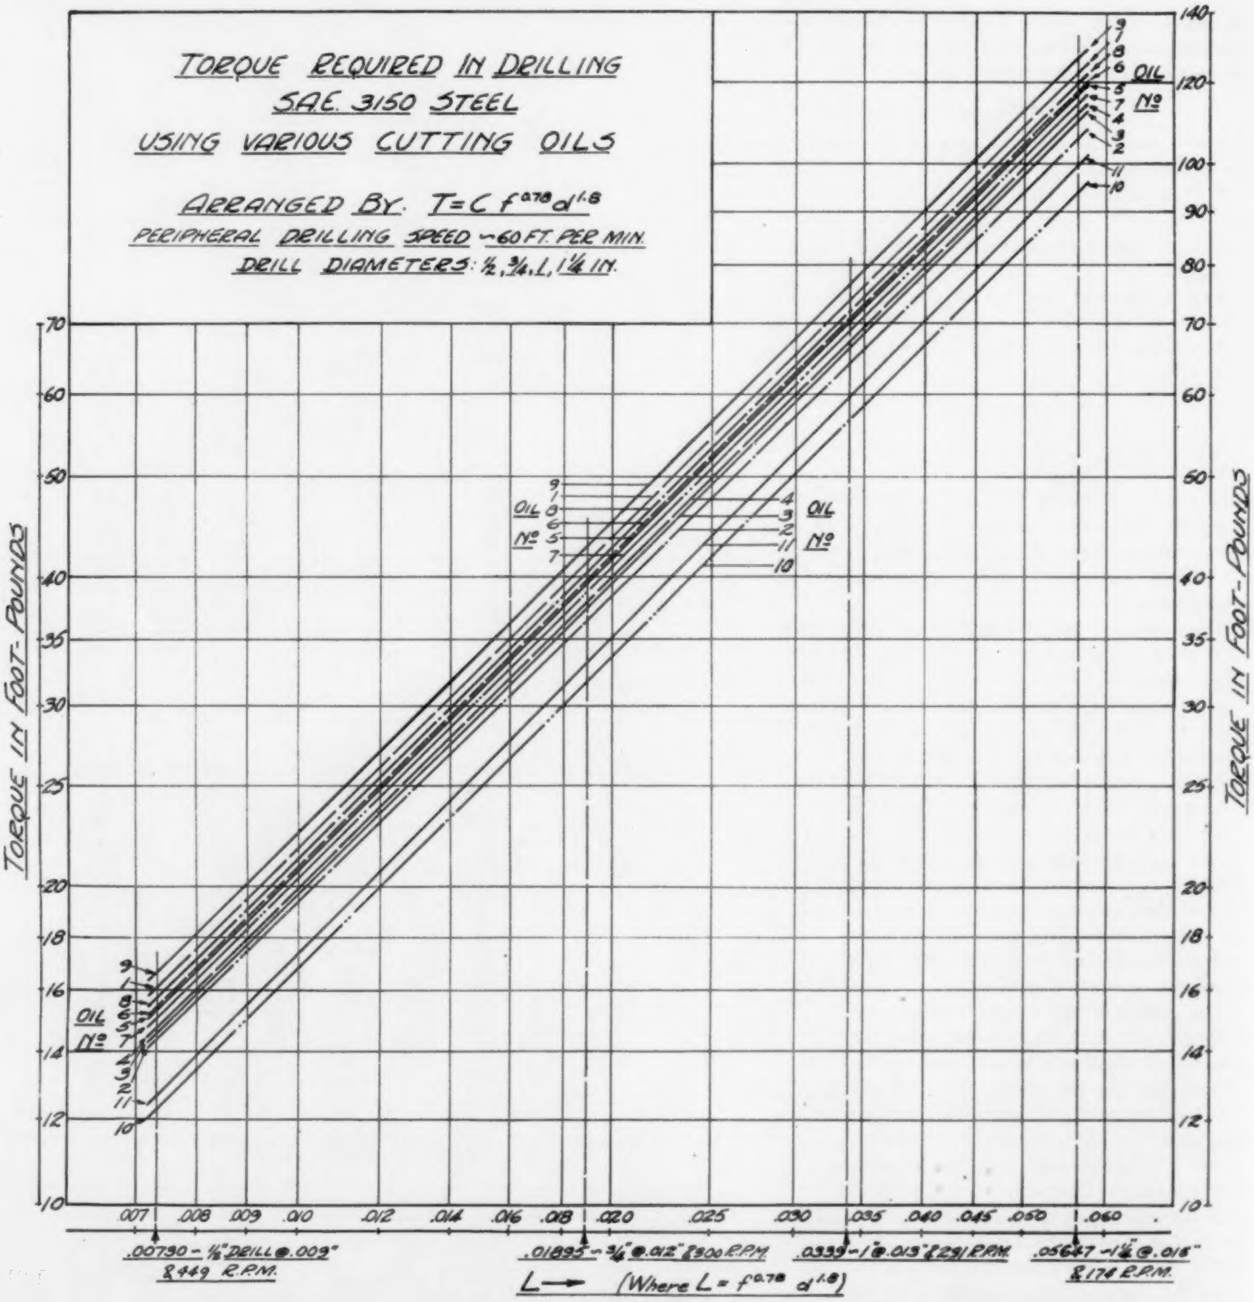

FIG. 12 TORQUE REQUIRED IN DRILLING S.A.E. 3150 STEEL, USING VARIOUS CUTTING OILS

oils are arranged in order of increasing torque constant and factor. It is seen from these factors that oil No. 9 produces a torque $1^{1}/_{2}$ per cent greater than that produced by oil No. 1, dry cutting, while oil No. 10 produces a torque of only 76.5 per cent of that for dry cutting.

The torque for any drill diameter operating at any feed using any of the oils covered by these experiments may be determined from the curves of Fig. 12 simply by computing the value of L, locating it on the abscissa axis, and projecting it vertically until the torque line for the desired oil is intersected.

Better to illustrate the relation between the torque values for the different drill diameters at their respective feeds between dry cutting and oil No. 10 (a 4 per cent sulphurized mineral oil), Fig. 13 has been prepared. Fig. 14 shows in a general way the relation between the torque required to drill the S.A.E. 3150 steel, using the various cutting oils for each cutting condition. The torque for the $1^{1}/_{4}$-in.-diameter drill operating at 0.015 in. feed is shown to be about 94 for oil No. 10, which is the lowest value. The oils are arranged in order of increasing torque values from left to right so that the torque of the $1^{1}/_{4}$-in.-diameter drill, operating at 0.015 in. feed, increases gradually to a value of 125 for oil No. 9 at the right. For the $1^{1}/_{4}$-in.-diameter drill the difference in torque between oil No. 1, dry cutting, and oil No. 10, the 4 per cent sulphurized mineral oil, is 22.8 per cent of the torque value for dry drilling. For the 1-in.-diameter drill, operating at 0.013 in. feed, this value is 24.6; for the $^{3}/_{4}$-in.-diameter drill at 0.012 in. feed, it is 24.1, and for the $^1/_2$-in.-diameter drill at 0.009 in. feed, 23.5 per cent. This shows a rather constant influence of oil No. 10, regardless of the value of the drill diameter and feed.

Knowing the torque T for any value of $L = f^{0.78}d^{1.8}$, the horsepower developed at the drill point due to the torque may be determined from the equation

$$HP_T = \frac{2\pi NT}{33{,}000} = 1904\ TN$$

in which T is the torque in foot-pounds and N is the revolutions per minute of the drill.

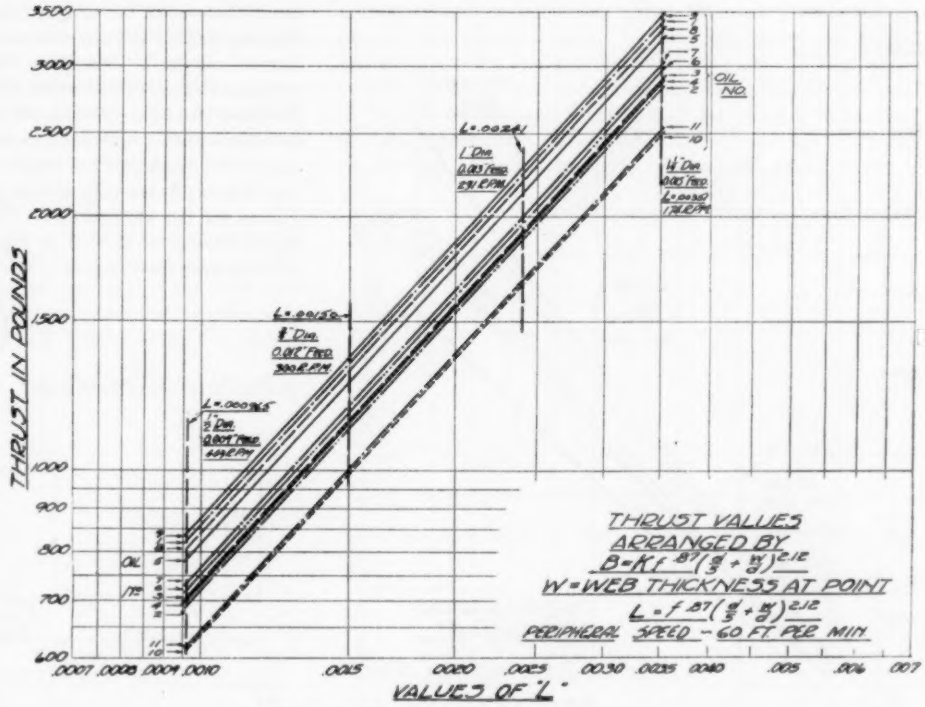

FIG. 15 THRUST FOR VARIOUS VALUES OF L

THRUST VALUES

Numerical averages of thrust required to drill the S.A.E. 3150 steel, using various cutting oils as determined from the commercial tests, are given in Table 5. As stated earlier, it was found that the best equation to represent a relation between thrust, feed, and drill diameter was such that the web thickness should be considered. The equation

$$B = K f^{0.87} \left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

was found to be satisfactory, in which B is the thrust in pounds, K a constant, f the feed in inches per revolution, d the drill diameter in inches, and w the web thickness in inches at the point of the drill.

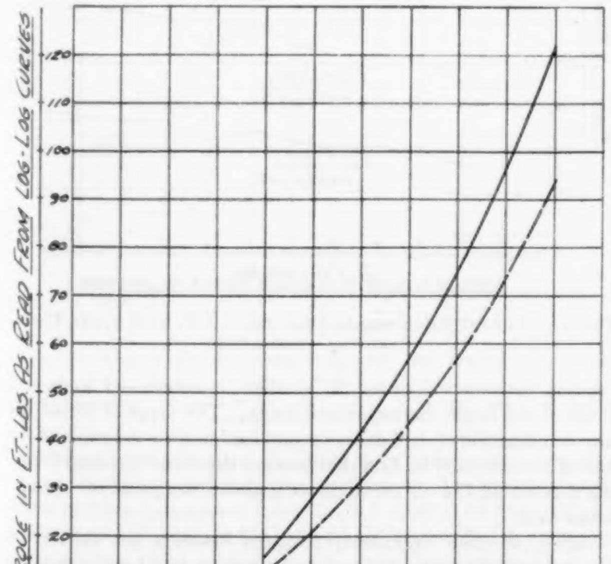

FIG. 13 COMPARISON OF TORQUE REQUIRED TO DRILL S.A.E. 3150 STEEL

(Solid line: dry; dashed line: oil No. 10.)

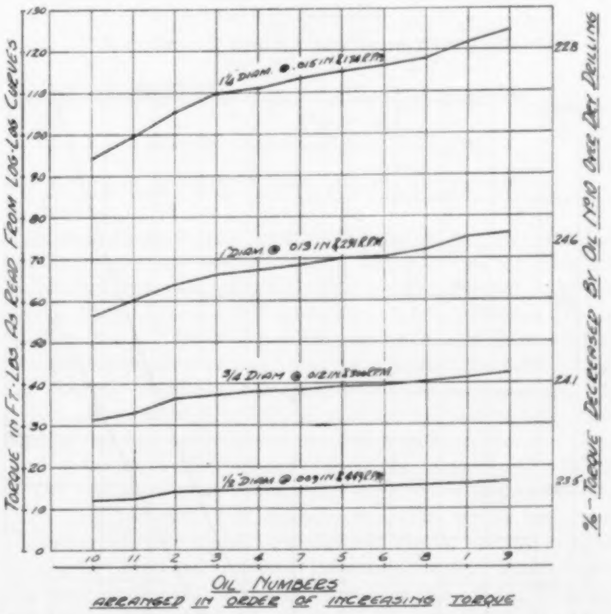

FIG 14 TORQUE REQUIRED TO DRILL S.A.E. 3150 STEEL, USING VARIOUS CUTTING OILS

The numerical averages of thrust were plotted on log-log paper as ordinates over abscissa values equal to $L = f^{0.87}\left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$ as shown in Fig. 15. The various thrust lines for the different oils are not only straight but appear to be very nearly parallel.

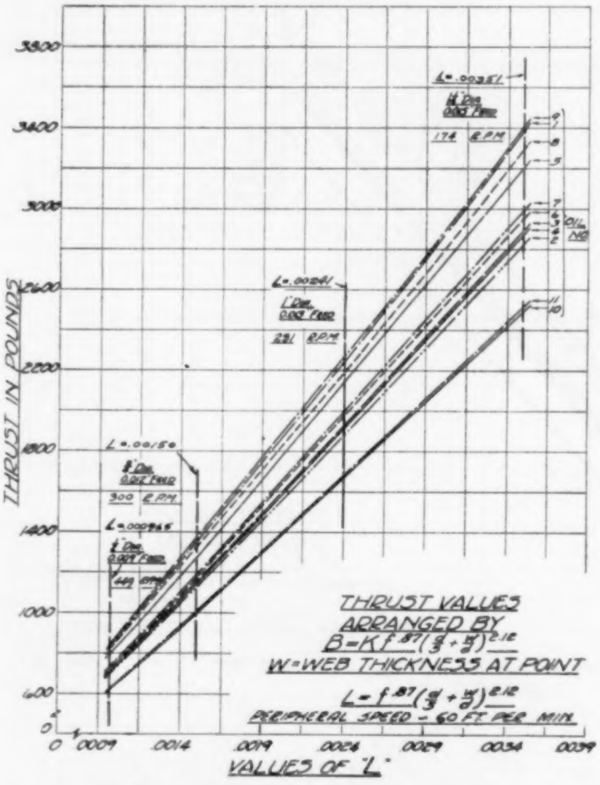

FIG. 16 THRUST FOR VARIOUS VALUES OF L

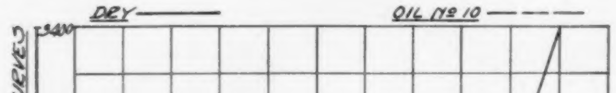

FIG. 17 COMPARISON OF THRUST REQUIRED TO DRILL S.A.E. 3150 STEEL

As in the case of the torque values, Fig. 12, the thrust values are highest for oil No. 9 and lowest for oil No. 10. It is seen that the thrust values for oils Nos. 10 and 11 are very nearly equal, whereas there is considerable difference between the torque values for these two oils. The thrust for oil 6, Fig. 15, is lower than that for oils 5 and 7, whereas the torque for oil 6 is higher than the torque for oils 5 and 7. In general, however, these thrust curves for various oils are quite similar in their arrangement to the torque curves for the various oils. The values for thrust for the commercial tests, as plotted in Fig. 15 on log-log paper, are shown plotted over the value of

$$L = f^{0.87}\left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

in Fig. 16 on coordinate paper. This indicates more definitely the relation between values for the smaller diameters and feeds and those of the larger diameters and feeds. The value of thrust for any combination of drill diameter and feed may be determined for any of the oils used by first determining the value of L and locating a point on the oil curve directly above the point on the abscissa axis.

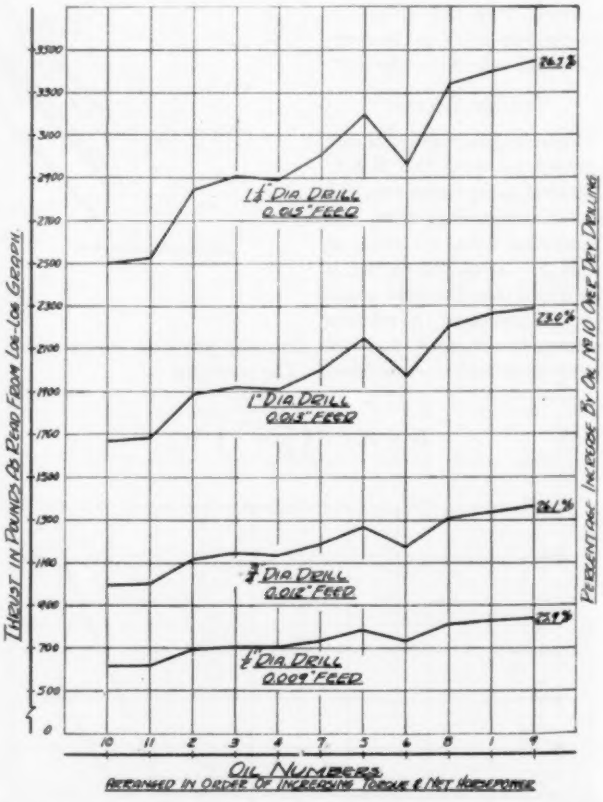

FIG. 18 THRUST REQUIRED IN DRILLING S.A.E. 3150 STEEL USING VARIOUS CUTTING OILS

Again, to show comparative values between the thrust for the different drill diameter and feed combinations for dry cutting and for oil No. 10, the values of thrust for these oils are shown plotted on coordinate paper in Fig. 17. The thrust values produced by each drill diameter at its respective feed are shown plotted over the oil numbers arranged in order of increasing torque (same as Fig. 14) in Fig. 18. It is seen that the thrust for the $1^1/_4$-in.-diameter drill, operating at 0.015 in. feed, with oil No. 10, is but 2500 lb., whereas for dry cutting it is about 3400 lb., and for oil No. 9 (5 per cent oleic acid in mineral oil) it is 3435 lb. For the 1¼-in.-diameter drill there is a saving of 26.5 per cent in thrust over dry cutting when oil No. 10 is used. For the 1-in.-diameter drill, this saving is 23 per cent; for the ¾-in.-diameter drill, 26.1 per cent; and for the ½-in.-diameter drill, 25.9 per cent. This saving appears to be practically constant in spite of the wide range of drill diameters and feeds.

Gross Power Input

The gross horsepower required to drive the drill press during the cutting operations was recorded by a wattmeter connected with the electric motor mounted on the rear of the drill-press column. The numerical averages from the various tests gave the gross kilowatts required to drill S.A.E. 3150 steel for the various cutting oils as tabulated in Table 6. Corresponding values of gross horsepower are also given in Table 6. The numerical averages of gross horsepower from Table 6 were plotted on cartesian coordinates as shown in Fig. 19, and are represented by smoothed-out curves. The values of the gross horsepower as determined from these smoothed-out curves are tabulated in Table 6.

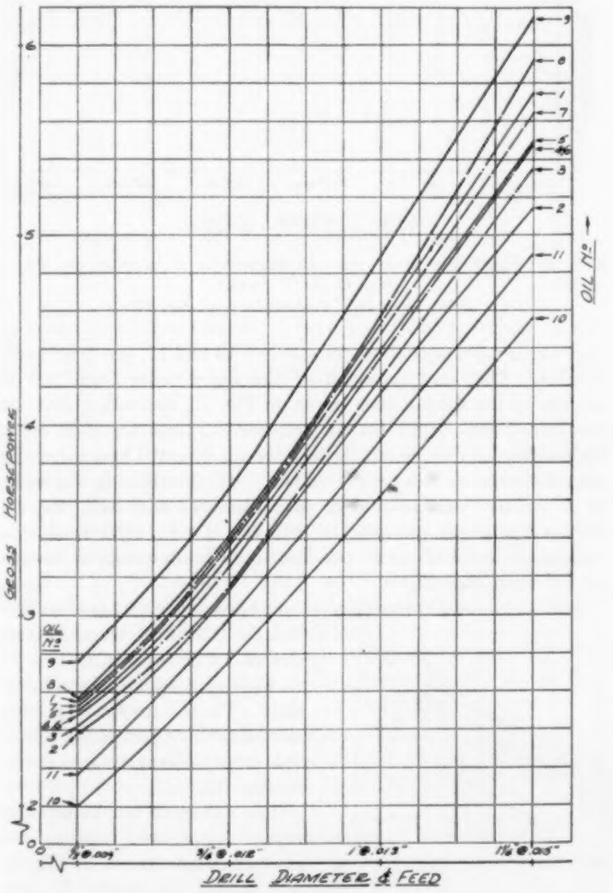

Fig. 19 Gross Horsepower Required to Drill S.A.E. 3150 Steel

(Drills operating at commercial feeds and at a cutting speed of approximately 60 ft. per min.)

These values are not shown plotted on log-log paper over the values of $L = f^{0.78} d^{1.8}$ as the torque values were, inasmuch as there is a constant in the form of tare power which would make the results misleading. The value of L would naturally hold for any drill diameter and feed, and yet the tare for one value of L would be small if a large-diameter drill were used and large if a small-diameter drill were used. The net-power values are plotted over these values of L, inasmuch as the net values are almost a direct speed function of the torque. The gross-horsepower values required to drill the S.A.E. 3150 steel as presented in Table 6 may be read directly from the various oil curves only at four points on the abscissa axis, namely, over the ½-in.-diameter drill at 0.009 in. feed, the ¾-in. drill at 0.012 in. feed, the 1-in. drill at 0.013 in. feed, and the 1¼-in. drill at 0.015 in. feed.

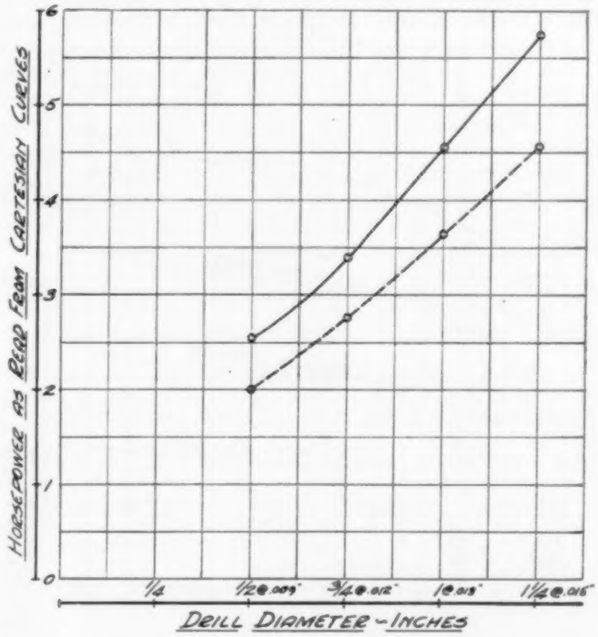

Fig. 20 Comparison of Gross Horsepower Required to Drill S.A.E. 3150 Steel

(Solid line: dry; dashed line: oil No. 10.)

A comparison of gross horsepower required to drill the S.A.E. 3150 steel dry and with oil No. 10 (the 4 per cent sulphurized mineral oil) is shown in Fig. 20. The gross horsepower developed by the ½-in.-diameter drill operating at 0.009 in. feed is 2.01 for oil No. 10 and 2.55 for dry cutting oil No. 1. This shows that dry cutting requires 21.2 per cent more power than cutting with oil No. 10. Similarly, the gross horsepower required for the 1¼-in.-diameter drill operating at 0.015 in. feed is 5.74 when cutting dry and only 4.57 when cutting with oil No. 10. This gives a saving of 20.4 per cent for oil No. 10 over dry cutting.

The values of gross horsepower required to drill the S.A.E. 3150 steel for each drill diameter operating at its respective commercial feed and speed are shown in Fig. 21 plotted over the oil numbers arranged in order of increasing torque. These curves are very similar to the torque curves, except for the constant tare power introduced for each combination of drill diameter, feed, and speed. The fact that the gross power is high for oil No. 7 and low for oils Nos. 6 and 1 may be due to an error in zero setting on the part of the wattmeter in recording the tare-power values. This irregularity is eliminated when the net-power values are determined as shown below. The percentage values along the right-hand edge of Fig. 21 are an indication for each drill size, feed, and speed of the saving in gross power over dry cutting when oil No. 10 is used.

Net Power Input

In every test the machine was started with the drill point

$^1/_4$ to $^3/_8$ in. from the surface of the metal to be drilled. This allowed the wattmeter to record the input power to drive the machine with the speed and feed gears engaged, but with no cutting. This tare power was subtracted from the gross values, resulting in the net power input. The numerical averages of the net power input are listed in Table 7 as both kilowatts and horsepower. The horsepower values were plotted on log-log paper, Fig. 22, over abscissa values equal to L, in which L equals $f^{0.78}d^{1.8}$. A series of straight lines are obtained which,

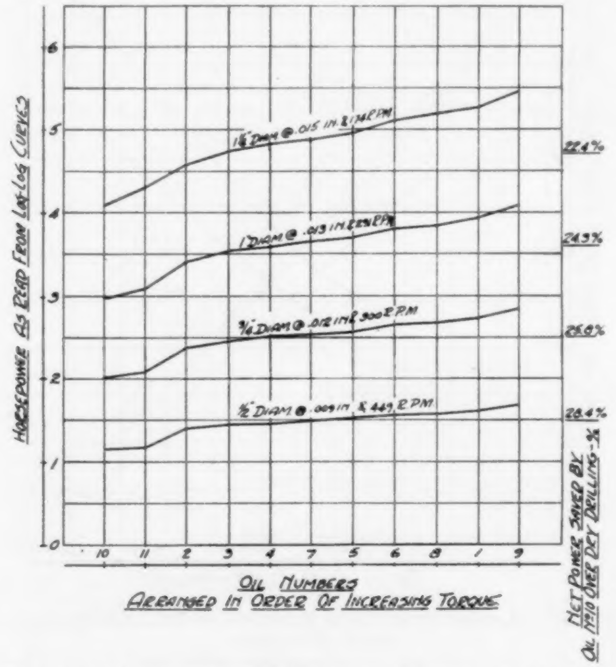

FIG. 21 GROSS HORSEPOWER REQUIRED TO DRILL S.A.E. 3150 STEEL

(Drills operating at commercial feeds and at a cutting speed of approximately 60 ft. per min.)

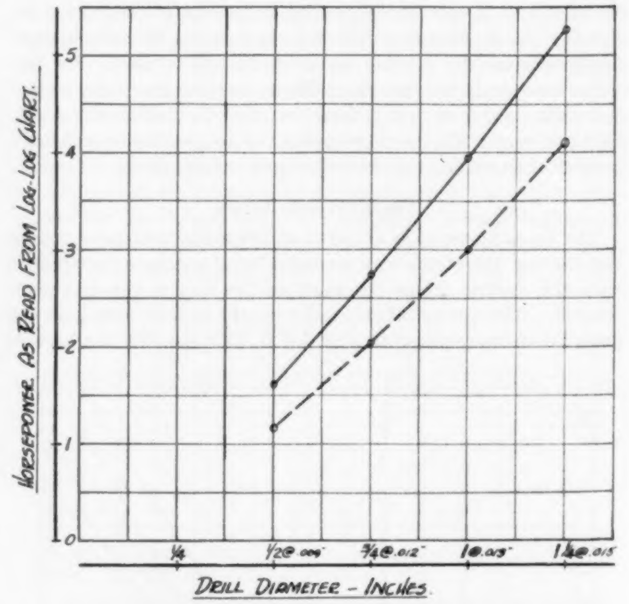

FIG. 23 COMPARISON OF NET HORSEPOWER REQUIRED TO DRILL S.A.E. 3150 STEEL

(Solid line: dry; dashed line: oil No. 10.)

with the exception of those for oils No. 10 and 11, are practically parallel. They are arranged in the same order from top to bottom as the torque lines shown in Fig. 12, indicating that the net horsepower input for all commercial tests for each oil is highest for oil No. 9 and lowest for oil No. 10, and otherwise placed similar to the torque values. By determining the value of L for any combination of drill diameter and feed, the net horsepower input required to drill the S.A.E. 3150 steel at a peripheral speed of 60 ft. per min. may be determined for any oil by using Fig. 22.

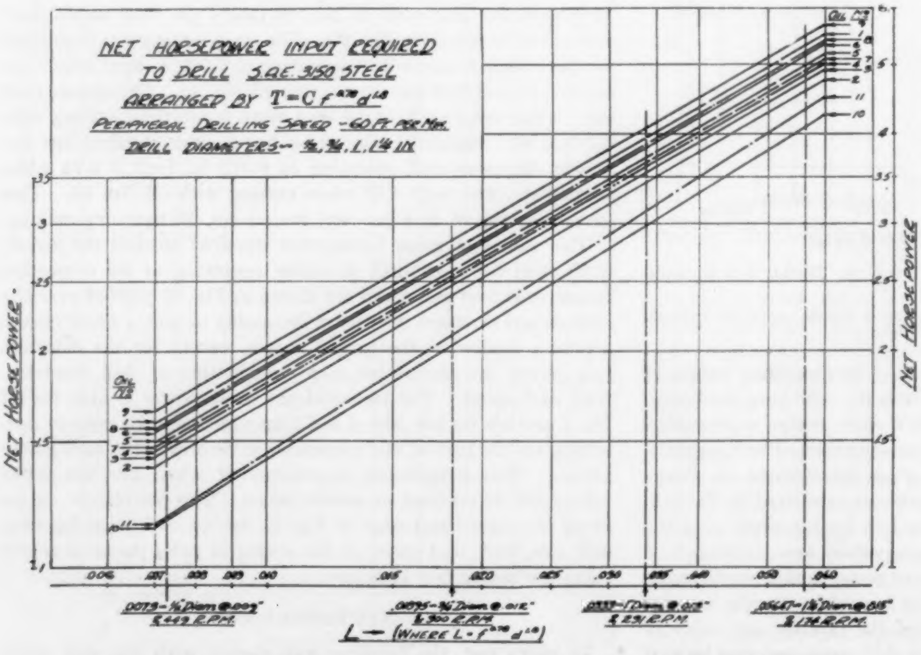

FIG. 22 NET HORSEPOWER INPUT REQUIRED TO DRILL S.A.E. 3150 STEEL

Fig. 23 shows a comparison of net horsepower required to drill S.A.E. 3150 steel when cutting dry and when using oil No. 10 (a 4 per cent sulphurized mineral oil). These curves are very similar to those comparing torque values for these two oils as shown in Fig. 13.

The values of net horsepower input as taken from the smoothed-out curves of Fig. 22 are shown in Table 7. The values of net horsepower of Table 7 are shown plotted in Fig. 24 for each drill diameter, feed, and speed combination over the various oil numbers arranged in order of increasing torque. These curves are very similar to the torque curves arranged over oil numbers in Fig. 14.

CHIPS FROM THE DRILLING EXPERIMENTS

Fig. 25 shows representative chips from each of the drill sizes operating at their respective feeds when the peripheral cutting

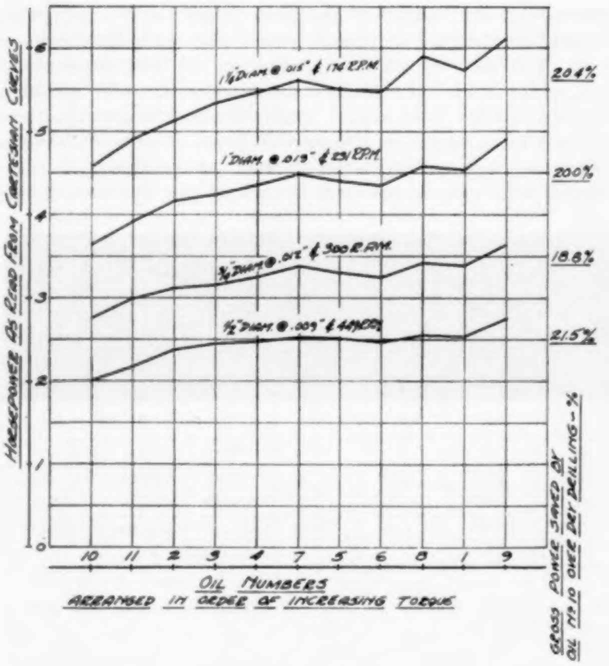

FIG. 24 NET HORSEPOWER INPUT REQUIRED TO DRILL S.A.E. 3150 STEEL

(Drills operating at commercial feeds and at a cutting speed of approximately 60 ft. per min.)

speed is approximately 60 ft. per min. The chips when cutting dry (oil No. 1) are all blued, indicating the development of excessive heat. The chips for oils Nos. 10 and 11 are browned, apparently due to the action of the sulphur in the oils rather than to high temperatures. The chips from oils Nos. 7, 8, and 9 appear to be well broken up. There were very few continuous chips. The chips from oil No. 6, which is the mineral oil having a viscosity of 110 Saybolt seconds at 100 deg. fahr., are broken up, but not so completely as are those for oil No. 7, which is a mineral oil having a viscosity of 210 Saybolt seconds at 100 deg. fahr. The chips from oil No. 6 also are colored, evidently due to high temperatures.

The chips from oil No. 2 (water containing $1^1/_2$ per cent borax) appear to be of the brightest steel-like color, giving the appearance of aluminum. This may be an indication of superior cooling qualities.

The chips from the 1-in.-diameter and $1^1/_4$-in.-diameter drills for oil No. 10 did not seem to be well broken up, but came out in large, long coils, throwing the oil about the room.

THE RESULTS OF THE PLANER TESTS

The planer cutting tests were conducted on the annealed S.A.E. 3150 steel also used in the drilling tests. The single tool shape described above was used on all cuts.

A cutting speed of 20 ft. per min. was maintained in all tests reported here. Four depths of cut were used: 0.030, $^1/_{16}$, $^1/_8$, and $^3/_{16}$ in. For each depth of cut three feeds were used, 0.0089, 0.020, and 0.036 in., respectively. In some instances feeds as light as 0.004 in. were employed, but for the shallow depths of cut the forces measured were so small that they were not considered wholly reliable.

The material being cut, which was a piece 2 in. × 6 in. in section and 24 in. long, was clamped rigidly in the bottom of the tank mounted on the dynamometer table. It was placed on its face with the length in the direction of the stroke so that cuts 24 in. in length could be started at one edge and the tool fed across the 6-in. face in taking subsequent cuts. Fig. 26 is a photograph of a short length of this top surface after a 0.030-in. depth of cut has been taken over the whole width. Starting from the left, the tool was given a feed of 0.0089 in. for about twenty cuts with cutting oil No. 1 (dry cutting). The feed was then increased to 0.020 in. for about ten cuts and then to 0.036 in. for about 6 cuts. The cutting force for each cut was measured and later averaged for each separate condition. The set-up depth of cut of 0.030 in. was maintained for the feeds of 0.0089 and 0.020 in., but was reduced 0.0005 in. for the 0.036-in. feed.

After the series of dry cuts at the 0.030-in. depth of cut, oil No. 5 (No. 1 lard oil) was used. Fig. 26 shows the actual depths for each feed for the No. 5 oil, as well as for each oil subsequently used. For each oil and depth of cut, the three feeds mentioned were employed as indicated by the resultant finish. The cuts shown in Fig. 26 are the beginning of the cuts 24 in. in length.

Fig. 27 shows a similar set of feed and actual depth readings with the resultant finishes for the same tool operating at 20 ft. per min. for the various cutting fluids when the depth of cut remained set at $^1/_{16}$ in. The bottom of the photograph represents the end

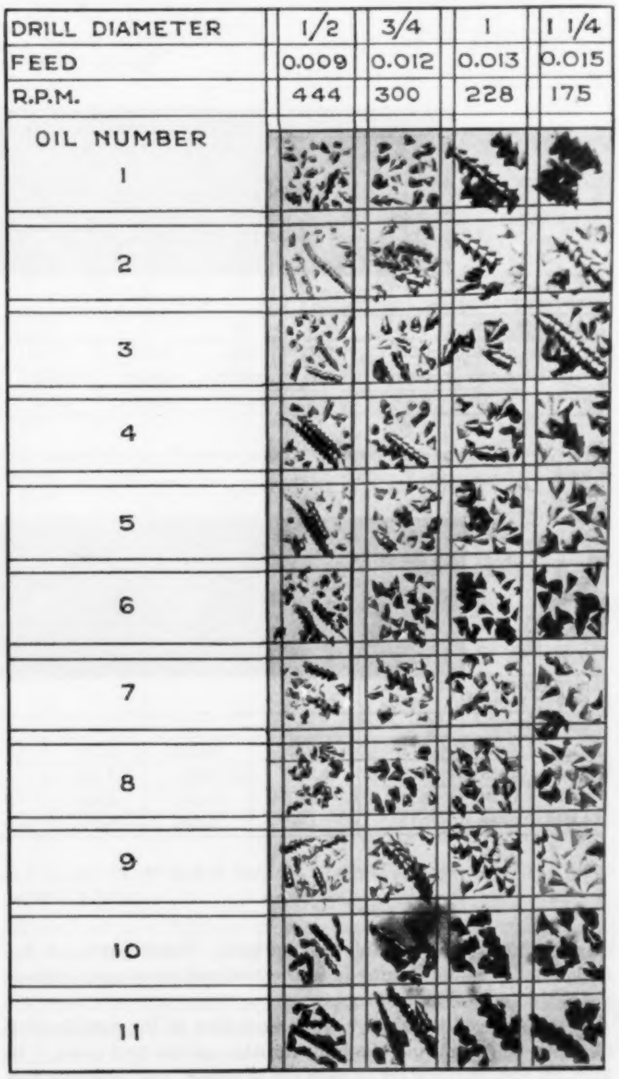

FIG. 25 DRILL CHIPS FROM VARIOUS CUTTING CONDITIONS

of the 24-in. length of cut and clearly shows how the chip was broken off at the end of the cut.

Fig. 28 shows the surface left on the bar for the beginning of each 24-in. length of cut when the set-up depth was $^1/_8$ in. The upper edge represents the beginning of each cut. This set-up depth was actually obtained by lowering the tool by means of a dial indicator. The actual depth differed from the set-up depth very little for the shallow cuts, but for the heavier cuts the difference became more noticeable and marked. This difference is due undoubtedly to the digging-in of the tool and subsequent springing of the tool holder and support.

It was noticed that every chip, regardless of the combination of depth and feed, had the built-up edge on the tool point. In Figs. 26 and 28 the start of each cut is shown, and after the first $^1/_2$ in. or so, a condition is reached which appears to be constant throughout the balance of the 24-in. length of cut. It is believed that the built-up edge is formed during the first $^1/_8$ in. of cut. This distance might be greater on the 0.030-in. depth of cut, as the finish left in some instances appears to be burnished at intervals for a somewhat longer length. In general, there appears to be very little difference in finish for cuts of the same dimensions but made with the different cutting fluids. In other words, these tests do not seem to indicate that the cutting fluid has any marked influence on the finish produced at the cutting speed of 20 ft. per min. This subject will be investigated further at a later date.

PLANING-FORCE CURVES

After running four complete sets of tests giving force values for each combination of depth of cut and feed, these values were plotted on coordinate paper as shown in Fig. 29. The force values for the actual depth were plotted and smooth lines were drawn through these points, representing force values for constant depth at the left in Fig. 29 and for constant feed at the right. The solid lines represent the force curves for different depths or feeds when cutting dry (cutting fluid No. 1), while the dashed lines represent corresponding values when cutting fluid No. 10 (4 per cent sulphurized mineral oil) was used.

Curves similar to those of Fig. 29 were drawn for the actual test data on the planer tool for each of the cutting fluids and the values thought most representative read off and plotted on log-log paper, as shown in Figs. 30 to 40, inclusive, for cutting fluids 1 to 11, inclusive. Fig. 30 represents the planer-force curves in cutting the S.A.E. 3150 steel at 20 ft. per min. when cutting dry or with cutting fluid No. 1. Two sets of curves are shown: the dashed lines are for the constant values of feed plotted over variable depths of cut, while the solid lines are for constant depths of cut for various values of feed. The straight lines on log-log paper presented in Figs. 30 to 40, inclusive, were studied for the purpose of arriving at an equation representing the force on the planer tool as a function of each cutting oil, the depth of cut, and the feed. From all of the figures nineteen lines of constant depth had a slope equal to 0.79, that is, the tangent of the angle made with the horizontal equaled 0.79. Seven lines had a slope of 0.78, while ten had a slope of 0.80. The average for the thirty-six lines is 0.792, which represents the value of y in the expression $P = CD^xf^y$. Similarly the slopes of the various constant-feed lines were averaged in order to determine the value of x in the

(Values plotted are averages from curves drawn through experimental points.)

foregoing equation. Average values for all of the constant-feed lines for oils 1 to 11 are, respectively, 0.926, 0.976, 0.993, 0.90, 0.92, 0.91, 0.97, 0.93, 0.92, 0.97, and 1.00. This gives a final average, including all oils, of 0.945. The equation representing the force on the planer tool for all cutting fluids on the S.A.E. 3150 steel could then be expressed as

$$P = CD^{0.95}f^{0.79}$$

Taylor's formula for steel is $P = CDF^{14/15}$

It is seen from the above slopes of the constant-feed curves that some of the oils have values consistently high, while others have values consistently low. The average value for cutting fluids 2, 3, 7, 10, and 11 is 0.98, so that for these cutting fluids the planing-force equation becomes

$$P = CD^{0.98}f^{0.79}$$

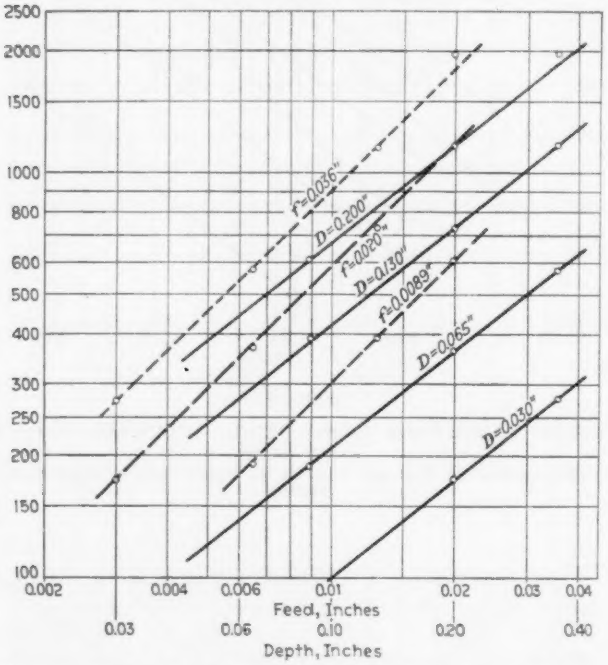

FIG. 40 PLANER-FORCE CURVES, S.A.E. 3150 STEEL—CUTTING FLUID NO. 11

(Values plotted are averages from curves drawn through experimental points.)

For the remainder of the cutting fluids consisting of 1, 4, 5, 6, 8, and 9 a value of 0.92 is obtained as the slope of the constant-feed curves, so that for these cutting fluids the planing-force equation becomes $P = CD^{0.92}f^{0.79}$.

Until further information is obtained for these various cutting fluids when cutting other metals, the general equation given above is considered satisfactory. Fig. 29 shows computed values determined from the first or general equation indicated as a cross on the solid-line curves for dry cutting, oil No. 1, and as a square on the dashed curves for which cutting fluid No. 10 was used. It is seen that these computed values as given by the general equation are very close to the curve obtained by smoothing out the experimental data. These are considered satisfactory in spite of the fact that cutting fluid No. 1 falls in the group having low exponents of depth, while cutting fluid No. 10 falls in the group of cutting fluids having the high exponents of depth.

Table 8 shows tabulated the force values on the planer tool for each combination of depth of cut and feed, for each of the cutting fluids. These values were read directly from the logarithmic curves of constant depth in Figs. 30 to 40, inclusive, for the respective cutting fluids. Numerical averages of corresponding values for oils 1 to 9, inclusive, are given at the end of the table. Differences between these averages and the values for any one of individual oils are seen to be very small.

The values of the force required to plane the S.A.E. 3150 steel as given in Table 8 are shown graphically in Figs. 41 and 42. The force values for each combination of depth of cut and feed are plotted as ordinates over the oil numbers as abscissas. The oil numbers are arranged in order of increasing torque in drilling as obtained from Figs. 12 and 14. It is to be noted that the force values for some of the oils are lower than others to the left on the same curve. The differences, however, are very small for the group of oils consisting of 2 to 9, inclusive. Considering the highest curve in Fig. 41, which is for a depth of cut of 0.200 in. and a feed of 0.036 in., the force for oils 4 and 5 is less than for oils 2 and 3, so that if the oils were arranged in the figure in order of increasing force, they would be arranged from left to right as follows: 10, 11, 5, 4, 8, 2, 6, 7, 9, 3, and 1. This indicates that dry cutting gives the largest force by a very narrow margin. Force values on the planer tool for additional combinations of cut and feed are given in Fig. 42.

By adding all the force values given for each oil in Table 8, a total sum is obtained as indicated in Table 9. Opposite this sum for each oil is listed the force on the planer tool required to remove a chip 0.130 in. in depth and 0.036 in. feed for the respective oils. It is seen that the sum for each oil is almost exactly ten times the value of the force for the 0.130-in. depth and 0.036-in. feed cut. This would indicate that the values given in Fig. 41 for this size of cut represent very closely a true force curve for the various oils.

Table 9 also lists the various values of the constant as determined from the general equation

$$P = C\,D^{0.95}\,f^{0.79}$$

[1] Sum of all forces given for each oil in Table 8.

[2] Force for 0.130 in. depth and 0.036 in. feed.

[3] Constant from general equation $P = CD^{0.95} f^{0.79}$

[4] D = depth of cut in inches; f = feed in inches.

in which P is the force on the planer tool in the direction of cut in pounds; C a constant depending on the material cut, the tool shape, and the cutting fluid used; D the depth of cut in inches; and f the feed per stroke in inches.

The Planer-Tool Chips

Representative chips retained from the various planing tests when cutting dry and with each of the cutting liquids are shown in Fig. 43. At the head of each vertical column is indicated the feed and set-up depth of cut in inches. The cuts taken were for four different set-up depths: 0.030, $^1/_{16}$, $^1/_8$, and $^3/_{16}$ in., respectively. For each depth, four feeds were used: namely, 0.004, 0.0089, 0.020, and 0.036 in., respectively. In some instances, chips were not obtained on the lightest feed. These tests were not run, inasmuch as it seemed that the force produced was too irregular to be considered reliable. The surfaces from which these chips were removed are shown in Figs. 26, 27, and 28.

It is obvious that the size and form of the chip is a function of the feed as well as the depth when cutting dry or with any of the coolants. When cutting dry, cutting fluid No. 1, there appears to be little evidence of heat, that is, chip coloration, except for the heaviest cut which had a depth of $^3/_{16}$ in., and a feed of 0.036 in. For all fluids and cuts there was a well-defined built-up nose on the cutting edge of the tool. For a feed of 0.004 in. and depths of $^1/_8$ and $^3/_{16}$ in., the chips appear to be in the form of small-diameter, low-pitch coils. The chips for the 0.004-in. feed and the $^1/_8$-in. depth are broken up for oil No. 3, but are continuous for the same feed and the $^3/_{16}$-in. depth of cut. The same condition applies for oils Nos. 9 and 10.

All chips from oil No. 10 are dark in color, apparently due to the action of sulphur rather than because of high temperatures. Most of these chips for oil No. 10 appear to be well broken up. This is of interest inasmuch as the force for oil No. 10 on all cuts is the lowest of similar cuts of all other fluids. The chips from oil No. 11 also were slightly brown, due evidently to the action of sulphur rather than high temperatures.

BEARING TESTS

A sample of each of the cutting fluids as used in the drilling tests was subjected to a lubrication test in order to determine the value of each of the cutting fluids as a lubricant. Dry lubrication was not included in these tests, although clear water was added.

These cutting fluids were tested on a bearing testing machine in which a journal rotates in a bearing. A new combination of journal and bearing was used for each test. The diameter of the journal was 1.000 in. The bearing was 1.007 in. in diameter and 1.000 in. long. Two sets of tests were run: one in which the journal was rotated at 25 r.p.m., and a second in which the journal was rotated at 100 r.p.m. The load in all cases was increased at a rate of 1000 lb. per sq. in. bearing pressure every 10 seconds.

Curves for each cutting fluid, which show the relation between the bearing pressure in pounds per square inch and the beam load on a lever arm 15.75 in. long, are given in Fig. 44 for 25 r.p.m. journal speed, and in Fig. 45 for 100 r.p.m. journal speed. Much greater loads are carried safely at the lower speed. The number adjacent to the curve indicates the number of the cutting fluid used. The curve ends at the point at which bearing seizure occurred. In Fig. 44, seizure occurred for cutting fluid No. 6 (light mineral oil) for a beam load of 300 lb. and a bearing pressure of 19,000 lb. per sq. in. for 25 r.p.m. of the journal. Fig. 45 shows that seizure occurred for oil No. 6 when the beam load was 130 lb. and the bearing pressure was 5000 lb. per sq. in. at 100 r.p.m. In Fig. 44 cutting fluids Nos. 5, 3, 2, 4, 11, and 10 caused the bearing to function satisfactorily up to and including the maximum load of 25,000 lb. per sq. in., at a speed of 25 r.p.m. Fig. 45 shows that for a speed of 100 r.p.m. none of the cutting fluids caused the bearing to function satisfactorily at a bearing pressure of over 14,000 lb. per sq. in. The actual bearing pressures at which seizure occurred for 25 r.p.m. and 100 r.p.m. are shown for each of the cutting fluids in Table 10.

Fig. 47 shows the journals at the completion of the tests referred to in Table 10. For the 100 r.p.m., seizure occurred in

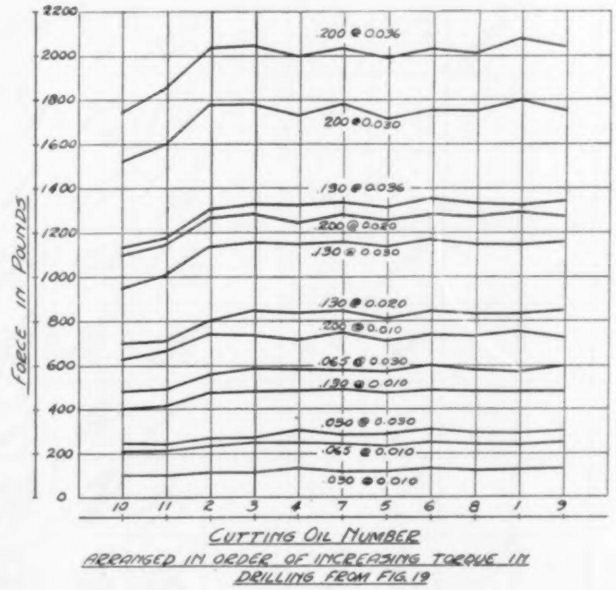

Fig. 41 Force Required to Plane S.A.E. 3150 Steel, Using Various Cutting Oils at Various Depths of Cut and Feeds

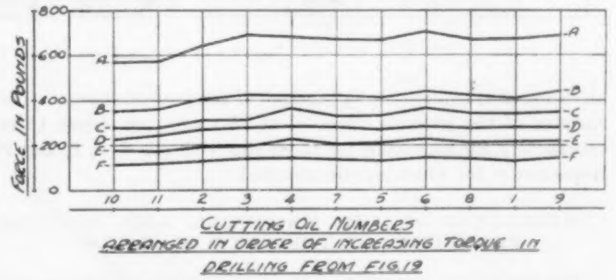

Fig. 42 Force Required to Plane S.A.E. 3150 Steel, Using Various Cutting Oils at Various Depths of Cut and Feeds (Depths (and feeds), inches: A, 0.065 (0.036); B, 0.065 (0.020); C, 0.030 (0.036); D, 0.130 (0.005); E, 0.030 (0.020); F, 0.065 (0.005).)

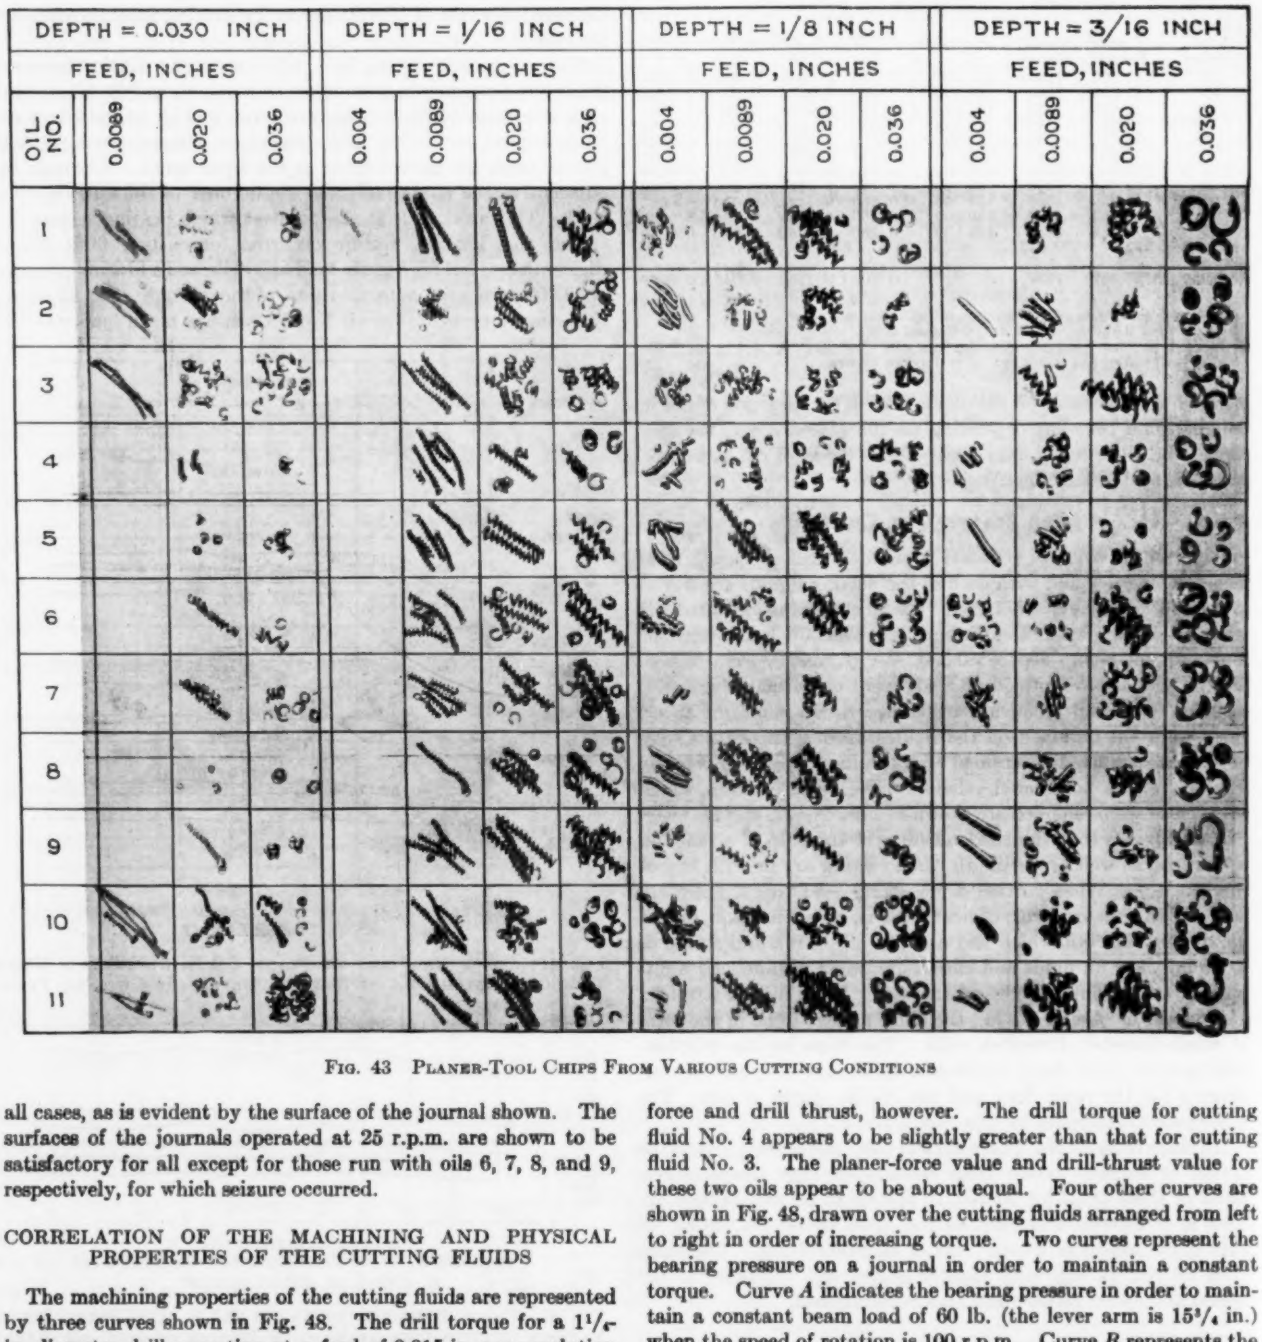

Fig. 43 Planer-Tool Chips From Various Cutting Conditions

all cases, as is evident by the surface of the journal shown. The surfaces of the journals operated at 25 r.p.m. are shown to be satisfactory for all except for those run with oils 6, 7, 8, and 9, respectively, for which seizure occurred.

CORRELATION OF THE MACHINING AND PHYSICAL PROPERTIES OF THE CUTTING FLUIDS

The machining properties of the cutting fluids are represented by three curves shown in Fig. 48. The drill torque for a $1^1/_4$-in.-diameter drill operating at a feed of 0.015 in. per revolution and a speed of 174 r.p.m. is shown plotted over the cutting fluids arranged in order from left to right of increasing torque. The thrust for the $1^1/_4$-in. drill corresponding to the torque curve is also shown plotted over each cutting fluid. The force on the planer tool in the direction of cut, when taking a cut 0.130 in. in depth by 0.036 in. feed, is shown plotted as being representative of the planer-force curves. These three machining curves by themselves show a rather close agreement.

In the drill-thrust curve, oil No. 6 shows a low value, whereas in the planer-force curve it shows an unusually high value. Also, oil No. 5, lard oil, shows a low value on the planer-force curve which seems to be out of proportion. These inconsistencies seem to occur for all other combinations of cut for the planer force and drill thrust, however. The drill torque for cutting fluid No. 4 appears to be slightly greater than that for cutting fluid No. 3. The planer-force value and drill-thrust value for these two oils appear to be about equal. Four other curves are shown in Fig. 48, drawn over the cutting fluids arranged from left to right in order of increasing torque. Two curves represent the bearing pressure on a journal in order to maintain a constant torque. Curve *A* indicates the bearing pressure in order to maintain a constant beam load of 60 lb. (the lever arm is $15^3/_4$ in.) when the speed of rotation is 100 r.p.m. Curve *B* represents the

TABLE 10 BEARING PRESSURES AT WHICH SEIZURE OCCURRED

Cutting fluid	Bearing pressure at which seizure occurs, lb. per sq. in. 25 r.p.m.	100 r.p.m.
Water	22,000	12,000
2	O.K.[1]	8,000
3	O.K.	11,000
4	O.K.	7,000
5	O.K.	13,000
6	19,000	5,000
7	23,000	7,000
8	19,000	8,000
9	17,000	6,000
10	O.K.	14,000
11	O.K.	11,000

---

[1] O.K. means that seizure had not occurred at the maximum load of 25,000 lb. per sq. in.

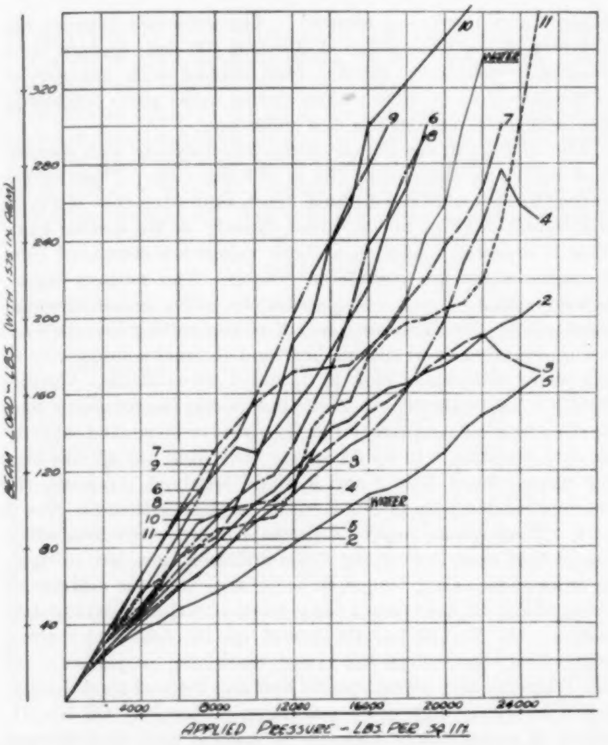

FIG. 44 BEARING-TEST CURVES FOR VARIOUS CUTTING FLUIDS (25 r.p.m. Load increased 1000 lb. each 10 sec. Journal 1 in. in diameter; bearing 1 in. long.)

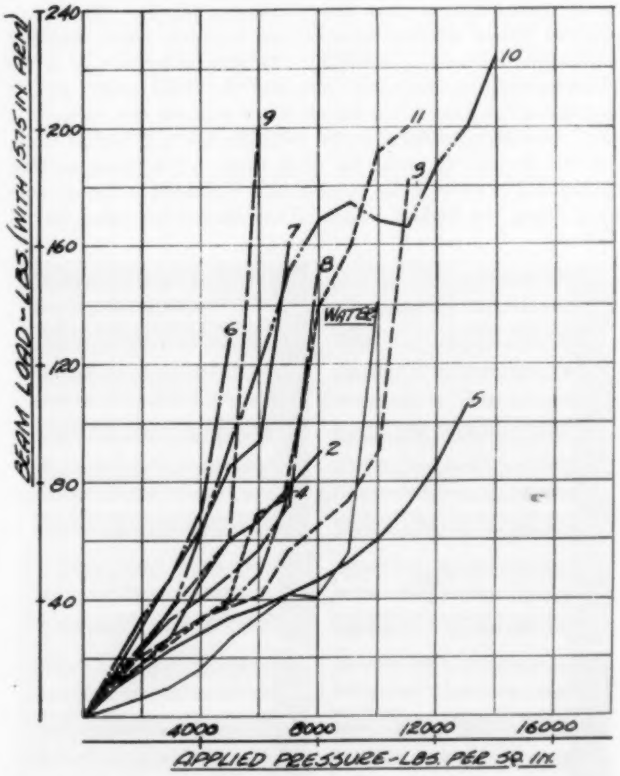

FIG. 45 BEARING TEST CURVES FOR VARIOUS CUTTING FLUIDS (100 r.p.m. Load increased 1000 lb. each 10 sec. Journal 1 in. in diameter; bearing 1 in. long.)

bearing pressure on the bearing in order to maintain a constant beam load of 160 lb. when the speed is 25 r.p.m. These two curves are very similar except for a few points. Values on curves *A* and *B* are close together for cutting fluids 10, 7, and 9. For oil 9, a lower bearing pressure is required to produce a 60-lb. beam load at 100 r.p.m. than to produce a 160-lb. beam load at 25 r.p.m.

Another curve in Fig. 48 represents the value of beam load at a journal speed of 25 r.p.m. in order to maintain a constant bearing pressure of 8000 lb. per sq. in. This curve appears to be the reciprocal of curve *B* which represents the bearing pressure for a journal speed of 25 r.p.m. in order to produce a constant beam load of 160 lb. It also appears to be more closely the reverse of curve *A*, which represents the bearing pressure at a journal speed of 100 r.p.m. for a constant beam load of 60 lb.

A curve representing the viscosity of each oil at 280 deg. fahr. is also shown in Fig. 48. This viscosity curve seems to follow the bearing-pressure

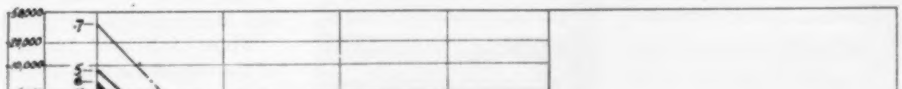

FIG. 46 TEMPERATURE-VISCOSITY RELATIONSHIP FOR CUTTING FLUIDS NOS. 5 TO 11, INCLUSIVE

curve better than it does the machining curves. There appears to be no relation between the viscosity curve and the drill-torque curve, for example. The only indication of a relation between the viscosity curve and the drill-thrust curve is that the drill-thrust is low for oil No. 6, whereas the viscosity is low. In the planer-force curve, both oils 5 and 6 appear to be out of order, as the point for oil 5 would fall between cutting fluids 2 and 3, whereas the value of oil 6 would fall at the extreme right, being the highest value. The planer-force value for oil 5 is low, while the beam load at 25 r.p.m. and a constant bearing pressure of 8000 lb. per sq. in. is low, and the viscosity and bearing pressures for constant beam load are high. The reverse is true for oil No. 6.

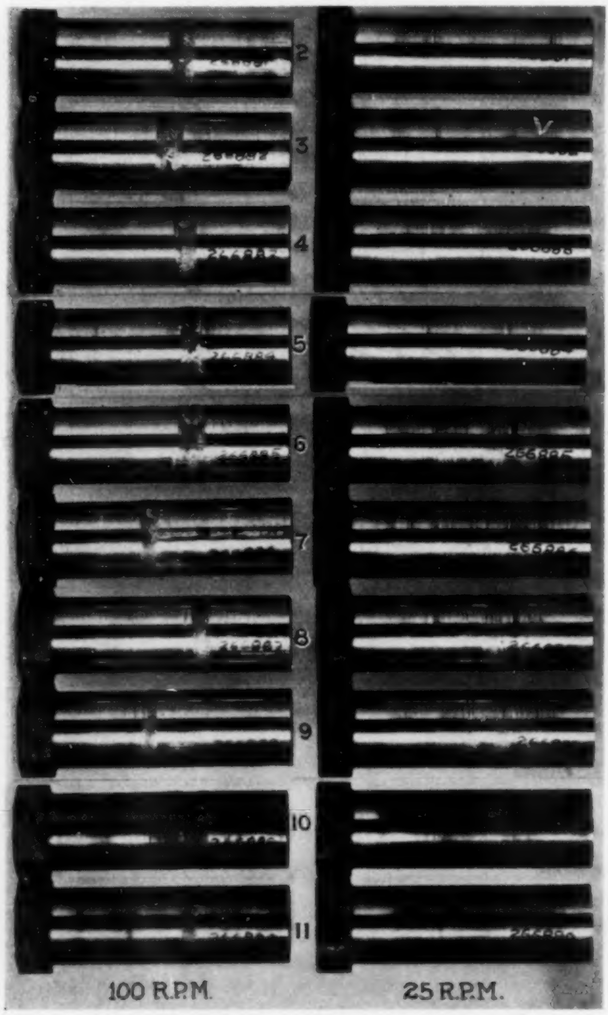

Fig. 47 Journals Used in Bearing Tests
(Figures at right refer to the cutting fluids used.)

The viscosity of the various oils used in the cutting tests at 100 deg. fahr. and 210 deg. fahr. is shown plotted in Fig. 49. The curve for viscosity at 210 deg. has no values for cutting fluids 2, 3, 4, and 1. The curve as shown has the same general shape, however, as the viscosity curve in Saybolt seconds for the oils at 280 deg. fahr., as shown in Fig. 48. The curve connecting the points of viscosity at 100 deg. fahr. is somewhat different, however. Viscosity values in Saybolt seconds for the soluble oils 3 and 4 are included in this curve, so that values for cutting fluids 2 and 1 only are omitted. The difference between the viscosity of the various oils at 210 and 100 deg. appears to be practically constant. Further tests dealing with the subject of temperatures developed when cutting under given conditions, but using these various oils, are under way.

Also in Fig. 49 are shown thermal-conductivity and specific-heat curves for the various oils at 210 deg. fahr. These curves appear to be a constant distance apart, indicating that the thermal-conductivity of an oil varies directly as its specific heat. This is expected inasmuch as both values are computed from formulas which are considered reliable. The authors regret, however, that it was not possible to make actual thermal-conductivity determinations for all of the cutting liquids used. No information as to specific heat and thermal conductivity of the water compounds Nos. 2, 3, and 4 are available. Cutting fluid No. 2 appears to have merits in reducing the force on a tool, or the power consumption, either by virtue or its cooling capacity or its lubrication. It would appear that while the specific heat for cutting fluids Nos. 2 and 3 would be about the same, the thermal conductivity of No. 2 would be greater than for Nos. 3 or 4. These specific-heat and thermal-conductivity curves which are plotted over the cutting fluids arranged from left to right, in order of increasing torque, in accordance with the drill-torque curve of Fig. 48, have only a vague relation to the machining-data curves. Oil No. 10 has the lowest specific heat and thermal conductivity as well as the lowest machining properties. Oil No. 6 has the next lowest specific heat and thermal conductivity, but is relatively high in its machining properties. Oil No. 11, which is exceptionally high in its specific heat and thermal conductivity, is exceptionally low in its machining properties. Also oils 8 and 9, which have high specific-heat and thermal-conductivity values, have the highest machining properties. Oils 7, 5, and 6, however, seem to be exceptions to the rule, inasmuch as they have low values of specific heat and thermal conductivity, but high machining properties.

Three additional curves representing lubricating properties of the various cutting oils are shown in Fig. 50. The upper curve *C* shows the bearing pressure exerted at the seizing point for the journal rotating at 100 r.p.m. This shows oils No. 10 and 5 to have approximately equal values and they are the highest of all. Cutting fluid No. 3, which is one part soluble oil in 50 parts of water, appears to be third best. The bearing pressure for cutting fluid No. 4, which is one part soluble oil to ten parts of water, is considerably lower than the value for oil No. 3. The values of the water compounds Nos. 2 and 4 appear to compare favorably with the corresponding values of the oils 7, 6, 8, and 9, which seems rather hard to explain. Small circles over cutting fluids Nos. 7, 6, 8, and 9 represent the values of bearing pressure in pounds per square inch at which seizure occurred when the journal was rotating at 25 r.p.m. Oils 7 and 6 have seizing pressures for 25 r.p.m. considerably above those for 100 r.p.m., whereas the seizing pressures for oils Nos. 8 and 9 at 25 r.p.m. are correspondingly lower.

Two beam-load curves are shown in Fig. 50 which represent for each oil the beam load at a radius of 15$^3/_4$ in. in curve *A* for a 4000-lb. bearing pressure and a journal speed of 100 r.p.m. and in curve *B* for a constant bearing pressure of 17,000 lb. for a journal speed of 25 r.p.m. The beam load representing the torque shows that the lowest torque or friction in the bearing is obtained for oil No. 5 (lard oil) in each curve. Oils Nos. 3 and 4 seem to provide the next lowest frictional loss. For the high speed of 100 r.p.m. the sulphurized lard oil No. 11 is very low, having a value equal approximately to that of cutting fluids Nos. 3 and 4. At the lower speed of 25 r.p.m. cutting fluid No. 11 has a value equal to that of No. 7, and considerably higher than the values for cutting fluids Nos. 2, 3, and 4. For the low speed of 25 r.p.m.

the beam load for oil No. 10 is slightly higher than that of oil No. 9, and yet in the machining curves oil No. 10 is shown to be superior in every case to all other oils. From curve *A*, representing beam-load values for a 4000-lb. load on the journal rotating at 100 r.p.m., the beam load for cutting fluid No. 10 is about equal to that of No. 7 and slightly less than that of No. 6. Nos. 10, 7, and 6, however, give the greatest beam loads. This does not seem to conform in any way with the results of the machining tests.

·CONCLUSIONS

Conclusions as to the results of the metal-cutting tests and the attempt to correlate the physical properties of the oils, with the results of the cutting tests, may be summarized briefly as follows:

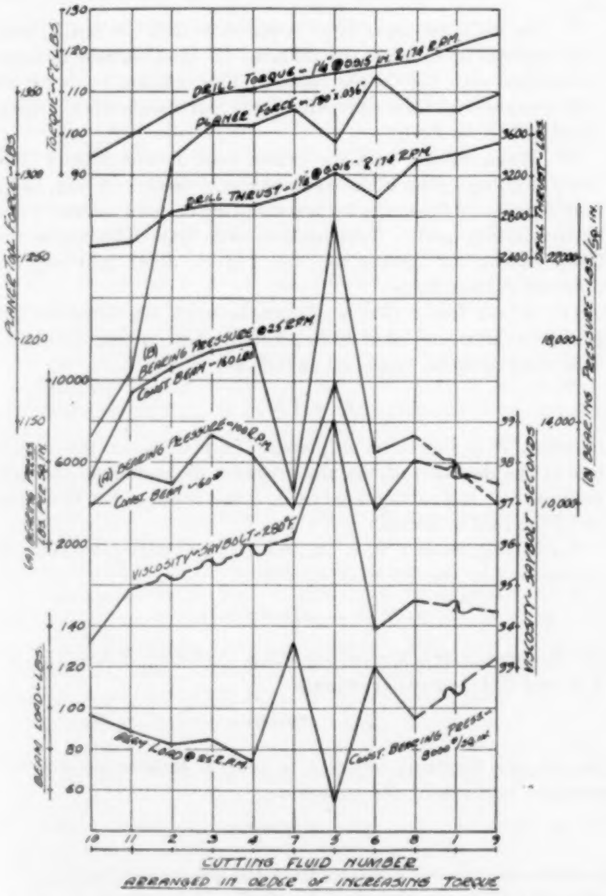

FIG. 48 MACHINING AND PHYSICAL PROPERTIES OF THE CUTTING FLUIDS

1 A newly sharpened drill produces a torque somewhat below its normal value during the first few inches of metal drilled. A normal value, or the value at which the torque remains practically constant for a considerable period of cutting, is reached sooner for a large drill diameter operating at a heavy feed than for a small drill diameter operating at a comparatively light feed. With this point in mind, newly sharpened drills were first used to drill several inches of metal before being used in tests.

2 The increase in torque and thrust appears to be less marked when drilling to almost the endurance limit of the drill if the cuts are made dry rather than with a cutting liquid. The torque and thrust are lower at the beginning of the cut when a coolant is used, but both the torque and thrust increase in value faster than when the cutting is done dry. The torque and thrust seem to be higher just before tool failure occurs, that is, after drilling many inches of metal, when a cutting fluid is used, than when cutting dry. These are conclusions which require further proof.

3 The formula representing the torque as a function of the material cut, the feed, and the drill diameter was found to be

$$T = Cf^{0.78}d^{1.8}$$

in which *T* is the torque in foot-pounds, *C* a constant depending

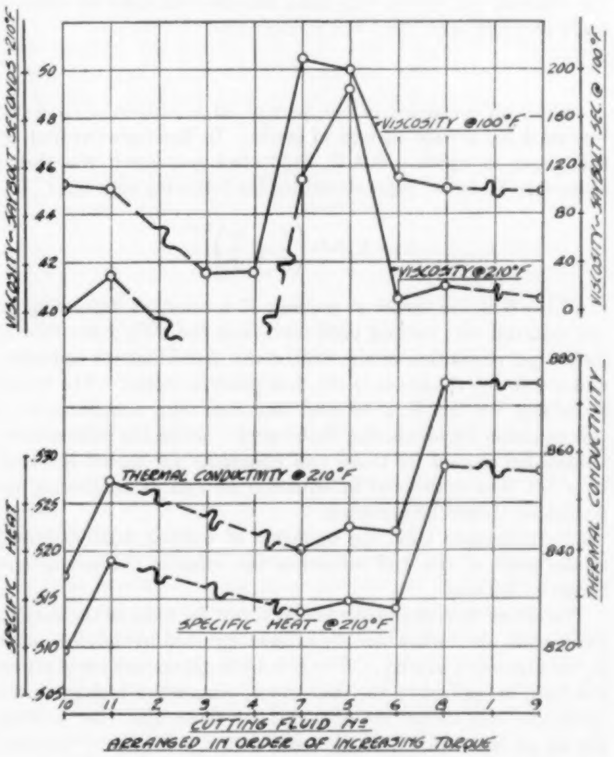

FIG. 49 PHYSICAL PROPERTIES OF THE CUTTING FLUIDS

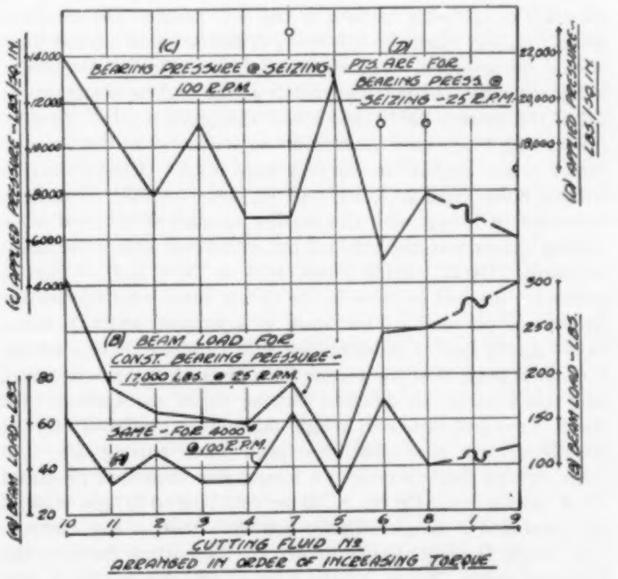

FIG. 50 PHYSICAL PROPERTIES OF THE CUTTING FLUIDS

on the material cut, the drill used, and the cutting fluid, f the feed in inches per revolution, and d the drill diameter in inches. This equation seems to hold for many types of steel and all cutting fluids used in the test.

4 In previous tests a formula for thrust as a function of the material cut, the cutting fluid, and the drill used for various feeds and drill diameters was found to be

$$B = Kf^{0.78}d$$

A soluble oil consisting of one part of oil to sixteen parts water was used for a wide variety of steels. In the tests covered by this paper in which a S.A.E. 3150 steel was used, the thrust seemed to be better represented by the following equation:

$$B = Kf^{0.87}\left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

in which B is the thrust in pounds, K a constant depending on the material cut, cutting fluid used, and the drill, f the feed in inches per revolution of the drill, d the drill diameter in inches, and w the web thickness at the drill point in inches. The thrust in drilling the S.A.E. 3150 steel conforms very satisfactorily to this equation for all cutting fluids used. While the difference in values determined by these two equations for thrust is small, it is felt that additional information as well as confirming information should be obtained.

5 It appears that the quantity of cutting fluid delivered at the point of the drill influences the value of the torque and thrust as follows:

The lowest torque and the lowest thrust for most of the cutting fluids were obtained when the oil was supplied to the drill point in the greatest quantity. If only a little oil, enough for continuous flow, is applied to the drill point, somewhat higher values of torque and thrust are obtained for most oils. By pouring the oil on the drill above the work at the point where the drill penetrates the work, values of torque and thrust are obtained which correspond quite favorably to the condition of a small quantity of oil being applied to the drill point. The torque is usually highest when the hole being drilled is full of oil, but when none is being added. The above would indicate that the torque is highest when the cutting fluid is at the highest temperature. All of the cutting fluids used follow this general rule. Some of the cutting fluids have practically no influence on the value of thrust when applied in varying quantities. Others, such as cutting fluids Nos. 2, 4, 10, and 11, seem actually to cause a reduction in thrust with the smaller amount of oil, and when drilling is done with the hole full, but with no oil added, the thrust is lowest. Other cutting fluids, such as Nos. 5, 6, 8, and 9, produce a marked increase in the thrust value with the smaller amount of oil used. This again is a subject which it seems would justify further investigation with a more elaborate set-up.

6 It appears that the torque for a given drill diameter, feed, and speed varies as different cutting fluids are applied. Oil No. 9 (5 per cent oleic acid in light mineral oil) produced a torque slightly greater than that developed when cutting dry. All other cutting fluids produced a torque less than that produced when cutting dry. Oil No. 8 (10 per cent lard oil in light mineral oil) produced a torque slightly less than that of dry cutting. The torque is reduced still further for the cutting fluids in the following order: No. 6 (a light mineral oil), No. 5 (No. 1 lard oil), No. 7 (a heavy mineral oil), No. 4 (a 1 to 10 soluble oil), No. 3 (a 1 to 50 soluble oil), No. 2 ($1^1/_2$ per cent borax in water), No. 11 (sulphurized-lard mineral oil), and lastly, oil No. 10 (a sulphurized mineral oil). The two sulphurized oils give the lowest values of torque under all conditions. The fact that the borax water gives the third lowest torque might indicate that the cutting fluid exerts a cooling influence rather than one of lubrication.

7 The order of the oils when arranged in order of increasing torque for a given drill diameter, feed, and speed, remains the same for all drill diameters at their respective feeds and speeds.

8 The thrust on a drill operating under given conditions of speed and feed varies in accordance with the specifications of the cutting fluid used. The thrust is reduced with the oils arranged in the same order as when the torque is reduced, except for oil No. 6 (light mineral oil), which seems to produce a thrust somewhat below the expected value for all drill sizes. The thrust for this oil is considerably less than that produced by oil No. 5, lard oil, and slightly less than that for oil No. 7, a heavy mineral oil.

9 The net horsepower input required to drill the S.A.E. 3150 steel appears to vary for the different oil specifications in exact accordance with the torque values. This relation holds for all drill diameters at their respective feeds and speeds when drilling the S.A.E. 3150 steel.

10 When cutting with the planer tool, it was noticed that every chip, regardless of the combination of depth and feed, had a built-up edge on the tool point when cutting dry and with all of the cutting liquids used. There appears to be little difference in the finish left by the cutting tool for a given depth and feed for different cutting fluids.

11 It was found that a relation between the force on the planer tool at the speed of 20 ft. per min. when cutting the S.A.E. 3150 steel could be expressed as follows:

$$P = CD^x f^y$$

in which P is the force or pressure in pounds on the planer tool in the direction of cut, C a constant depending on the tool, material cut, and cutting fluid used, D the depth of cut in inches, and f the feed in inches.

For cutting fluids 2, 3, 7, 10, and 11, this relation was closely represented by the following equation:

$$P = CD^{0.98}f^{0.79}$$

For the remainder of the cutting fluids consisting of Nos. 1, 4, 5, 6, 8, and 9 this equation becomes

$$P = CD^{0.93}f^{0.79}$$

For all oils together, however, a general satisfactory relation seems to be given by the equation

$$P = CD^{0.95}f^{0.79}$$

in which the value of C ranges from 108,200 for cutting fluid No. 10 to 129,100 for cutting fluid No. 9 (See Table 9).

12 In planing with any given cut there appears to be little difference in the planing force for the cutting fluids as a group with Nos. 10 and 11 omitted. For this same group, the drilling torque and thrust for all drill diameters at their respective feeds and speeds showed a definite influence of the cutting fluid.

13 The curve representing the values of drill torque over the cutting fluids seems to conform very closely to the curves representing planer force and drill thrust; that is, the properties of the cutting fluids seem to be equally well represented by any one of the machining-data curves.

14 The torque or beam-load curves, representing the frictional resistance of any cutting fluid used as a lubricant in a bearing, show similar characteristics for various speeds and loads. The beam-load curve at 25 r.p.m. for a constant pressure of 8000 lb. shown in Fig. 48, when plotted to the same scale as the beam-load curve for 25 r.p.m. and 17,000 lb. bearing pressure shown in Fig. 50, appears to be much more horizontal. The

beam load for the first five cutting fluids at the left consisting of Nos. 10, 11, 2, 3, and 4 present nearly a horizontal line. The values for all of these five cutting fluids are lower than all other values, except that for oil No. 5. Except for oils Nos. 10 and 11 these beam-load curves show an approximate relation to the machining-data curves.

15 The bearing-pressure curves at a given r.p.m. and constant beam load seem to show no relation to the machining-data curves.

16 The oil viscosity curves at various temperatures show similar characteristics. Lard oil and those oils containing as little as 10 per cent lard oil show a tendency to change their viscosity less for a given change of temperature than the other oils. The slopes of the viscosity-temperature lines for oils Nos. 5, 8, and 11 in Fig. 46 are less than the others.

17 The bearing pressures required to cause seizing of the bearing when plotted over the cutting-fluid numbers arranged in order of increasing torque from left to right, show a general slope downward to the right for speeds of 25 and 100 r.p.m. While the curve for bearing pressures for a journal speed of 100 r.p.m. fluctuates a great deal, it slopes down generally to the right, whereas the machining curves slope generally up to the right. This might indicate that those oils which permit seizing at a low pressure produce high power consumption in metal cutting.

18 The specific-heat and thermal-conductivity curves shown in Fig. 49 appear to be of no assistance in the solution of the metal-cutting problem. The fact that the sulphurized oil No. 10 has the lowest specific heat does not seem to agree with the fact that it produces the lowest power consumption in metal cutting, particularly in view of the fact that the borax water which presumably would have the highest specific heat also produces a very low power consumption.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to Messrs. Charles E. Kraus, R. Paul Harrington, and William V. Foster, who ran the tests and prepared the data for final analysis.

Materials for the project in the form of drills, planer-tool bits, and cutting fluids were furnished gratis by National Twist Drill and Tool Company, Detroit; Columbia Tool Steel Company, Chicago; Standard Oil Company of Indiana, Chicago; Sun Oil Company, Philadelphia; Atlantic Refining Company, Philadelphia; Swift & Company, Chicago; D. A. Stuart Co., Chicago.

The authors wish also to express their appreciation to Mr. H. J. Saladin, of the Standard Oil Company of Chicago, and to Mr. W. C. Mitchell, of the General Motors Company, Detroit, for many valuable suggestions received and for furnishing experimental data dealing with physical properties of the oils.

The funds for carrying out this project were made available to The American Society of Mechanical Engineers by the Engineering Foundation. These funds then were turned over to the Department of Engineering Research of the University of Michigan, where the work was conducted as a research project under the direct supervision of the Subcommittee on Cutting Fluids of the A.S.M.E. Special Research Committee on the Cutting of Metals. The experimental work was carried on in the Department of Engineering Shop of the University of Michigan.

Discussion

F. T. HARRINGTON.[3] This paper is a valuable piece of engineering investigation, and the limited field that it covers serves to emphasize the enormity of the task which confronts the Subcommittee on Cutting Fluids of the Society's Special Research Committee on the Cutting of Metals. The paper covers very completely the effects of the commonly used cutting fluids on the power required to drill and plane this one material, i.e., annealed S.A.E. 3150 steel.

The writer will attempt to confine his discussion to a few questions relative to the paper.

(1) What explanation can be offered for the fact that both torque and thrust increase more rapidly during the first 70 in. of drilling when No. 4 cutting fluid is used than when drilling dry? This is covered by graphs in Figs. 6 and 5 and on the sixth page of the text. This is also mentioned in conclusion 2.

	Dry	With oil No. 4
Thrust of 1-in. drill at start of test, lb.	1790	1700
Thrust of same at end of 70-in. drilling, lb.	1900	1925
Torque of 1-in. drill at start of test, ft-lb.	72.5	67.5
Torque of same at end of 70-in. drilling, ft-lb.	74.5	72.0

(2) The two endurance or "breakdown" tests just cited confirm actual practice, for it is common knowledge that the life of a drill is prolonged by the presence of a cutting oil as compared with running dry, but they also show that the drill can be run at increased torque and thrust loads without failure because of some property of the cutting fluid used.

(3) The paper points out that the formulas derived for torque and thrust when using oil No. 3 by the method illustrated in Fig. 7 and explained on the sixth and seventh pages, are not theoretically correct for all of the other cutting compounds used when drilling S.A.E. 3150 steel. Are these formulas sufficiently accurate for other steels? It is stated in item (3) in the conclusion that the equation for torque seems to hold for many types of steel. Were any tests conducted using other steels to verify this conclusion? Is it believed that these formulas will hold for cast iron or nonferrous metals? Will the formulas be applicable for other cutting compounds and other ratios of coolant constituents? Based on the findings to date, do the authors expect the constants and factors for torque values as listed in Table 3 to apply when the respective coolants are used with other steels?

(4) Will the research project be extended to cover other coolants and other proportions of the coolant constituents already used, in an effort to determine what combinations approach the ideal compound for the material and machining method employed?

(5) Is the formula for torque ($T = Cf^{0.78}d^{1.8}$) applicable at peripheral drilling speeds other than 60 ft. per min.? Were any tests made to confirm this fact? This question is asked because in most instances where the formula is shown, reference is made to the cutting speed of 60 ft. per min. Is cutting speed necessarily an essential factor in the torque formula or does it only enter into power considerations?

(6) How was the slope of the expression $(d/5+W/d)$ determined in Fig. 7 where it forms a part of the line represented by the equation $B \sim (d/5 + W/d)^{2.12}$?

(7) What explanation may be given for the fact that values of gross horsepower for oil No. 8 as represented graphically in Fig. 19 and in Table 6 are greater than for compound No. 1 when computed values for both torque and thrust for No. 1 fluid exceed those for No. 8?

(8) These remarks will not include the portion of the paper devoted to the planer tests, but the writer would like to inquire as to whether the cuts showing examples of the planer work contained in Figs. 26, 27, and 28 are to exact size. With reference to these same cuts, the text on the fifteenth and sixteenth pages explains that both Figs. 26 and 28 show the start of the tool cut. What explanation may be offered for the fact that with a depth of cut of $^1/_8$ in., as used in Fig. 28, there is little indication of the tearing of the metal at the start of the cut when compared with the pronounced condition along the lower edge of Fig. 26? The text also explains that the lower edge of Fig. 17 represents clearly how the chips where broken off at the end of the cut, but the photo-

---

[3] Whitman & Barnes, Inc., Detroit, Mich.

graph from all appearances is the same along both edges. What does the text have reference to in this instance? It appears that the lower edge of Fig. 26 is the finish of a cut and shows how the tool breaks out of the steel.

(9) Based on tests using the oil-hole drill, conclusion 5 states that, with certain mentioned exceptions, the application of large quantities of coolant tends to reduce the torque and thrust together with the heat produced by drilling. What explanation could be given for the tendency for borax water (No. 2 compound) to show the exact opposite results in so far as thrust to this more general axiom? This is illustrated in Fig. 11.

(10) In the lubrication tests cited, from what materials were the bearings and journals made? Would the tests have been of more value if the journals were made of hardened high-speed steel and the bearing of the annealed S.A.E. 3150 material?—if the journal had been revolved at 231 r.p.m. or 60 f.p.m. to approximate a 1-in.-diameter drill? Were the bearings completely immersed in the oil during the test?

(11) In the first part of the twenty-third page, in a comparative discussion of constant beam loads and variable bearing pressures, the statement is made, "For oil 9, a greater bearing pressure is required to produce a 60-lb. beam load at 100 r.p.m. than to produce a 160-lb. beam load at 25 r.p.m." This statement is in error, because data taken from the curves on Figs. 44, 45, and 48 show the bearing pressure to be 10,000 lb. for the 160-lb. beam load at 25 r.p.m. and 5000 lb. for the 60-lb. beam load at 100 r.p.m. This statement no doubt originated from the fact that the two constant beam-load curves cross on Fig. 48, but they are plotted to different scales.

(12) From the constant bearing pressure curves in Fig. 50 it appears that No. 10 oil is among the poorest oils in so far as lubricating qualities are concerned, and yet it withstands the greatest bearing pressure before seizure, and also is the best coolant for drilling because it gives minimum values for torque, thrust, and power. How can the high bearing pressure at seizure be associated with the poor lubricating qualities of this oil?

In conclusion 17 it is stated that the seizure curve indicates that oils which permit seizure at low pressures produce high power consumption during drilling. This deduction appears to be quite logical. Could this fact be associated with a tendency for the material being drilled to build up on the cutting edges and margins of the drills while working, which might be compared with a similar action which takes place in bearing seizure? The photograph in Fig. 47 shows this action in the case of journals used during the bearing tests. If this reasoning is correct, then the coolant, which in this project proves to be No. 10, that withstands the highest bearing load before seizure, will tend to keep the steel being drilled from building on the cutting edges and margins, which in turn would roughen these surfaces and increase torque and power during drilling.

(13) It might be suggested that an attempt be made to determine torque, thrust, and power values for drilling when the drill approaches the point of failure or "breakdown" instead of when it is newly pointed. It is believed that the project might have more practical value if these characteristics were secured when the drill approached a "dull" condition, because it is these maximum values, as acknowledged in conclusion 2, that would benefit machine-tool design. It is appreciated that this would increase the work on the project tremendously, but the writer is merely making the suggestion for what it is worth. In this same connection the determination of the cutting fluid which gives ultimate tool life would be of considerable value from a practical standpoint.

(14) The writer might also suggest that during the course of further investigations of cutting fluids less attention be directed to planing, as the majority of planing and shaping is done without a coolant. For this reason it is believed that the project would be of greater value if more emphasis were placed on the common methods of machining metals where coolants are normally used in practice. These include turning, milling, and drilling.

C. H. Casberg.[4] This is a very interesting and valuable paper and the authors should be commended for their good work.

On the eighth page, second column, middle of second paragraph in the sentence, "The values of the thrust as shown in Fig. 10 show a tendency to increase in value," it is believed that a typographical error has been made, and it should read, "The values of the torque," etc. [Corrected.]

It would have been better to have left out the discussion on what the authors call "net power input."

On the bottom of the thirteenth page and the top of the fourteenth it is explained what is meant by the "net power input."

The tare power is obtained by running the machine at the speed and feed and the reading taken of the wattmeter. If the authors assume that this is all power consumed by the machine while drilling, the assumption is not correct. In fact, as soon as the drill starts cutting at this given speed and feed the machine consumes more power because the load on the bearings and the gears increases. Losses in the motor also change with the load.

The power consumed by the machine if the machine is loaded to its capacity will be surprising because thrust of the drill will cause some of the bearings to be thrown out of alignment. If the authors wished to obtain the power at the drill point, it should have been computed from the torque and thrust. By using the values of the torque and thrust given in Tables 3 and 5 the power consumed at the drill point can be computed. The power consumed by the drill point of the $^1/_2$-in. drill is, approximately, for oil No. 10, 1.05 hp. The net horsepower for oil No. 10 in Table 7 is 1.174, or a difference in power consumption of about 0.12 hp.

The net power as shown in Table 7 for oil No. 10 for the $1^1/_4$-in. drill is 4.081, while the power consumed at the drill point is approximately 3.14, a difference of approximately 1 hp.

For oil No. 9 from Table 7 the net horsepower is 5.544 hp. and the power at the drill point is approximately 4.15 hp., a difference or about 1.4 hp., which goes to show the greater the load on the machine the more power loss in the machine due to friction of gears and bearings and distortion of the machine. The curves of net power (Fig. 22) pertain only to the machine upon which the tests were run and would not be of much value if applied to other machines. If the values of the power at the drill point were plotted on this curve, it is doubtful if the curves would be a straight line.

The foregoing is of minor importance compared with many interesting facts brought to light by this paper.

Fred H. Colvin.[5] One factor which affects the performance of cutting fluids and many other things is imagination on the part of the operator or foreman, or both. There are many instances where putting the same fluid in a different container has made it either much better or decidedly worse than it was before, in the opinion of the operator.

Authors' Closure

By O. W. Boston. The authors are indeed pleased to note the interest in this investigation as evidenced by the numerous and valuable comments. They wish to express their appreciation for those who have assisted in bringing out points which were not clear or in emphasizing various phases of the paper, or in adding the results of their own experiences.

[5] Editor, *The American Machinist*, New York, N. Y. Mem. A.S.M.E.

The discussion by Mr. F. T. Harrington raises a number of points, which are answered corresponding to the question numbers as follows;

(1) The fact that torque and thrust values increase more rapidly when drilling with cutting fluid No. 4, 1 to 10 soluble oil, than is the case when drilling dry, cannot be explained at this time. The results as shown in Figs. 5 and 6, together with those in Fig. 4, appeared sufficient for the purpose for which they were intended; that is, to determine how long a drill may be used and still be considered sharp. The two similar dulling tests referred to, as shown graphically in Figs. 5 and 6, were run with different drills, both 1 in. in diameter, the "R" drill being used for the cutting dry test and the No. 44 drill for the tests with the No. 4 cutting fluid. The drills were nearly identical in shape, and the authors feel that the variance in results is due to the difference in cutting fluids used rather than any difference between the drills. The results indicate that while the torque and thrust values are less at the start, there is a greater rate of increase when the No. 4 cutting fluid is used than when cutting dry. The authors feel that extensive tests to determine the influence on the rate of dulling of various cutting fluids would be of considerable value applied to drilling, inasmuch as technical information regarding this subject as well as that of drill life is inadequate. The limited funds available for this project did not permit diverting too freely from the main object of the paper.

In some recent tests comparing the cutting qualities of the same 11 cutting fluids used in these tests, a hacksaw was used. It has been found that the time required to saw a given specimen increases at varying rates as the saw dulls, using the different oils. With the data so far at hand, the conclusion is reached (perhaps prematurely) that borax water (cutting fluid No. 2) has more effect than all other cutting fluids in increasing the time required to saw a given cross-sectional area. These results will be presented later.

(2) No comment necessary.

(3) The equations given for torque and thrust have been found to hold quite accurately for some 18 carbon and alloy steels. The derivation of these formulas was presented in two previous papers by the authors—"Power Required to Drill Cast Iron and Steel," Trans. A.S.M.E., MSP-52-2, January to April, 1930, and "Torque, Thrust, and Power for Drilling," *Jour. S.A.E.*, Vol. 28, No. 3, March, 1931. These formulas do not hold for cast iron or malleable iron, non-ferrous or non-metallic materials, each of which seems to have formulas characteristic of the materials. For drilling and in general for planing and milling, the effect of the cutting fluid used is only to change the constants in the equation as long as the material is constant. The exponents of feed and depth of cut do not change. When materials other than S.A.E. 3150 steel are cut, a different order of the oils is found which indicates the ease of machinability, and different constants and factors are therefore necessary. (A report of results on a wide variety of metals being drilled with each of the 11 cutting fluids is now in preparation and will be published soon.)

(4) It is intended, if funds permit, to extend in the near future the investigation to other coolants in the hope of learning more of the influences of various constituents.

(5) Torque and thrust are independent of speed, as reported on in the paper MSP-52-2. In order that the so-called commercial tests might be made on a basis comparable to commercial practice, the drills of different diameters were all rotated to give a peripheral speed as near as possible to 60 ft. per min. Other tests, however, in which the speed was varied from 74 to 500 r.p.m. for various drill diameters indicate that the torque and thrust remain constant throughout this range. When power such as net power output is considered, however, the speed must be known, inasmuch as the power varies directly as the speed. The torque times the angular velocity of the drill gives about 99 per cent of the net power output.

(6) The exponent of a variable is found by taking a tangent of the angle made by the line through the experimental points plotted on log-log paper with the horizontal. The expression $(d/5 + W/d)$ was determined by the cut and try method.

(7) Differences in gross horsepower as determined on the wattmeter usually can be traced to an error in reading the value on a comparatively small scale. Also, frequently the datum line of the wattmeter varies between one test and another. These errors usually are small. Often the zero reading on the wattmeter changes slightly because of the weight of the ink in the pen and the friction between the pen and the chart. The consistency of the grease and oil used in lubricating the motor and drill press as affected by temperature and use affect the input power value. In our experience, the wattmeter readings are not as accurate as those representing the output power at the drill point, such as the torque and thrust.

(8) The photographs represented by Figs. 26, 27, and 28, as given in the preprinted paper, were mixed and also mutilated. These have been corrected and now agree with the comments on the manuscript.

(9) The author's knowledge of this phenomenon is confined to the experimental data presented, and no additional explanation can be given at this time.

(10) The pins and bearings used in the lubrication tests were made of carburized low-carbon steel hardened and ground. Changes in composition of the steel, according to other tests in the laboratories of the General Motors Corporation, would make very little difference in the results, providing the steel was hardened to an equal degree in all cases. If the steel should be run against other materials, such as bronze or cast iron, the results would be radically different.

(11) Mr. Harrington's statement is correct, inasmuch as Fig. 44 shows that for a 160-lb. beam load at 25 r.p.m., the applied pressure is 10,000 lb., whereas for a 60-lb. beam load for oil No. 9 at 100 r.p.m., as indicated in Fig. 45, it is about 5000 lb.

(12) The fact that oil No. 10, a sulphurized mineral oil, gives the greatest pressure at seizure indicates good lubricating qualities, while the fact that it gives almost the highest beam load for a 17,000-lb. bearing load at 2500 r.p.m. indicates that this is a poor lubricant. It apparently follows that two things are involved—frictional resistance and oil film. The oil appears to be good from the fact that it does maintain an oil film at high pressure, but it is poor from a power-lubrication standpoint. This may be due to the condition of the sulphur in the sulphurized mineral oil, as the sulphurized lard-mineral oil No. 11 has somewhat the reverse influence; that is, for high bearing load at seizure, it still gives low frictional resistance.

(13) No comment.

(14) The planer was used in these tests inasmuch as it was already equipped with a dynamometer for measuring the force in the direction of cut. Further, this dynamometer measures with a considerable degree of accuracy.

Additional equipment for tests of this nature have now been installed, such as a heavy-duty engine lathe on which is mounted a Losenhausen force dynamometer which measures three components of the cutting force and records them graphically. This same lathe is equipped with a potentiometer device so that temperatures between the tool and work can be measured by the tool-work thermocouple. Simultaneously with the recording of these two values, tool life can be obtained. It is expected that the lathe will be used extensively in the future for tests of this nature, and it will replace the planer. Already considerable information on the use of cutting fluids in milling has been determined as a separate project and will be published soon.

Professor Casberg's correction in his second paragraph is correct. The second paragraph of the second column on the eighth page should read "The values of the torque" rather than "The values of the thrust."

Professor Casberg's suggestion that the discussion on "net power input" be omitted is not in agreement with the authors. This information was obtained for all of the tests, and it was felt that it was all valuable inasmuch as it represented, nearer than any other value, the net power output. This close agreement is shown throughout. It naturally is a little higher due to frictional resistance, etc. The method of obtaining the tare was completely described in the paper, Trans. A.S.M.E., MSP-52-2. It was therefore not thought desirable to repeat that in this paper, inasmuch as this paper is primarily to show by comparison the merits of various cutting fluids when cutting one steel.

Professor Casberg has mentioned the influence of losses in the motor as well as increased friction in the machine due to change in the load. These statements are correct. Actual efficiency of net output over net input power is given in the first paper for various drill sizes operating at different r.p.m. This shows the highest efficiency to be for the smallest drills operating at the highest rotating speeds. The rotating speeds were based on a peripheral speed of 60 ft. per min. This indicates that the increase in net input power is due primarily to load rather than speed.

The computed values of efficiency based on net power output as compared with the net power input for the $^1/_2$-in. drill and the $1^1/_4$-in. drill agree very favorably with the values given in Table 6 of the paper MSP-52-2.

The authors do not understand Professor Casberg's statement that the values of power at the drill point as plotted would not give straight lines. The torque values do give straight lines as indicated in Fig. 12. The net output power at the drill point is, approximately, $99^1/_2$ per cent due to the torque. Therefore, the net power output values should give approximately straight lines. It apparently is a coincidence that the net power input curves shown in Fig. 22 are straight lines, due to the fact that for all values there is a slight frictional or motor horsepower loss included.

MSP-54-3

Preloaded Ball Bearings as Applied to Machine-Tool Spindles

By H. E. BRUNNER,[1] NEW YORK, N. Y.

In attaining precision of operation of machines fitted with ball bearings, after all initial looseness had been removed and dimensional tolerances held to very close limits, it was found that another factor remained which prevented attaining the high degree of accuracy of dimension and finish required of precision machine tools. This was that elastic deformation in the ball bearing had a great effect on quality. The cure was effected by preloading, this initial loading serving to remove all looseness between the balls and the raceways, as well as the more objectionable effects of early deformation that develops in a ball bearing under load. The proper value of the preload can be determined only after full consideration of the work loads involved.

UNTIL recent years the use of anti-friction bearings in machine tools was restricted to those parts which did not directly affect the work done. On the work spindles the high degree of accuracy to which plain bearings can be built had invariably militated against the use of anti-friction bearings built to the less accurate dimensions and tolerances laid down by the different ball- and roller-bearing standardization bodies. It was not until 1920 that earnest and well-considered efforts were made to produce anti-friction bearings with finer tolerances and a closer degree of precision than are required for the general run of machine applications. The advance made in this period of approximately ten years, however, has increased the appreciation of the machine-tool manufacturers for anti-friction bearings and warrants a fuller understanding by the industry in general of the accuracy and advantages that are now obtainable from a properly designed mounting.

The anti-friction bearing, by virtue of its construction, introduces an element of error that is not present in the plain sleeve type of bearing; viz., "run-out." In an anti-friction bearing some form of raceway must be applied to the spindle, with rolling elements interposed between the inner and outer races. Though the utmost care be exercised in the manufacture of the raceway and rolling elements, some degree of "run-out" is inevitable. On the other hand, with a sleeve type of bearing, no parts need ordinarily be interposed between the spindle and the bearing surface, thus eliminating any error due to run-out.

As a starting point, therefore, in the production of anti-friction bearings that would have precision qualities comparable with the well-designed plain bearings, attention was first directed to the determination of the type of raceway and rolling elements that would lend themselves best to minimizing run-out. It was soon apparent that a ball was the logical choice, as it can be produced today with exceptionally fine equipment enabling the restriction of all dimensional errors to within 0.000025 in. and at the same time producing a smooth surface. Having settled upon the selection of the ball as the most desirable rolling element from the standpoint of dimensional accuracy, a further advantage was recognized in that it was the one practicable geometric shape that did not require some form of guiding aside from some conventional shape of raceway. Attention was next directed toward improving the tolerances on all dimensions of the ball bearing that might affect the accuracy of operation, such as bore, outside diameter, width, and parallelism of grooves with face and squareness of faces with bore, along with a better finish on the surfaces of raceways.

The improved tolerances obtained were a decided advance in the right direction, but there still remained further opportunity for improvement. Experience derived from the use of bearings showed that looseness also seriously affected the quality of finish on work produced. The next step was to remove all looseness or clearance between the balls and races so as to obtain an internal fit approximating a line-to-line contact. When this was done, a further improvement was noted, but still this tighter and very precisely made ball bearing fell short of meeting the exacting demands of present-day machine tools where comparatively heavy cuts and a high quality of finish under light cuts were required.

Necessity for Preloading

Although all initial looseness had been removed from the bearings at the time of manufacture and the dimensional tolerances held to very close limits, it was found that still another factor entered into the problem to militate against success and which was responsible to a large extent for the failure of the bearings to meet the high degree of accuracy of dimension and finish required of precision machine tools. It became evident that the elastic deformation in the ball bearing had its effect on the quality of finish and dimensional accuracy of work produced. Where internal looseness existed, chatter resulted on the finished work due to vibration in the spindle.

It will readily be appreciated that a bearing having radial or axial looseness will reflect all existing run-out error. By applying proper preloading, all early deformation or what may be termed "sponginess" is removed. This initial loading serves to correct or minimize the run-out error and increase the rigidity of the spindle because of the elastic character of the materials. Consequently the dimensional accuracy and quality of finish fully compare with results obtained from sleeve bearings.

Methods of Preloading

Preloading a bearing has therefore come to mean the applica-

Co., Philadelphia, and since 1918 in his present position. Has been closely identified with the development and successful use of anti-friction bearings on railway equipment and is a member of the following engineering committees dealing with ball and roller bearings: A.S.M.E. Sectional Committee on Ball and Roller Bearings; Ball and Roller Bearing Division of S.A.E., and was chairman from 1924 to 1928; A.S.M.E. Special Research Committee on Heavy Duty Anti-Friction Bearings; A.S.M.E. Sectional Committee on Plain Limit Gages for General Engineering Work.

Presented before a meeting, Cincinnati, Ohio, January 20, 1931, of the Cincinnati Section of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tion of an initial load that will remove all looseness between the balls and raceways as well as the more objectionable effects of early deformation that develops in a ball bearing under load. The proper value of the preload can of course be determined only after a full consideration of the work loads involved. A variety of methods were developed to load the bearings initially, but with varying degrees of success, due to the fact that almost all of them involved the necessity of manual adjustments that were dependent upon the skill of a mechanic or his sense of feel. To load a ball bearing excessively through the adjustment was equally as objectionable as an adjustment which failed to cause sufficient initial yield.

A few of the principal methods that have been tried and found not fully satisfactory will be touched upon.

Loading by Threaded End Covers. This was one of the earliest methods of imposing an internal load on bearings. Applying one bearing at each end of a spindle, the outer races were displaced either inwardly or outwardly by using threaded end covers. It was found that although this might prove satisfactory occasionally when the adjustment was carefully made, the method would not permit the application of an exact predetermined load, and in many cases the bearings were loaded beyond their safe capacities.

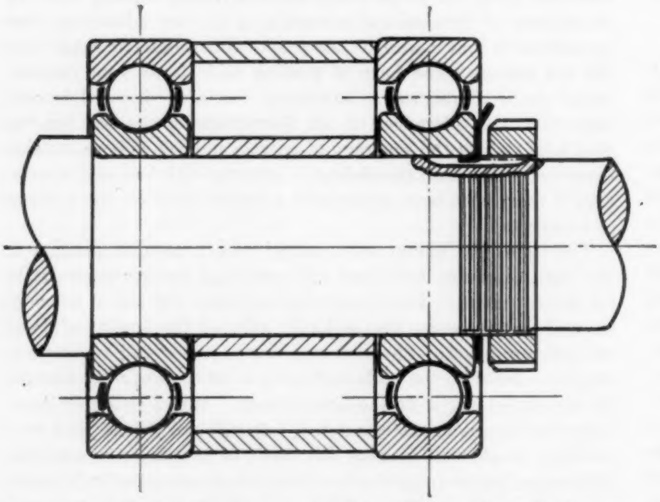

FIG. 1 TWO PRELOADED BEARINGS WITH SPACING SLEEVES PREPARATORY TO BEING LOCKED IN PLACE

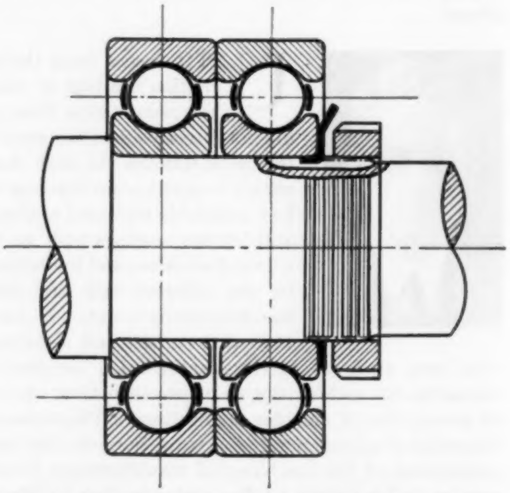

FIG. 2 TWO PRELOADED BEARINGS WITHOUT SPACING SLEEVES PREPARATORY TO BEING LOCKED IN PLACE

Loading by Springs. This method aimed to accomplish the same result by loading the bearing through the outer races. With this method a small initial load could be imposed sufficient for light duty or where the load was uniform, but it was totally inadequate on applications where the load was fluctuating owing to the varying characteristics of springs.

Loading by Oversize Balls. A small initial load can be applied by using oversize balls, but this method is greatly limited by the danger of damaging the carefully made balls and raceway surfaces during the assembly of the bearing. A further limitation of this method is the weak control the manufacturer will have in producing the required deformation through having to resort to measurements—in other words, being dependent upon manual adjustments. Hence, although occasionally successful on light-duty work, such bearings were entirely unsuited to the average run of precision applications.

Loading by Unequal Length Spacing Sleeves. This method in the development of a satisfactory preloaded ball bearing utilized two single-row ball bearings at each end of a spindle with steel sleeves of unequal length between the outer and inner races. In this way the races were displaced axially and an internal load was imposed on the bearings. The method has been found wanting for a number of reasons. It imposes on an ordinary assembly department in a plant the responsibility of machining and fitting the sleeves which is properly the work for a precision-machine department. It also necessitates relying on the judgment of the workman assembling the unit to determine the proper adjustment, resulting in a wide range of preloading with a consequent effect on the uniformity of operation. A further weakness is the fact that if replacement of bearings is required there is no positive assurance that the same degree of loading as originally built into the unit by the machine manufacturer will be duplicated, because each particular pair of bearings possesses its own individual tolerance characteristics. In any event the method requires calculations and measurements to determine the proper length of sleeves necessary to produce the desired preloading.

EXACT PREDETERMINED PRELOADING

For a ball-bearing spindle mounting to be entirely satisfactory it must not only be possible to load it with an exact predetermined load, but it should also be possible to freely interchange bearings of the same type without altering the proved requirements of the spindle. These essential requirements are met only in the type of ball bearing about to be described which is loaded at time of manufacture with a definite predetermined load. This advance in bearing design has resulted in removing the problem of adjustment from the field of uncertainty so that it is now possible to obtain the exact degree of tightness necessary for smooth and accurate spindle operation.

The principle followed in the manufacture of the preloaded ball bearing is to displace the inner race with respect to the outer race under a predetermined thrust load and to surface-grind the face of the projecting inner race until it is flush with the side of the outer race. The bearing is then reversed and the procedure repeated by applying the fixed thrust load to the inner race again, but in the opposite direction. When two such bearings are assembled on a spindle and drawn up until the inner races are in contact, the predetermined thrust under which the bearings were ground is reproduced exactly within them.

Fig. 1 shows two bearings on a spindle preparatory to being locked in place, with spacing sleeves of equal length between the outer and inner races. Fig. 2 illustrates the same two bearings mounted on a spindle with the outer races in contact preparatory to being drawn up by a locknut and lock washer. Fig. 1 is the more preferable method through the increased rigidity obtained, but where space limitations prevail Fig. 2 can be used.

Analysis of Deflection and Stresses

An analysis of the deflections and stresses in a pair of preloaded ball bearings will make clear the principles involved. If a ball bearing under thrust load acted the same as a piece of steel under compression in a testing machine, the yield under increasing loads would follow a straight line up to the elastic limit of the material—Hooke's Law (see Fig. 3). However, a ball bearing has a distinct advantage in this respect because as the load increases the supporting areas also increase from point contact at no load to comparatively large ellipses at higher loads. Hence, the deflection of a ball bearing will become less and less under equal increments of loads.

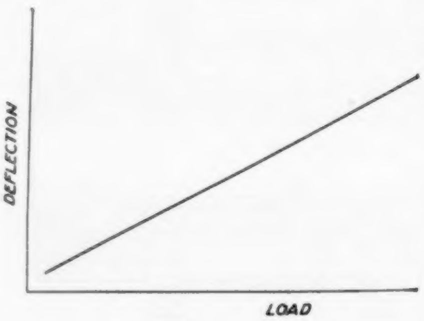

Fig. 3 Hooke's Law

Fig. 4 shows the axial deflection under thrust of a single-row preloaded ball bearing having no initial looseness. Reference to the curve will show that when carrying a thrust load P the axial deflection is D—in this case, 0.0015 in. By doubling the load ($2P$), a deflection F results, but instead of being 0.003 in., it is only 0.00225 in. An inspection of the curve will indicate clearly that the greater the initial thrust load the less the added deflection by doubling it, because the curve flattens out decidedly with increase in load.

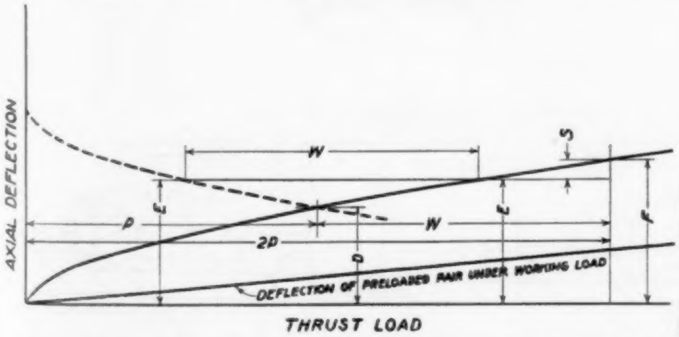

Fig. 4 Load-Deflection Curve for a Pair of Preloaded Ball Bearings

Further, if the preload is established by a second bearing opposed to the first, a still smaller increase in deflection will result from the addition of a working thrust upon the two. A study of Figs. 5 and 6 will show why this is so.

Fig. 5 shows the forces set up by tightening the locknut against two bearings designed for preloading. The preload P produces equal compression of both sets of balls and races, mutual compression between the two outer races, and tension in the shaft between the shoulder and nut.

If there is now applied a working thrust W, for sake of convenience made equal to P (see Fig. 6), the stresses in bearing A will be increased, but those in bearing B will be decreased, because the increased deflection of the balls in bearing A allows the inner races to move axially, thus relieving the pressure on bearing B. This relief will reduce the shaft tension by an amount R, and likewise decrease the preload pressure on bearing A by the same amount R. It will thus be seen that a working load does not add nearly so much to the burden borne by bearing A nor to its axial deflection as it would were A not preloaded.

The effect of the working load discussed is graphically shown in Fig. 4, where the continuous curve represents bearing A carrying the working load, while the dotted curve, exactly the same, but inverted for convenience, represents the opposed bearing B.

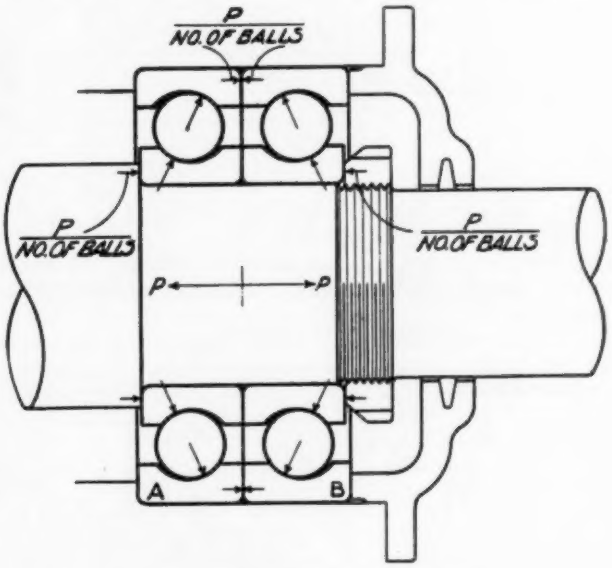

Fig. 5 Pair of Bearings Opposed to Effect Preloading

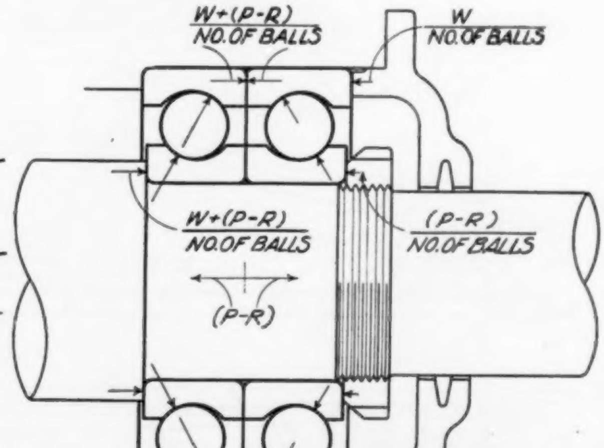

Fig. 6 Pair of Bearings Carrying Preload and Working Load

When the working load W is applied, it will take from B as much of the deflection due to the preload as it adds to A, because the "action" of B carried through the shaft by tension must equal the "reaction" of A. Hence one must determine total deflection by placing the working load W horizontally across the two curves and not by adding it to P. The resulting deflection of bearing A from its original unloaded position is shown by E, and the saving in deflection S will be evident by comparing E

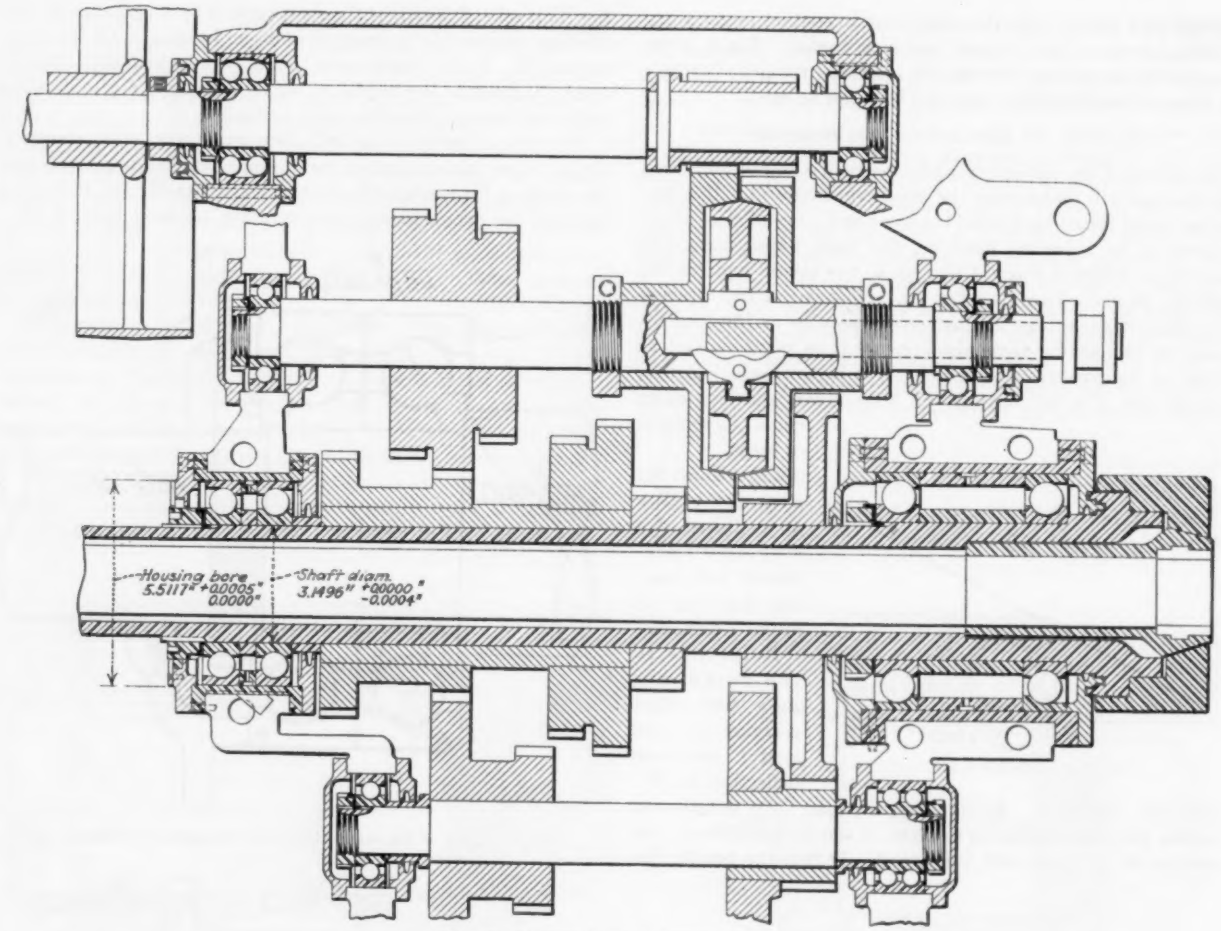

FIG. 7 HEAVY-DUTY TURRET LATHE

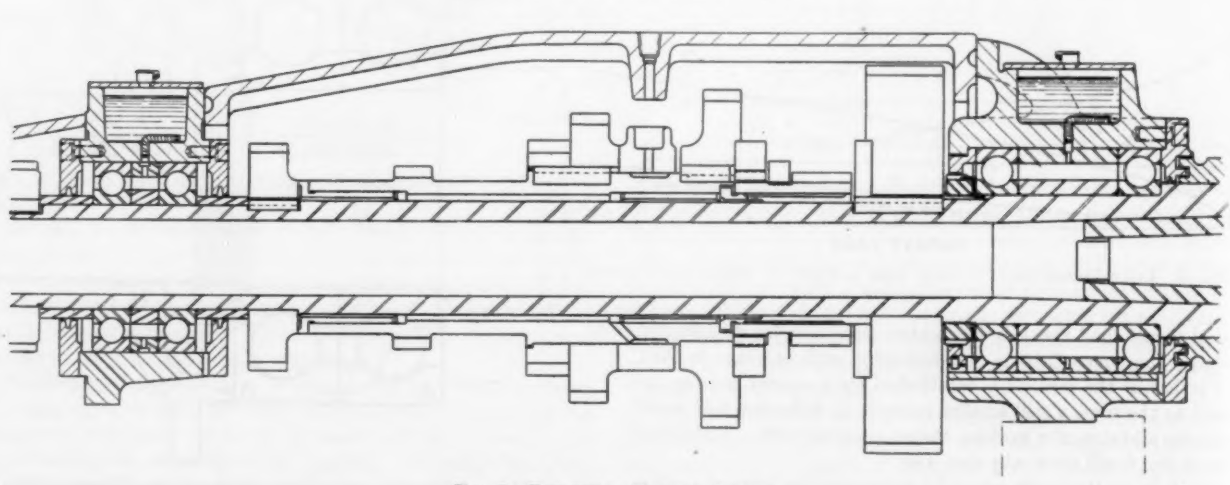

FIG. 8 PRECISION ENGINE LATHE

with *F*. Zero position of the spindle is that which it assumes when the two bearings are drawn together applying the preload. The line marked "Deflection of Preloaded Pair Under Working Load" shows the axial deflection of the spindle under various working loads.

ADVANTAGES OF PRELOADED BALL BEARINGS

Preloaded ball bearings give the following advantages:

(1) Any two such bearings can be separated with spacing sleeves of equal length, which is preferable, or if not convenient, they can be placed side by side.

(2) The necessary preloading within the safe capacity of the bearing can be definitely established for any particular application. This avoids possibility of premature failure being caused by excessive preloading through improper adjustment.

(3) The bearings are fully interchangeable as they are not

matched in pairs. If, therefore, they should be removed for any reason after mounting, it is not necessary when replacing them to have the same faces in contact or adjacent to one another. The original preload will be maintained regardless of the bearing faces in contact.

(4) The bearings do not need to be locked in the housing in order to subject them to the predetermined load. Once the locknut on the spindle is properly tightened, the predetermined load is reproduced.

(5) A spindle can be located axially on one pair of bearings and the other pair can be allowed to float in the housing without affecting in any way the initial adjustment.

Bearing Types Best Suited to Preloading

The single-row Conrad and the open-side angular-contact types of ball bearings are well suited to preloading and are the two types generally used in this manner for precision-machine spindles. The choice between them is one of design solely. For certain heavy-duty machines where thrust loads predominate and are of large magnitude, the open-side bearing has an advantage as a thrust carrier due to its greater number of balls.

Design of Application

In the preloaded ball bearing the bearing manufacturer has succeeded in developing a product that is as accurate in dimension and finish as the most modern grinding processes will produce. It is therefore essential that the machine manufacturer exercise an equivalent degree of care in the design, machining, and assembly of all other machine parts in order to obtain the full benefit of the precision that is built into the bearings. Unless this is done errors will be introduced into the finished work and for which the bearings cannot be expected to compensate.

The preloaded ball bearing is being used today with uniform

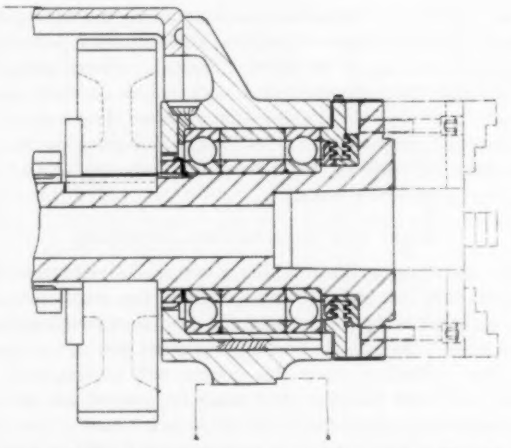

Fig. 9 Alternative Lubrication Design for Fig. 8

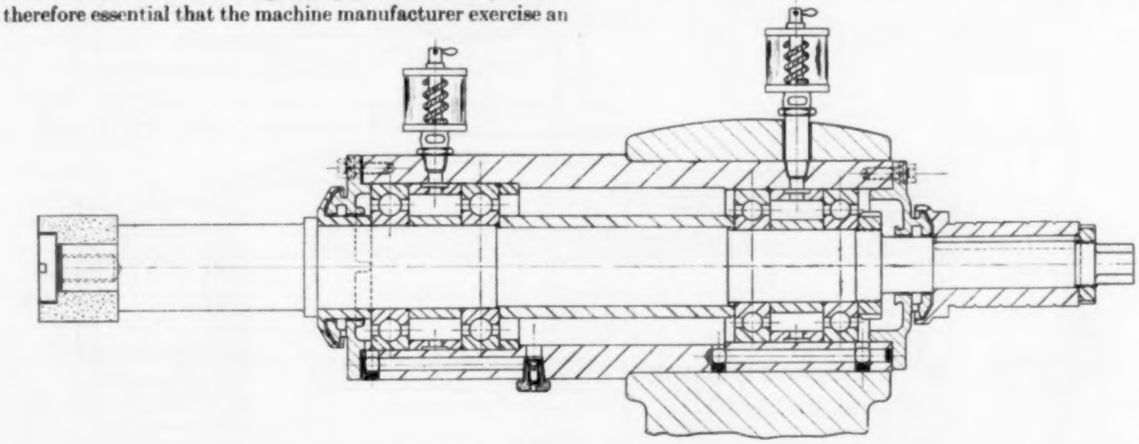

Fig. 10 High-Speed Internal Grinder

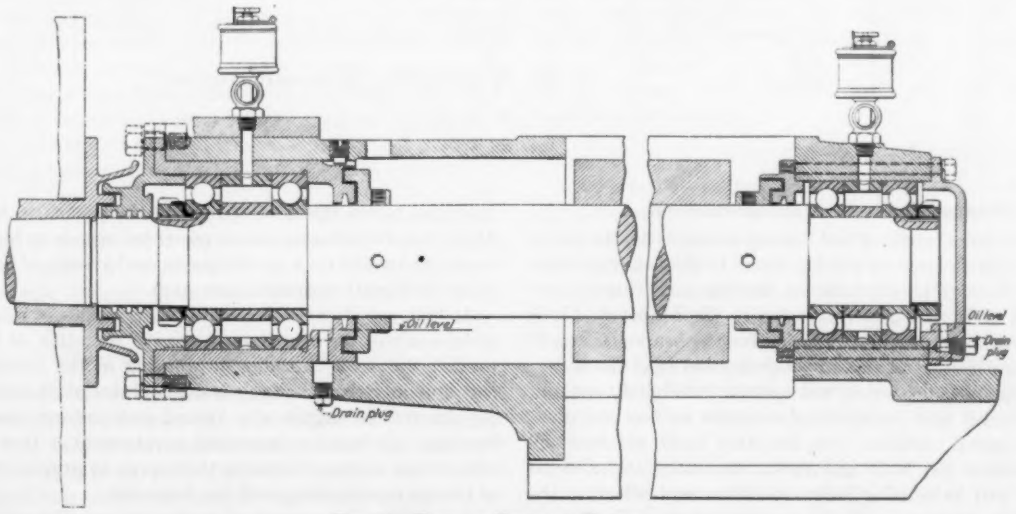

Fig. 11 Rotary Surface Grinder

success on a variety of machines such as milling machines, lathes, grinders, and other types of machine tools where a positive predetermined loading is required. Smooth, vibrationless, and accurate operation can be relied upon when properly loaded, mounted, and applied. In precision grinders they have proved their dependability on almost every type of machine from the heavy-duty roll grinder to the lighter duty high-speed units operating up to 30,000 r.p.m.

SHAFT AND HOUSING FITS IMPORTANT

Shaft and housing fits must be given special attention where preloaded ball bearings are used. These fits must not be too heavy on the spindle or otherwise the predetermined loading will be disturbed. Again, the housing fits must not be too loose in order that vibration from this source will be avoided. The bearing seat and housing bore must be ground accurately to dimensions that will result in a fit of the inner race on the spindle ranging from a line-to-line to not more than 0.0002 to 0.0003 in. press fit. The fit between the outer race and the housing should range from a line-to-line to not more than 0.0002 to 0.0003 in. loose.

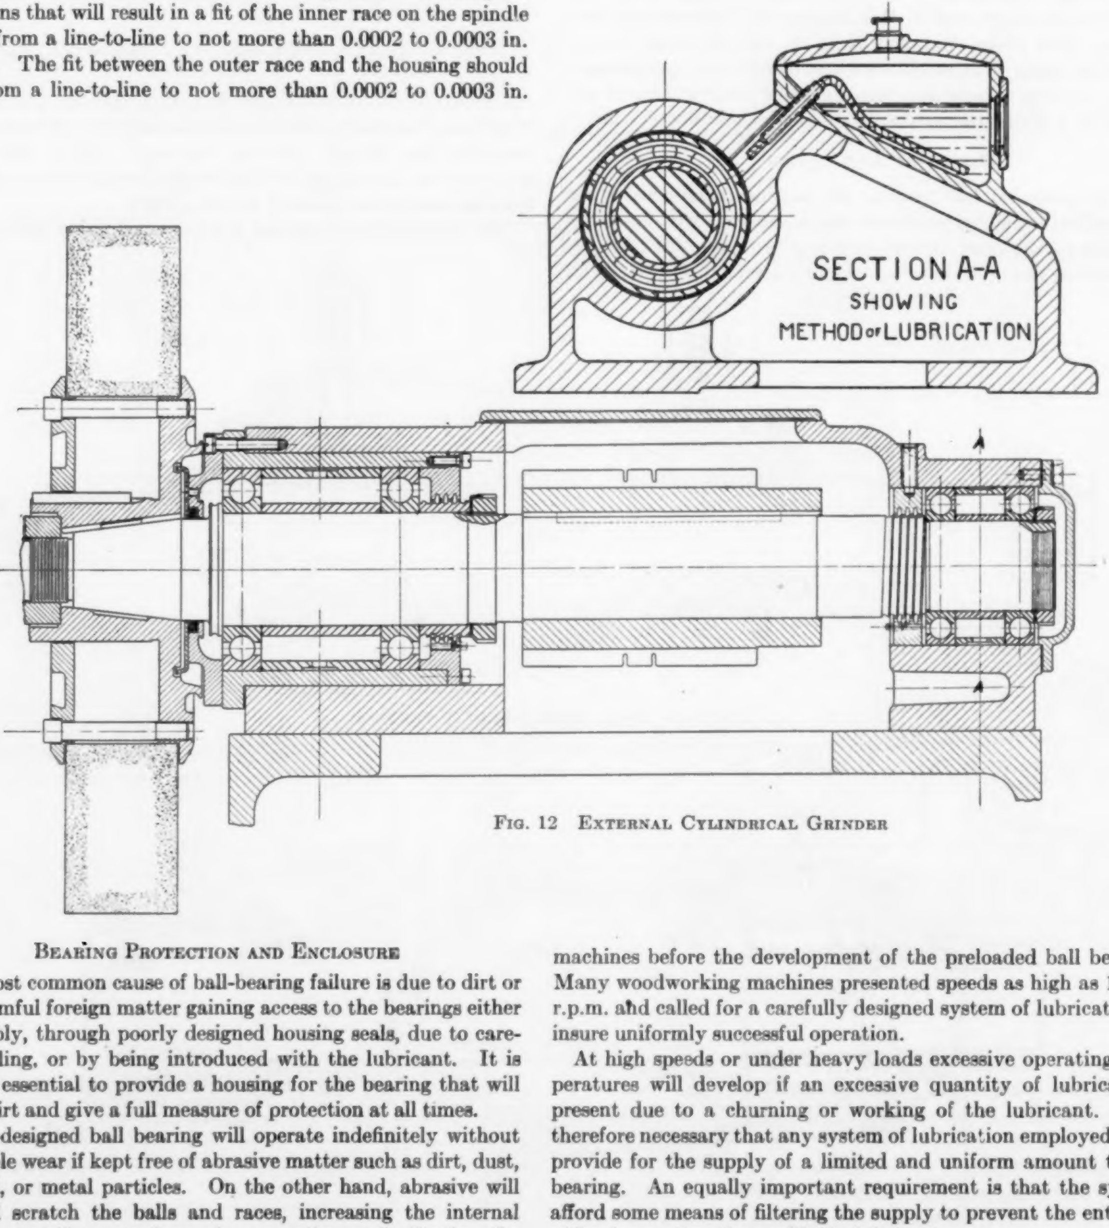

FIG. 12 EXTERNAL CYLINDRICAL GRINDER

BEARING PROTECTION AND ENCLOSURE

The most common cause of ball-bearing failure is due to dirt or other harmful foreign matter gaining access to the bearings either at assembly, through poorly designed housing seals, due to careless handling, or by being introduced with the lubricant. It is therefore essential to provide a housing for the bearing that will exclude dirt and give a full measure of protection at all times.

A well-designed ball bearing will operate indefinitely without appreciable wear if kept free of abrasive matter such as dirt, dust, core sand, or metal particles. On the other hand, abrasive will wear and scratch the balls and races, increasing the internal looseness as well as causing noisy operation and affecting the quality of work produced. Water or moisture must likewise be kept out of the bearing housing. If this is not done, the balls and races will corrode, causing unsatisfactory operation and premature failure. Bearings should be left in their original cartons until they are to be applied to the spindles. The slushing grease used by the bearing manufacturers is always thoroughly clean and has been chosen as a good protective agent. It is compounded from high-grade mineral products and will readily mix with any additional lubricant introduced afterward.

LUBRICATION

The importance of correct lubrication was recognized in the early efforts to apply anti-friction bearings to machine tools and other precision equipment. The necessity of a clean supply of lubricant was immediately observed. In fact, this requirement became evident in the use of bearings on other classes of precision machines before the development of the preloaded ball bearing. Many woodworking machines presented speeds as high as 10,000 r.p.m. and called for a carefully designed system of lubrication to insure uniformly successful operation.

At high speeds or under heavy loads excessive operating temperatures will develop if an excessive quantity of lubricant is present due to a churning or working of the lubricant. It is therefore necessary that any system of lubrication employed must provide for the supply of a limited and uniform amount to the bearing. An equally important requirement is that the system afford some means of filtering the supply to prevent the entrance of foreign matter along with the lubricant.

A considerable amount of study and experimental work was done in an effort to develop systems that would meet these essential requirements in a practical manner. We eventually succeeded in utilizing various systems of wick feed for oil lubrication in ways that have produced most gratifying results on a great many applications. By means of the wick it is possible to feed a limited quantity of lubricant into the bearing chamber and at the same time filter the supply.

There are two principal methods by which this has been accomplished. The first is to provide in the machine design for a reservoir or chamber of adequate size from which the oil will be fed by gravity into the bearing chamber. This reservoir should be so located that renewal of lubricant can be readily effected and at the same time insure that a sufficient head of oil will always be present to cause a continuous flow to the bearings. It is not entirely safe to depend upon capillary action. Where capillary action is depended upon, there is always the danger of the supply becoming choked or suspended.

In the second method wicks are also used, but gears or ring oilers are employed to lead the lubricant to a storage reservoir formed in the machine frame. A design of this type is indicated in Fig. 9.

The point at which the oil is brought into the housing is very important with either method, because where two or more bearings are to be lubricated from the one reservoir or source of supply the wick should enter midway between the bearings so as to insure an equal flow through the bearings on either side. Further, the drain should be so arranged that the oil will be carried off only after it has passed through the bearing. The various designs which follow illustrate these principles.

Where grease is used it is equally important that the system employed in applying it provide some means for supplying a proper quantity to the bearings and at the same time afford protection against dirt intrusion. This is not as easily accomplished as in the case of oil, especially from the standpoint of the quantity supplied. However, systems have been worked out that accomplish the fundamental requirements as to quantity and cleanliness, but on the majority of machine-tool applications the use of grease has been confined to those applications where the effect of deterioration of balls and grooves was not of serious concern.

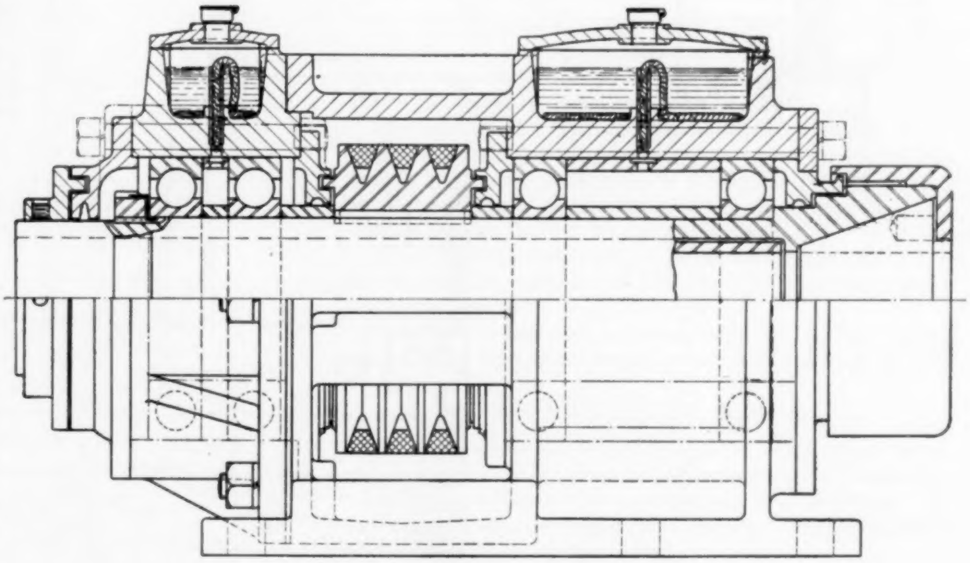

FIG. 13 DIAMOND BORING MACHINE

TYPICAL MOUNTING DESIGNS

Some typical mounting designs are presented, not only to illustrate the variety of application, but to bring out the more important design features upon which depends to a large extent the success to be obtained.

HEAVY-DUTY TURRET LATHE

Fig. 7 shows a heavy-duty, low-speed, turret lathe equipped throughout with ball bearings. In this design the frame is split so that it would be difficult to machine it with sufficient accuracy to receive the outer races of the preloaded bearings on the work spindle. This can be readily overcome, however, and the assembly facilitated by utilizing a sub-housing around each pair of bearings. As a result the work spindle, bearings, and sub-housings can be assembled on a bench and inserted as a unit in the frame, assuring a maximum of protection to the bearings. The bearings at each location are spread apart by means of equal length spacing sleeves to secure maximum rigidity.

The work spindle is located axially by holding the outer races of the two bearings at the front end between the lips of the end covers, while the pair at the rear have ample freedom to position themselves laterally in the sub-housing without affecting in any way the predetermined adjustment.

The housing seal at the front of the main spindle is of a labyrinth type to prevent the entrance of dirt or water into the bearings. At the opposite end the housing seal need not be so elaborate, and a split brass ring is used held in place by a plate screwed to the end cover.

The lubrication system is not fully indicated in Fig. 7. For the work spindle an oil trap is incorporated in the upper half of the frame, and from it the lubricant is fed to each pair of bearings through a wick which not only controls the rate of feed but acts as a filter also. The lubricant enters each bearing housing midway between the two bearings, and after passing through them is drained back to the gear casing through the plug shown. The plug is drilled and fitted with a wick to prevent dirt or foreign matter gaining access through the drain hole and working its way into the bearings.

PRECISION ENGINE LATHE

The precision engine lathe is called upon to perform heavy roughing work as well as work requiring extreme accuracy. Preloaded ball bearings are being used with very satisfactory results on this class of equipment.

Alternative mounting designs are illustrated by Figs. 8 and 9 which differ only in the system of lubrication employed. In Fig. 8 an oil reservoir is cast integral with each housing and from which the lubricant is supplied to the bearings through wicks. After passing through the bearings the oil is returned to the main reservoir. This provides a simple system for circulating and filtering the oil.

A modification of the foregoing system of lubrication that has been used on engine lathes is shown by Fig. 9. In this design an oil trap is cast integral with the gear casing at each end and entraps oil thrown by the gears. This oil is conducted through wicks to the bearings and is returned to the gear casing after passing through the bearings.

In both of the designs shown two bearings are mounted at each end of the spindle spaced apart by means of sleeves of equal length, and the spindle is located axially by holding the outer races of the bearings at the chuck end between lips on the housing end covers. The two bearings at the opposite end are free to position themselves axially in the housing without affecting the initial adjustment.

A labyrinth housing seal is incorporated at the chuck end to prevent the entrance of grit or moisture into the bearings.

High-Speed Internal Grinder

Fig. 10 illustrates a high-speed internal grinding spindle design which operates at speeds as high as 25,000 to 30,000 r.p.m. and is a splendid example of the success attained with ball bearings in high-speed precision machine tools. In designs of this nature it is particularly essential that they be thoroughly protected against the intrusion of any abrasives or other harmful substances. Also where such high speed prevails, the lubrication system must be such as to introduce clean lubricant in a limited and uniform quantity. In this design oil cups equipped with wicks are shown, which introduce a clean supply of lubricant between each pair of bearings, insuring uniform distribution. The oil is drained out at the housing through a pipe plug fitted with a filter to prevent the entrance of foreign matter through this opening.

Rotary Surface Grinder

A mounting for the work spindle of a rotary surface grinder is shown in Fig. 11. This design has two preloaded bearings at each end of the spindle mounted with spacing sleeves of equal length between the inner and outer races. In order to permit the spindle, bearings, and pulley to be assembled as a unit and inserted in place, the bearings at the grinding wheel end are mounted in a sub-housing. This permits boring the frame to a diameter slightly larger than the pulley diameter, thus allowing the pulley to pass through.

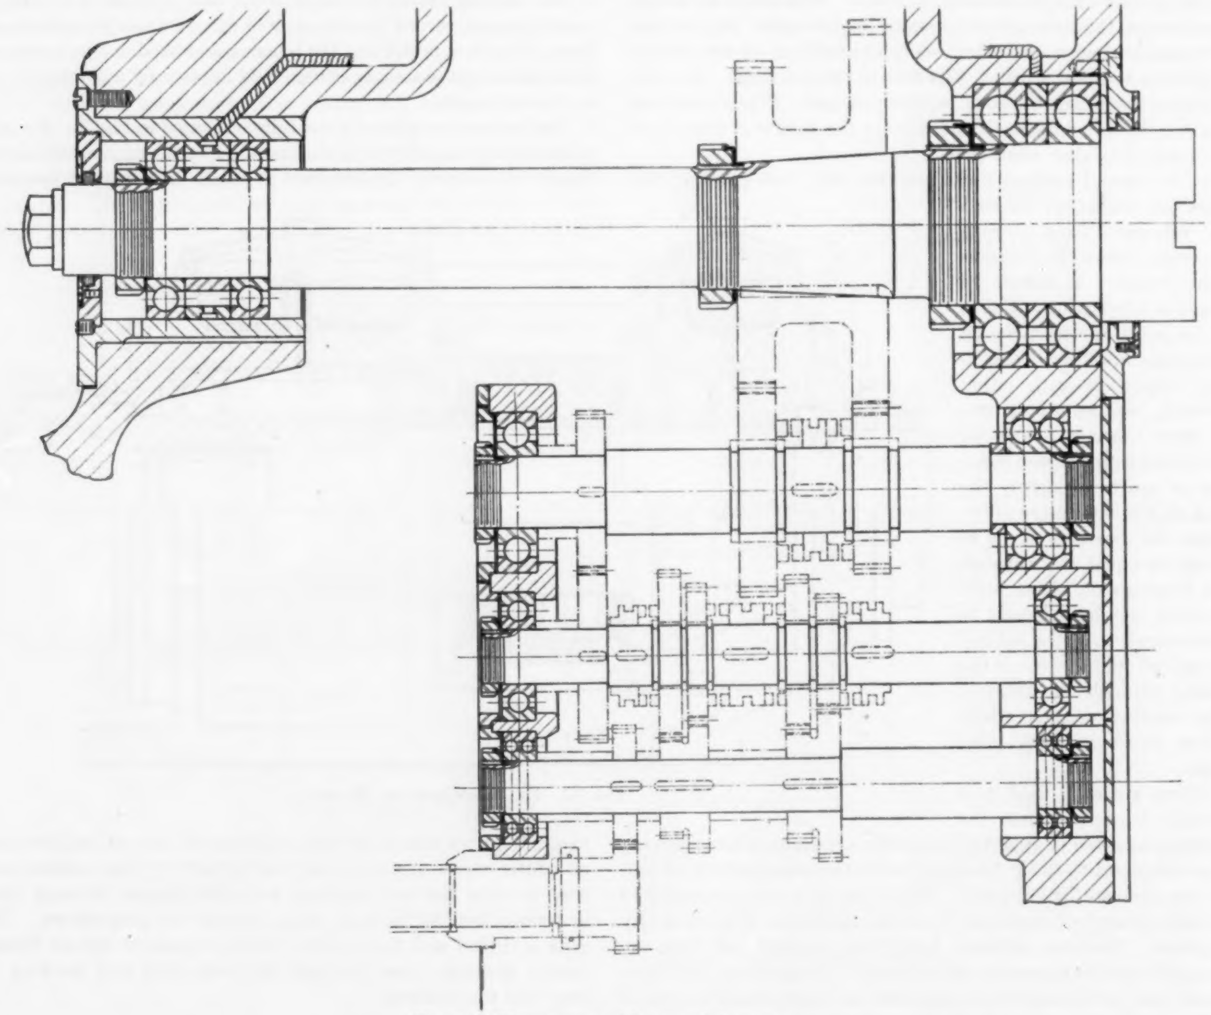

Fig. 14 Horizontal Milling Machine

The housing at the end away from the wheel is closed on one side as the spindle terminates in it. Each of the other housing enclosures consists of a labyrinth flinger and oil groove. This arrangement provides an effective seal against the intrusion of dirt or water into the bearings. As an added precaution the flinger at the enclosure next to the wheel is shaped so that any water or cooling compound that may gather on it will be drained off without getting into the clearances of the labyrinth.

Lubrication is accomplished by means of sight-feed wick oilers from which the lubricant is fed into the housings midway between each pair of bearings. The oil is allowed to accumulate in each housing, but when the level rises to the center of the lowermost balls in the bearings it is drained off through the overflow plug.

In this design the spindle is located against end movement by holding the outer races of the two bearings adjacent to the wheel, between a shoulder in the sub-housing and a lip on the outside end cover. The pair of bearings at the end away from the wheel have ample clearance on either side of the outer races so that they are free to move laterally in the housing without disturbing in any way the initial adjustment.

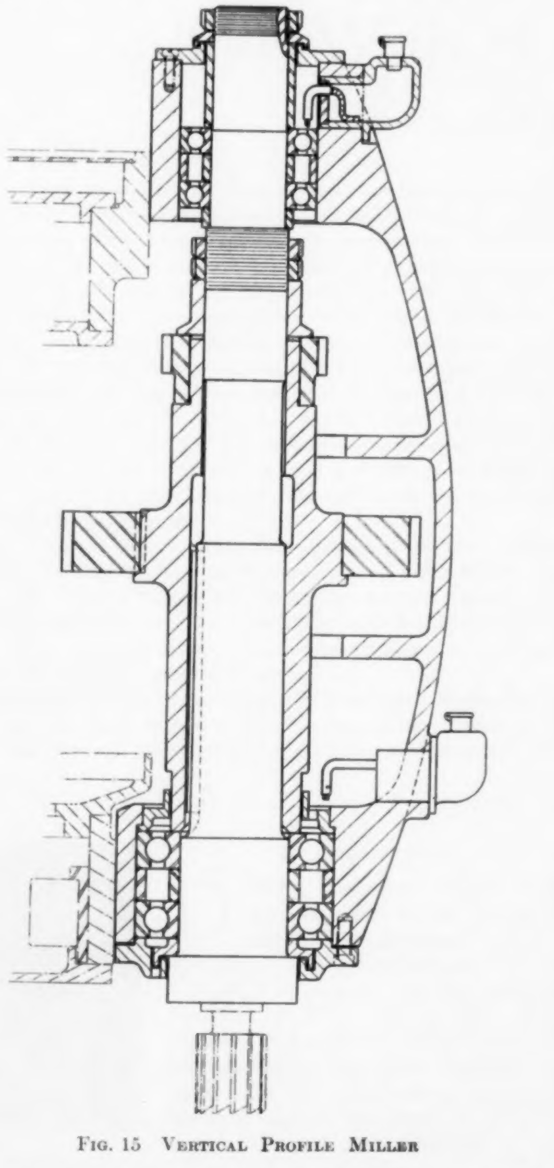

Fig. 15 Vertical Profile Miller

External Cylindrical Grinder

An external cylindrical grinding spindle is illustrated by Fig. 12. This type of machine has a wide range of application and is called upon to produce work to very close tolerances. Two preloaded ball bearings are employed at each end separated by equal length spacing sleeves to secure maximum rigidity. The spindle is located axially by holding the two bearings at the wheel end while the two bearings at the opposite end are free to float in the housing under any changes in length of spindle due to temperature variations without affecting the initial positioning of the grinding wheel.

The bearings are lubricated by means of oil that is fed to each pair of bearings from a reservoir cast integral with the frame. The rate of feed is controlled and the supply filtered by a wick. The oil enters each housing midway between the bearings and after passing through each bearing is drained out.

Particular care must be paid to the enclosures, as these machines usually operate under dirty conditions. In the design shown a labyrinth seal, together with a packing gland, is used at the wheel end.

Diamond Boring Machine

Fig. 13 is another mounting design which illustrates the wide variety of uses to which preloaded ball bearings are adaptable. In this design the chuck spindle of a diamond boring machine is shown supported on preloaded bearings.

The bearings in a machine of this kind are subjected to very severe service, not only because it operates at moderately high speeds, but in very short cycles of starting and stopping. It is also equipped with an automatic loading device that passes the product through the hollow spindle into the chuck.

A feature of this design is that the two bearings at each end are held in place by means of one lock nut only, located at the rear end of the spindle.

Suitable labyrinth seals are incorporated, as is also a wick-feed system of oil lubrication similar to others described in previous designs.

Horizontal Milling Machine

The design of bearing mounting suitable for application to the main cutter spindle of horizontal milling machines is illustrated in Fig. 14. In addition, the intermediate drive shafts are also shown supported on deep groove ball bearings, assuring maximum power being applied to the cutter.

The bearings on the work spindle are spaced apart at each end by means of sleeves of equal length to assure maximum rigidity. The pair at the tool end are held at the outer races between shoulders to locate the spindle axially, while the pair at the opposite end are free to float, obviating the necessity of extreme accuracy in the distance between spindle shoulders.

Vertical Profile Miller

Preloaded ball bearings are as readily adaptable to vertical spindles as to horizontal spindles. Fig. 15 shows the spindle of a vertical profile milling machine supported on these bearings. It will be seen that the mounting is similar to that used on horizontal spindles.

The upper seal consists of an external labyrinth flinger which prevents dirt or other foreign matter from working down the spindle and into the bearings. At the lower enclosure an external labyrinth flinger is provided to prevent leakage of lubricant.

Lubrication is accomplished by means of oil that is supplied to the bearings through wicks leading from reservoirs attached to the frame.

MSP-54-4

Influence of Chemical Composition and Heat Treatment of Steel Forgings on Machinability With Shallow Lathe Cuts

By T. G. Digges,[1] Washington, D. C.

The tests described in this report were made primarily as a study of lathe-tool performance with shallow cuts as affected by variations in chemical composition and heat treatment of the steels cut. The cutting tests were made dry with high-speed-steel tools of a selected size, form, composition, and heat treatment, with a feed of 0.0115 in. per rev. and 0.010 in. depth of cut. Comparisons were made of the Taylor speeds on the basis of equal tensile strengths when cutting 0.4 per cent carbon (S.A.E. 1040), chromium-vanadium (S.A.E. 6140), nickel-chromium (S.A.E. 3140 and 3435), chromium-molybdenum (S.A.E. 4140), and $3^1/_2$ per cent nickel (S.A.E. 2340) steel forgings heat treated to give tensile strengths between 75,000 and 220,000 lb. per sq. in.

The study also included consideration of the surface finishes of the various steel forgings as affected by the test conditions, the microstructures of the steels cut, and tool performance as affected by the additions of 3.5 to 11.7 per cent cobalt to the customary 18 per cent tungsten type of high-speed tool steel.

If machinability is measured by the cutting speed permitting the tools to last a definite time, then measurable differences were observed between the various steels cut in the lathe test with shallow cuts. The fact, however, that some given steel permits a higher cutting speed than another steel for some tensile strength which is the same for both materials does not necessarily indicate that the two steels maintain the same relationship for another tensile strength.

Of the different steels cut in the lathe tests, the plain carbon steel was the most difficult to machine other than an annealed nickel-chromium steel.

The surface finish on the plain carbon steel was also considered to be inferior to the surface finish of the alloy steels.

The results showed that the effect of changes in chemical composition of steel forgings upon their cutting speeds was dependent upon the tensile strength at which the comparisons were made. In the different steels cut with shallow cuts the most effective special alloying elements for improving machinability were the combinations of nickel and chromium or chromium and vanadium for the high tensile strengths in the neighborhood of 180,000 lb. per sq. in., while chromium and molybdenum were the most effective in the lower range of about 90,000 lb. per sq. in.

I—Introduction

During the past ten years a study has been made at the Bureau of Standards of lathe-tool performance with both roughing and shallow cuts. The lathe breakdown test for roughing cuts was used in studying the effects upon tool performance of changes in chemical composition and heat treatment of commercial and experimental high-speed steels[2,3,4] and of variations in chemical composition and heat treatment of the steels cut.[5] The lathe breakdown test has also been extended to include cutting tests with cemented tungsten-carbide tools.[6]

A method for testing lathe tools with shallow cuts was developed and used for studying the effects upon tool performance of changes in chemical composition and heat treatment of the tools. Relations between the cutting speed, feed, and depth of cut and the tool life for carbon and high-speed-steel tools were also determined.[7,8] Most of the tests with shallow cuts were made in cutting $3^1/_2$ per cent nickel-steel forgings, heat treated to have tensile strengths of about 80,000 to 100,000 lb. per sq. in.

Contributed by the A.S.M.E. Special Research Committee on Cutting of Metals and presented at the Machine Shop Practice Session of the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers. Published with the approval of the Director, National Bureau of Standards, Washington, D. C.

The tests described in this report were made primarily as a study of high-speed-steel lathe-tool performance with shallow cuts as affected by variations in the chemical composition and heat treatment of the steels cut. The study also included consideration of the surface finishes of the various steel forgings as affected by the conditions of cutting and of the microstructures of the steels cut.

The lathe tests were made in cutting a plain carbon and various alloy-steel forgings heat-treated to have tensile strengths between 75,000 and 220,000 lb. per sq. in. The form, size, heat treatment, and composition of the high-speed-steel tools were not varied, except that a study was made of tool performance as affected by the addition of cobalt to the 18 per cent tungsten type of tool steel.

In most cases the limiting factor of machinability is tool failure, and machinability can best be measured in terms of the cutting speed permitting a definite tool life. That is, machinability is proportional to the cutting speed permitting a definite tool life, and it is upon this basis that the term is used in this report. From this it follows that those materials, which under otherwise fixed conditions permit the longest cuts without regrinding of the tools, are described as the most readily machinable or to have the highest degree of machinability.

With finishing cuts, close adherence to dimensions and the nature of the finish left on the work piece are probably as important factors as tool life. However, no very satisfactory method has yet been worked out for the evaluation of the appearance or type of finish produced by a cutting tool.[9] The method of test selected made possible a close adherence to the desired dimensions.

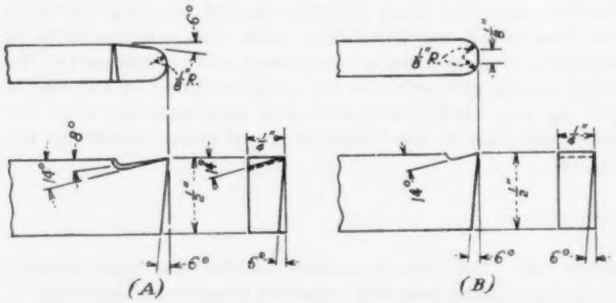

FIG. 1 DIMENSIONS AND FORMS OF THE TOOLS USED IN THE LATHE TESTS

[(*A*) Tool for roughing cuts. (*B*) Tool for shallow cuts.]

II—PREVIOUS INVESTIGATIONS

The results of previous lathe tests[8] made with high-speed-steel tools with shallow cuts showed that with a constant feed and depth of cut, there was a continuous increase in tool life as the cutting speed was decreased which could be represented approximately by the equation

$$VT^n = V_0T_0^n = c \qquad [1]$$

in which V = cutting speed, feet per minute
T = tool life, minutes
T_0 = 20 minutes
V_0 = Taylor speed; that is, the speed which would give a tool life of 20 minutes
c = a constant for the metal (with specified heat treatment) which is being cut
n = a constant experimentally determined by varying V.

The tests made at different cutting speeds with a feed of 0.0115 in. per revolution and depths of cut of 0.010 and 0.020 in. showed that within a range of tool life of from 2 to 125 min., the experimental results could be closely represented by Equation [1] with $n = 1/10$. This equation with $n = 1/10$ has therefore been used in the present report for all computations involving the relation between the cutting speed and tool life, and gives results sufficiently accurate for all practical purposes except when extrapolating for very long tool life from tests of short duration.

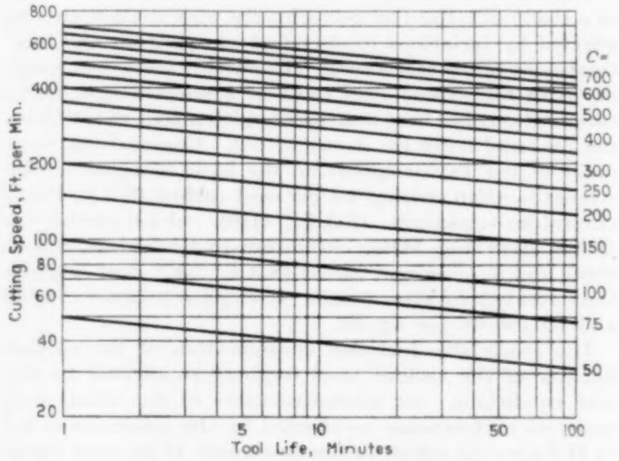

FIG. 2 CHART GIVING THE RELATION BETWEEN THE CUTTING SPEED AND THE TOOL LIFE WITH SHALLOW CUTS

(This chart applies only to "dry" turning of steels with shallow cuts with high-speed-steel tools. Lines drawn according to equation $VT^{1/10} = c$, in which V = cutting speed, T = tool life, and c = a constant.)

Equation [1] with $n = 1/10$ was established with broad-nose high-speed-steel tools, illustrated in Fig. 1(*B*), in dry cutting $3^1/_2$ per cent nickel-steel forgings having tensile strengths between 80,000 to 100,000 lb. per sq. in. This equation is represented graphically by straight lines when logarithmic coordinates are used The chart shown in Fig. 2 for finishing cuts is of a convenient form for computing the life of tools at various speeds. Numerically the constant c is the cutting speed corresponding to a tool life of one minute.

III—METHOD OF TEST

The method used for testing lathe tools with shallow cuts has been described in detail in a previous report.[8] With this method the test and indicating tools were set at equal depths in a special tool holder at the start of the test. The indicating tool began to cut when the wear on the test tool was from 0.001 to 0.002 in., and this was considered as the point of failure of the test tool. In most cases it was found that the wear of 0.001 to 0.002 in. coincided with a complete breakdown of the tool comparable to that found with heavy cuts in rough turning.

From six to ten tools were tested for each condition investigated, and only average values of tool life were used for computation and comparison purposes.

The lathe tests with shallow cuts were made with high-speed-

[9] R. E. W. Harrison, "A Survey of Surface Quality Standards and Tolerance Based on 1929–30 Precision Grinding Practice," paper presented at the A.S.M.E. annual meeting, 1930. The finish calibrator described in this paper could possibly have been adapted to the work described in the present report and might have given results of more value than did the method used for evaluation of the surface finish. However, the experimental work of the present investigation was practically completed before the report by Harrison was published.

[1] Forgings Nos. 46, 47, 48, 49, 50, and 51 were first annealed by heating at 1400 to 1420 deg. fahr. and cooled in furnace to 1100 to 1200 deg. fahr. and then cooled in air to room temperature. These forgings were approximately 8 in. in diameter and hollow bored with holes 3 in. in diameter. Forging No. 46A had the same chemical composition and heat treatment as No. 46 except for the retempering treatment, 46B has the same heat treatment as 46A except for the retempering treatment, etc. This procedure was followed in numbering and heat-treating the forgings used in the tests with shallow cuts. The forgings at the time of the second quenching treatment were smaller in diameter than at the time of first quenching treatment. This change in size accounts for the higher tensile strengths and hardness obtained in the latter case.

[2] Refer to Table 2 for chemical composition.

[3] Forgings were heated with the furnace to the hardening temperatures in 3 to 4½ hr., held at temperatures from 1½ to 3½ hr. and cooled as indicated.

[4] Forgings were cooled in air from the tempering temperatures except those marked with an asterisk (*), which were cooled slowly in the furnace.

steel tools of the broad-nose type, having dimensions and form shown in Fig. 1(*B*). A round-nose tool, Fig. 1(*A*), was used for the indicator. Chemical compositions and heat treatments of the high-speed steels used are given in Table 1.

The pieces on which the cuts were made, commonly referred to as forgings, were selected with the view of obtaining representative steels that come to the ordinary shop for machining operations. The chemical compositions of the forgings are given in Table 2. The forgings were initially about 8 in. in diameter and hollow bored with holes approximately 3 in. in diameter. Some of the forgings, after being used for a series of cutting tests, were heat-treated to higher tensile strengths and hardness values and used for further tests. The forgings having the same S.A.E. number were from the same original forging.

The heat treatments and corresponding average mechanical properties of the forgings are given in Table 3. Average mechanical properties were determined from two or more specimens cut longitudinally from the forgings so as to represent the average properties of the metal removed during cutting. Likewise the micrographs were made on sections representing the metal that had been removed during the cutting tests.

The hardness of some of the forgings after heat treatment was above the range of what is considered commercially machinable with the present high-speed-steel tools. This condition made

[1] The lathe tests were made dry with high-speed-tool steel numbered AA. Composition and heat treatment of tools are given in Table 1. Selected size and form of tool shown in Fig. 1(*B*).

[2] Computed from the average tool life by means of Equation [1] of the text with $n = {}^{1}/_{10}$, or obtained from Fig. 2.

possible a survey of the entire machinable range from the soft or annealed steel to the upper limit of the usual machinability range.

All cutting tests were made "dry" with a constant feed of 0.0115 in. per revolution, depth of cut of 0.010 in., and variable speed depending upon the properties of the metal cut. The cutting speed was varied with the different steel forgings, but was kept constant for each series of tests on a given forging with given mechanical properties. In general the cutting speeds selected were such as to give a tool life of from 10 to 30 min. as is shown in Table 4. From the data thus obtained the cutting speed permitting a 20-min. tool life (Taylor speed) was computed from the average tool-life value by means of Equation [1] with $n = {}^{1}/_{10}$, or by extrapolating by using the chart shown in Fig. 2.

IV—Results of Cutting Tests

The machining properties of a steel forging are recognized as being affected by (1) its chemical composition, (2) heat treatment after working, and (3) quality of the metal cut. The term "quality" refers to those details of composition and constitution not defined by ordinary chemical analysis or by a statement of the heat treatment, but which nevertheless may play a part in making a metal well suited for a particular service. So-called high quality for one service may be inferior for a different service; the term is general in nature as used in this report. It simply implies recognition of the fact that there are other factors beside chemical composition and heat treatment which may contribute to the final properties of the metal.

In the following experiments most attention was given to the first variable, chemical composition. However, the data throw some light upon the second variable, heat treatment; the quality of the metal was assumed to be practically constant in so far as each type composition was concerned.

As is shown in Table 2, most of the forgings selected were alloy steels which contained approximately 0.4 per cent carbon. A plain carbon steel of similar carbon content was included so that comparisons could be made of the effects on tool performance or machinability of chromium, molybdenum, vanadium, and nickel, either alone or in combination.

The alloy steels were supplied through the courtesy of the Central Alloy Steel Corporation, now the Central Alloy Division of the Republic Steel Corporation, Massillon, Ohio. The plain-carbon-steel forging was contributed by the Illinois Steel Company, Chicago, Ill.

It is not practicable to select a single cutting speed with a fixed feed and depth of cut for tool testing on steel forgings with tensile strengths varying over the wide range of 75,000 to 220,000 lb. per sq. in. For example, if a cutting speed was selected to give a tool life of 10 to 30 min. on a forging heat-treated to give a tensile strength of 90,000 lb. per sq. in. and then an attempt was made to use the same cutting condition on a forging of similar composition but with a tensile strength of 200,000 lb. per sq. in., the result would be immediate tool failure. Similarly, if the cutting speed was selected to give the desired tool life on the forging with high strength, then the tool life on the forging of lower strength would be extremely long. As already shown, the relation between the cutting speed and tool life of high-speed-steel tools, under fixed feed and depth of cut, can be closely represented by an empirical equation, and this fact was used in selecting the speeds at which the tool tests were made.

The comparisons of the different steels cut may conveniently be made on the basis of equal tensile strengths and the Taylor speed, such a comparison being taken as a measure of machinability.

The results of the tests with shallow cuts are given in Table 4 and summarized in Fig. 3. These data show that if machinability with shallow cuts is measured by the cutting speed permitting the tool to last a definite time, then measurable and consistent differences are observed in the machinability of the carbon and various alloy steels used in the experimental work. The fact, however, that some given steel permits a higher cutting speed than another steel for a selected tensile strength which is the same for both materials, does not necessarily indicate that the two steels maintain the same relationship for another tensile strength. This is illustrated in Fig. 3 in that, for the conditions of cutting under consideration, the chromium-molybdenum steel (S.A.E. 4140) had the best machinability of the entire group of steels at a tensile strength of 90,000 lb. per sq. in. At a tensile strength of about 110,000 lb. per sq. in. the chromium-vanadium steel (S.A.E. 6140) had the best machinability of the group, and retained this superiority up to a tensile strength in the neighborhood of 175,000 to 180,000 lb. per sq. in. At this point the tensile-strength–Taylor-speed curve for the chromium-vanadium steel crosses the curves for the nickel-chromium steels (S.A.E. 3140 and 3435), and above this range the latter steels permit the higher cutting speeds.

As is also shown in Fig. 3, the slopes of the tensile-strength–Taylor-speed curves vary for the different steels. The curves for any two compositions may cross, and so reverse the order of superiority. In some cases the slopes were not very different, and there was an appreciable range in tensile strength at which, for all practical purposes, the cutting speeds were the same.

The plain carbon steel (S.A.E. 1040), within the range of tensile strengths obtained by heat treatments, was the most difficult of the group to machine other than the annealed nickel-chromium steel (S.A.E. 3435). This would indicate that the special alloying elements, nickel, chromium, molybdenum, and vanadium, either alone or in combination, when added to the plain carbon steel, improve machinability from the standpoint of the cutting speed, permitting a definite tool life with shallow cuts. However, the superiority in machinability of the alloy steels over the plain-carbon type is not to be attributed solely to any single alloying element, but rather to the combined effects of the alloying elements present in any particular steel, considering carbon also as one of the alloying additions. This is evident from the fact that the same alloying elements which in one case increased the cutting speed, under other conditions, as, for example, when present in different relative proportions and requiring different heat treatments to give comparable tensile strengths, may be without any marked effect on the cutting speed.

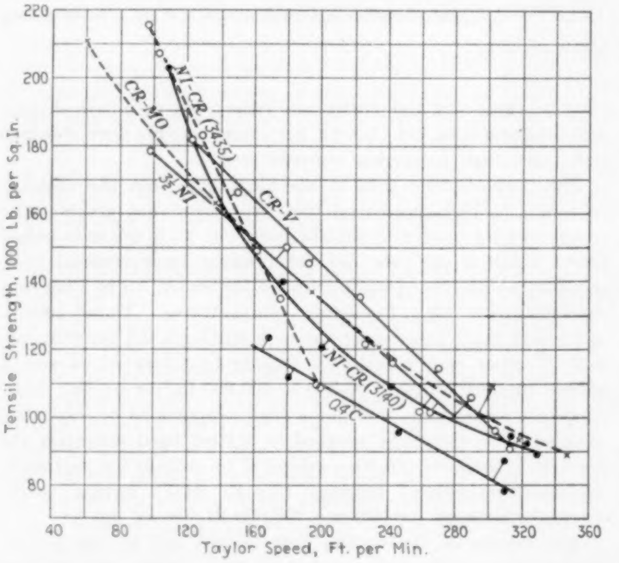

FIG. 3 RELATION OF THE TAYLOR SPEED TO THE TENSILE STRENGTH OF THE SPECIAL STEELS CUT IN THE LATHE TESTS

[For details of chemical composition and heat treatment of steel cut, see Tables 2 and 3. The composition and heat treatment of high-speed-steel tools No. AA used in the tests are given in Table 1. The lathe tests were made "dry" with the size and form of tool shown in Fig. 1(*B*), with 0.0115 in. per revolution feed and 0.010 in. depth of cut.]

This is illustrated by comparisons of the Taylor speeds of the nickel-chromium steels with that of the carbon steel at a tensile strength of 110,000 lb. per sq. in. The nickel-chromium steel containing 0.37 per cent carbon, 0.50 per cent chromium, and 1.26 per cent nickel had a Taylor speed of about 244 ft. per min., while the nickel-chromium steel containing 0.39 per cent carbon, 0.76 per cent chromium, and 2.96 per cent nickel showed the same Taylor speed as the plain 0.42 per cent carbon steel, namely, 198 ft. per min. Thus, at this particular tensile strength the addition of 0.5 per cent chromium and 1.26 per cent nickel increased the Taylor speed by 46 ft. per min., but higher proportions of nickel and chromium additions did not improve the Taylor speed over that of the plain carbon steel.

A comparison of the permissible cutting speeds or machinability of the nickel-chromium steels with those of the other alloy steels used in the experiments is of particular interest. At the higher tensile strengths superior machinability was secured with nickel-chromium alloy steels, but as already stated, certain combinations of these elements may cause a lowering of the cutting speeds of the annealed steels. As shown in Fig. 3, the slope of the tensile-strength–Taylor-speed curve for the steel containing the higher proportions of nickel and chromium was such as to permit a very wide range of tensile values without a marked change in cutting speeds. This fact may possibly be used to advantage in the industrial application of this steel.

With the exception of the nickel-chromium steels, the differences in the Taylor speeds of the alloy steels were within a range of about 20 ft. per min. when considering steels of 100,000 lb. per sq. in. tensile strength. The range increased slightly with increase in tensile strength and reached a value of about 30 ft. per min. when cutting steels of 170,000 lb. per sq. in. The Taylor speed for the 3½ per cent nickel steel was on the low side throughout the entire range. Thus, the 3½ per cent nickel steel was more difficult to machine than the chromium-vanadium steel, and was either more difficult or as difficult to machine as the chromium-molybdenum steel.

The results shown in Fig. 3 indicate that the effect of changes in chemical composition of steel forgings upon their cutting speeds was dependent upon the tensile strength at which comparisons were made. Since the highest tensile-strength values considered in these tests are only produced by quenching, with or without subsequent tempering, changes in chemical composition may act in opposite directions, depending upon whether the steel cut is close to the fully hardened (martensitic) or the annealed (pearlitic) condition.

Elements which cause a lowering in the cutting speeds of the annealed steels may improve the cutting speeds when considering higher tensile strengths. Of the special elements that improved machinability of the different steels cut with shallow cuts, the most effective were the combinations of nickel and chromium or chromium and vanadium for the higher tensile strengths in the neighborhood of 180,000 lb. per sq. in., while the combustion of chromium and molybdenum was the most effective in the lower range of about 90,000 lb. per sq. in.

The mechanical properties of the forgings, given in Table 3, and the cutting-test results, given in Table 4, permit comparisons to be made other than on the tensile-strength–Taylor-speed basis as given in the text. The relative order of machinability of the different steel forgings when comparisons were made on the Brinell-hardness-numbers–Taylor-speed basis agree very closely with the order as given by the tensile-strength–Taylor-speed basis. This agreement might be expected. The order of machinability as given by the tensile-strength–Taylor-speed was changed when comparisons were made on the basis of the Rockwell-hardness (B or C scale)–Taylor-speed, or Shore-hardness–Taylor-speed.

The heat treatments of the forgings, as given in Table 3, show that the desired range of tensile properties was obtained by annealing, or by quenching followed by tempering at different temperatures. The results also show that in some cases approximately equal tensile strengths were produced with a given forging by varying the methods of heat treatment.

The data given in Table 5 show that, in general, the cutting speeds were not appreciably affected by the method of heat treatment by which a given tensile strength was produced. The cutting speeds are slightly higher with the high tempering temperature when comparisons are made of the different methods of quenching and tempering to produce approximately equal strengths. In two cases, namely, with the plain carbon steel (S.A.E. 1040) and 3½ per cent nickel steel (S.A.E. 2340), the better machinability was produced by the heat treatment con-

The lathe tests were made dry with high-speed tool steel AA (Table 1), with a feed of 0.0115 in. per revolution and 0.010 in. depth of cut. Selected form and size of tool shown in Fig. 1(*B*).

[1] Estimated from the known relation between tempering temperature and tensile strength.

[2] Value obtained from tensile strength—Taylor speed curve of Fig. 3.

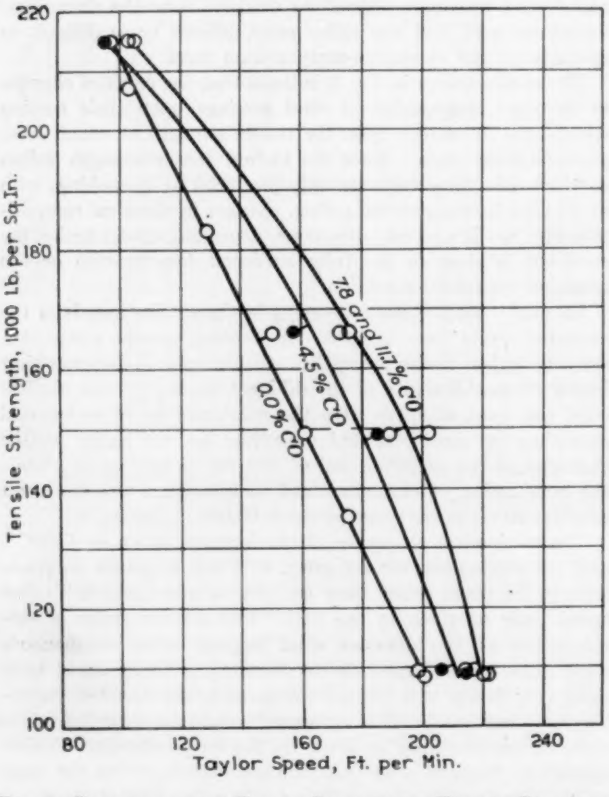

FIG. 4 RELATION OF THE TAYLOR SPEED TO THE TENSILE STRENGTH OF THE NICKEL-CHROMIUM S.A.E. 3435 STEEL CUT WITH HIGH-SPEED-STEEL TOOLS CONTAINING DIFFERENT PROPORTIONS OF COBALT

[Chemical composition and heat treatment of the high-speed-steel tools are given in Table 1. Chemical composition, heat treatment, and mechanical properties of the steel cut are given in Tables 2 and 3. The lathe tests were made "dry" with the size and form of tool shown in Fig. 1(*B*), with feed of 0.0115 in. per revolution and 0.010 in. depth of cut.]

sisting of quenching and subsequently tempering at a high temperature than with the annealing treatment used.

V—TESTS WITH COBALT HIGH-SPEED-STEEL TOOLS

High-speed-steel tools containing considerable proportions of cobalt have been reported to give excellent performance when cutting hard metals, and to have made possible the commercial machining of high-manganese steel. In previous tests made at the Bureau of Standards,[8] it was found that cobalt improved the performance of high-speed-steel lathe tools, with both shallow and roughing cuts, but that the maximum benefits were obtained only with high hardening temperatures.

The proportionate gain in machinability from the addition of cobalt to high-speed-steel tools was somewhat greater with rough turning than with shallow cuts, but an increase in cobalt above about 5 per cent did not produce improvements commensurate with those resulting from additions of 3.5 to 5 per cent together with high hardening temperatures. These conclusions were made from experiments in cutting a 0.3 per cent carbon, $3^1/_2$ per cent nickel-steel forging heat treated to give a tensile strength of about 90,000 to 100,000 lb. per sq. in. Since high-speed-steel tools containing high proportions of cobalt are claimed to be especially adapted to cutting hard materials, the tests with shallow cuts were extended to include the cutting of nickel-chromium-steel forgings (S.A.E. 3435) having tensile strengths between 100,000 and 220,000 lb. per sq. in.

The results of the cutting test carried out in the present investigation with high-speed-steel tools, with and without cobalt, are summarized in Fig. 4. The data show that lathe-tool performance with shallow cuts was improved by the additions of cobalt (together with higher hardening temperatures) to the customary 18 per cent tungsten type of high-speed steel. Maximum gain in performance was obtained when cutting the forgings with tensile strengths up to about 170,000 lb. per sq. in.; above this strength the gain in performance by increasing the cobalt additions was not so marked. Confirmation was also obtained of the previous test results, namely, that the increase in cobalt above about 5 per cent did not produce improvements of the same order as those resulting from 3.5 to 5 per cent together with high hardening temperatures.

VI—MICROSTRUCTURES AND SURFACE FINISHES

Although most attention was given to tool life with shallow cuts in studying the machinability of the different forgings cut in the lathe tests, it was also recognized that the structure and appearance of the surface finish are important factors in finishing cuts, and possibly may be considered as factors in any index to machinability.

Photographs were made of representative surface conditions while cutting with sharp tools for each series of cutting tests, and these photographs were later compared with the appearances as recorded by the observer during the machining operations. There was a fair agreement between the classification by the two methods. It was found that the photographs were a convenient but not an entirely satisfactory basis for making comparisons. All photographs were "natural size" and no attempts were made to show the surface conditions at greater magnifications.

The samples for microscopic examination were etched in 2 per cent nitric acid in alcohol and all micrographs are given at 500 magnifications. The microstructure shown in Fig. 5G corresponded to the best surface finish (shown at 5-H) of the entire series of plain carbon steels (S.A.E. 1040) used in the experiments with shallow cuts. The resulting surface was fairly smooth and polished, with some tool marks, and while not so good as some of the surfaces produced on the different alloy-steel forgings, it may be classed as satisfactory. The finishes as shown in Fig. 5-B, D, F, and J were dull, badly torn, with small bright particles embedded in the surface. None of the latter condition was considered satisfactory so far as the appearance of the finish was concerned.

An interesting feature is shown by comparing the heat treatments, microstructures, tensile properties, finishes, and machinability of forgings 51C and 51D. Forging 51C, quenched from 1650 deg. fahr. in water and subsequently tempered at 1300 deg. fahr. and cooled in air shows some spheroidization or agglomeration of the cementite (Fig. 5-G), satisfactory surface finish, 87,500 lb. per sq. in. tensile strength, and a Taylor speed of 310 ft. per min. Forging **51D**, quenched from 1650 deg. fahr. in water and subsequently annealed at 1550 deg. fahr., slowly cooled in the furnace, shows distinctly lamellar pearlite (Fig. 5-I), 81,500 lb. per sq. in. tensile strength, and a Taylor speed of 310 ft. per min. Forging 51C, therefore, showed the best machinability both from the viewpoint of the cutting speed and appearance of the surface finish, provided comparisons of cutting speeds were made on the basis of equal tensile strengths.

For the cutting conditions investigated, the chromium vanadium, chromium-molybdenum, nickel-chromium (3135), and 3$^1/_2$ per cent nickel-steel forgings were considered as producing surfaces of approximately equivalent smoothness and were slightly superior to the nickel-chromium steel (3435). However, there were no very marked differences observed in the appearance of the surfaces of the forgings of the different alloy compositions, and all may be classified as satisfactory. Each type of alloy steel showed surfaces that were considered much superior to that of the plain carbon steel.

The characteristic finish of the different alloy steels may be described as smooth, medium to highly polished, with but little tearing and showing some tool marks.

The microstructures and surface finishes of all the alloy-steel forgings with the varying heat treatments were examined, but no correlation between structure, surface finish and machinability appeared possible. Fig. 6 showing the microstructures and surface finishes of the chromium-vanadium forgings is representative of the results obtained with the alloy groups.

Vanick and Wickenden[10] have shown in some lathe tests of plain and alloy low-carbon steels of the carburizing type that for each steel and its particular heat treatment there was a critical range of volume removal rates within which a rough finish was obtained. By avoiding this critical range, smoothly finished surfaces could be obtained. It was found that cutting conditions leaving a rough surface could be changed to give a smooth finish by: (1) either lowering, or preferably increasing, the cutting speed until it is outside the critical range; (2) maintaining the speed but changing the cut or feed; (3) sharpening the cutting angle of the tool and maintaining speed and shape of chip; (4) changing the hardness of the steel being cut; usually increasing it in order that a good finish is produced at an easily obtainable speed.

---

[10] J. S. Vanick and T. H. Wickenden, "Smooth Finish Machining of Low Carbon Plain and Alloy Steels," Trans. A.S.S.T., vol. 11 (1927), p. 551.

Rapatz,[11] in a study of the surface conditions of plain carbon and nickel-chromium steels of different strengths and hardness in some lathe turning tests, found that higher tensile strengths, higher speeds, and greater depths of cut favored the production of smooth surfaces, assuming the turning is performed with perfect tools. Yield point, elongation, and reduction of area were less important for obtaining smooth surfaces.

Although some of the surface finishes of the alloy-steel forgings used in the present investigation were more highly polished and came nearer to being smooth than others, the differences observed in the general characteristics of the finishes were not large. The order in which the forgings were arranged in regard to the surface appearance, under the conditions of test used, possibly might be different if the cutting conditions were changed.

VII—SUMMARY AND CONCLUSIONS

1 The tests described in this report were made primarily as a study of high-speed-steel-tool performance with shallow cuts as affected by variations in the chemical composition and heat treatment of the steels cut. The study also included consideration of the surface finish of the various steel forgings, the microstructures of the metals cut, and also of the tool performance as affected by additions of from 3.5 to 11.7 per cent cobalt to the 18 per cent tungsten type of high-speed steel.

2 The method used for testing lathe tools with shallow cuts was based upon the fact that when two tools are set at equal depths in one tool holder, the second, or indicating tool, will not cut so long as the leading, or test tool, shows no wear. With this method of test, the indicating tool began to cut when the wear on the test tool was from 0.001 to 0.002 in., and this was considered as the point of failure of the test tool. In most cases it was found that the wear of 0.001 to 0.002 in. coincided with a complete breakdown of the tool comparable to that found with heavy cuts in rough turning.

3 The lathe cutting tests were made dry with high-speed-steel tools of a selected size, form, composition, and heat treatment, with a fixed feed of 0.0115 in. per revolution, 0.010 in. depth of cut, and variable cutting speeds depending upon the properties of the material cut.

4 The metals cut included a plain carbon and various alloy-steel forgings heat treated to give tensile strengths between 75,000 and 220,000 lb. per sq. in.

5 The measure of machinability was the cutting speed permitting a definite tool life.

6 Measurable and consistent differences were observed in the machinability of the carbon and alloy steels used. The fact, however, that some given steel permits a higher cutting speed than another steel for some tensile strength which is the same for both materials, does not necessarily indicate that the two steels maintain the same relationship for another tensile strength.

nickel-chromium steel. The surface finishes of the carbon-steel forgings were also inferior to those produced on the alloy-steel forgings. However, with a particular heat treatment of the plain carbon steel, showing a microstructure of partially spheroidized or agglomerated cementite, a medium smooth and satisfactory finish was obtained with the cutting condition used. This same heat treatment also resulted in the best machinability of the group of carbon steels when comparisons were made on the basis of the cutting speeds at equal tensile strengths.

8 The superiority in cutting speeds of the alloy steels over the plain carbon type is not to be attributed solely to any single alloying element, but rather to the combined effects of the alloying elements present in any particular steel, considering carbon also as one of the alloying additions.

9 The results of the present tests with shallow cuts compared with previously reported tests with roughing cuts[5] show that the effect of change in chemical composition of steel forgings upon their cutting speeds is dependent not only upon the tensile strength at which comparisons are made, but also upon the conditions of cutting. That is, steel forgings that show superior machinability with shallow cuts at some tensile strength do not necessarily show a similar superiority with roughing cuts.

10 Of the special elements that improved machinability of the different steels cut with shallow cuts, the most effective were the combinations of nickel and chromium or chromium and vanadium for the higher tensile strengths, in the neighborhood of 180,000 lb. per sq. in., and chromium and molybdenum in the lower range of tensile strengths, about 90,000 lb. per sq. in.

11 In general, the cutting speeds were not appreciably affected by the method of heat treatment by which a given tensile strength was produced. The cutting speeds were slightly higher with the higher tempering temperature when comparisons were made of different methods of quenching and tempering to produce approximately equal tensile strengths. In two steels, namely, with the plain carbon steel and $3^1/_2$ per cent nickel steel, the better machinability was produced by the heat treatment consisting of quenching and subsequently tempering at a high temperature than with the annealing treatments used.

12 Lathe-tool performance with shallow cuts was improved by the additions of cobalt (together with higher hardening temperatures) to the customary 18 per cent tungsten type of high-speed-tool steel. The maximum gain in performance was shown when cutting the forgings with tensile strengths up to about 170,000 lb. per sq. in., but above this strength the gain in performance was not so marked.

13 Confirmation was also obtained of previous test results, namely, that the increase in cobalt above about 5 per cent did not produce improvements in tool performance of the same order as those resulting from $3^1/_2$ to 5 per cent and higher hardening temperatures.

14 The differences observed in the surface finish of the different types of alloy-steel forgings were not large, and all were considered as being satisfactory and of about equivalent smoothness.

15 A correlation of the cutting speeds, tool life, surface finish, etc., shows that, with the test method used, the machinability of the carbon- and different alloy-steel forgings used in the experiments may be properly determined or measured by the cutting speed permitting the tool to last a definite time.

VIII—ACKNOWLEDGMENTS

The author acknowledges the assistance of E. C. Smith, chief metallurgical engineer, formerly of the Central Alloy Steel Corporation, Massillon, Ohio, for supplying the alloy-steel forgings and of S. Epstein, metallurgist, formerly of the Illinois Steel Company, So. Chicago, Illinois, for supplying the carbon-steel forging used in the cutting tests.

Grateful acknowledgment is also due to W. V. Magruder, laboratory aid, formerly of the Bureau of Standards, for his assistance in carrying out the many tests; to Louis Jordan, senior metallurgist, for his suggestions in the presentation of the test data, and to S. E. Sinclair, junior metallurgist, for the micrographs given in this report.

Discussion

Joseph Geschelin.[12] The formal methods of testing procedure, correlation of data, and other details involved need no comment. Any research job coming from the Bureau of Standards carries its own seal of approval.

What interests more than anything else is the value of the results to the production men and other investigators in the field of the cutting of metal. Much has been said in the past about machinability. In fact, at least two different machines have been introduced during the last two years for measuring machinability. But the simplest statement heard thus far is the one made by the author—namely, that the measure of machinability was the cutting speed permitting a definite tool life. This might well be linked with the quality of the surface finish, inasmuch as this is frequently a factor of prime importance.

It is very important to know that alloy steels are superior in machinability to the plain carbon type from the standpoint of cutting speed, permitting a definite tool life with shallow cuts. At higher tensile strengths, superior machinability was secured with nickel-chromium alloy steel, and as shown in Fig. 3, the steel containing the higher proportions of nickel and chromium permitted a wide range of tensile values without a marked change in cutting speed. This is, undoubtedly, valuable information to the production executive.

Another very important point is the value of combinations of chromium and vanadium, or nickel and chromium, to improve machinability for the higher tensile strengths in the neighborhood of 180,000 lb. per sq. in. Vanadium has many desirable qualities in alloying, most important of which are in the field of drop-forged steel for engine crankshafts in automotive works. It is certainly noteworthy that this element also aids machinability.

The author raised an interesting point about the possibility of using R. E. W. Harrison's method for comparing surface finishes. The criteria established by Mr. Harrison for measuring surface quality standards may have much wider application than any of us realized at the time the paper was first read.

W. S. Huson.[13] There is much in this paper that invites discussion. The data are valuable additions to those already published and bring out features in tests that may answer to some degree why in the machining of steels a certain tool will stand up longer on one grade of steel than on another generally classed in the shop as this or that alloy steel. Study of the life of a tool is desirable, say where black-bar stuff is bought on the basis of as little stock as possible to be removed to bring to size on a production basis. How much of these data can be absorbed is conjectural; each high-speed cutting tool claims superiority in some particular over the other, usually in that the cutting edge will stand up longer at higher speeds; when it does not perhaps the cutting edge is not shaped just right, and so on—shop practice often being governed by empiric finding rather than real investigation.

Maybe this thought is born of an excerpt from R. W. Kent's paper (Trans. MAN-52-2b), "Use of Economic Manufacturing

---

[12] Engineering Editor, *Automotive Industries*, Philadelphia, Pa.

[13] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

Quantities—Obstacles Encountered in Introducing Mathematical Formulas for Economic Manufacturing Quantities."

While the inference of stricture can be put aside, the remark that "Since the average manufacturing executive does not appear to have sufficient mathematical mental agility to clearly, thoroughly, and readily grasp the development of formulas for mathematical determination of economic production lots or manufacturing quantities, he should prepare himself to settle down and really seriously and patiently set about understanding how the particular formula recommended for his use was derived," carried some truth with it and can be broadened into the consideration of Digges' paper.

With ten years' background of study and the ample bibliography quoted, the analyses of tool action on various grades of steel can well be put into service if time is given them, not only that dependable practice will result, but also a grasp of how the laboratory is endeavoring to help in the better, quicker, and less arduous production of finished material.

O. W. Boston.[14] The paper is a valuable contribution to the interesting subject of metal cutting. It gives the results of a great amount of painstaking experimental work, for which the Society should be grateful. The data are of value to hundreds of industries interested in finish machining.

It seems, however, that a word of caution might be offered to stress the point that the data presented apply to a particular shape of tool and to certain cutting conditions as to size. It is believed that the exponent of tool life in Equation [1] is dependent both on the shape and size of the tool and upon the depth of cut and feed per revolution. The value of this exponent has been taken as $^1/_{10}$ for the specific conditions indicated. If the tool shape were changed, it is believed that this exponent would change correspondingly. Further, if the size of tool, depth of cut, and feed were changed, it is believed that the exponent would again be changed. The author has previously shown that in rough turning, the value of this exponent is $^1/_7$ for a different tool (see author's reference 5). It seems that one important missing link in our knowledge of metal cutting is the transition from this $^1/_7$ to $^1/_{10}$. In other words, it seems that still more information of an experimental nature should be presented for different shapes and sizes of tools, each covering the whole range from heavy to finishing cuts.

It is perhaps unfortunate that the author has not attempted to correlate the results of tool life as a function of tensile strength for various steels as shown in Fig. 3 for finishing cuts with similar data obtained by taking roughing cuts, as presented in an earlier paper. The same applies to the influence of the amount of cobalt in the high-speed steel of which the tools were made.

The use of the term "machinability" has been referred to in the discussion of this paper. The writer is of the opinion that there should be a number of definitions for the word machinability, and that the word machinability has a proper place in our vocabulary. He deplores, however, the random use of the word, such as indicating that this steel has good machinability and that bad machinability, unless the meaning of machinability in the particular case is made perfectly clear.

The author has used the term machinability with reference to tool life in such a way that the material having the greatest or best machinability permits the greatest life of the standardized tool. In the latter part of the paper a study of surface finish is made in which, naturally, that structure which gives the best finish would be the most machinable in this particular sense. There are many methods of designating machinability, all of which are of peculiar interest. They may be outlined in part as follows:

(1) Tool life in turning, milling, drilling, broaching, tapping, etc.
(2) Torque in drilling
(3) Thrust in drilling
(4) Cutability as measured by drill penetration, or the penetration of a hacksaw subjected to a given feeding load, rather than the rate of feed
(5) The surface produced by a given tool
(6) Power required when cutting by various processes.

There is no known relation between these various processes; 13 per cent manganese steel cuts with great difficulty, and yet the torque in drilling with a certain size and shape of drill is no more than that produced by a number of other commonly used steels; the thrust, however, is much greater. Truly then, we are interested in this phase of machinability as it affects the drill shape and size for strength and as it affects the design of the machine tool.

A coolant on a tool may produce longer tool life and lower power in turning, drilling, etc., but when used in a hacksaw with gravity feed, it may slow up the cutting action.

These are only a few of the complexities of metal cutting, and the writer pleads for tolerance in the use of the word machinability in its various specific applications.

G. A. Bouvier.[15] The paper furnishes new proof that an understanding of the problem of machinability is extremely difficult. This is at least partly due to the fact that the definition of the term machinability is still subject to personal opinion and depends, to a large extent, upon the practical purpose of the investigation.

Since F. W. Taylor first published his book on the art of cutting metals, much work has been done in this country and abroad to throw new light on this problem. It is significant that the tests described in this paper deal with shallow cuts; i.e., cuts which Mr. Taylor did not consider as giving conclusive information on the machinability of a metal. Our manufacturing methods have, however, changed to such an extent that a knowledge of the machinability at shallow cuts is imperative. In the application of tools of the tungsten-carbide type, for instance, it has been found that increased benefit from these tools can be derived from higher speeds rather than from heavier cuts.

The trailer-tool method employed by the author for measuring tool wear seems to correspond to actual shop conditions, to the extent that a machined diameter must be held within certain limits. There is, however, doubt in my mind that this method can be consistently relied upon to give a tool life or end point comparable to that obtained with the breakdown test.

As an illustration, let us assume that a hard and a soft material are to be investigated. It seems rather certain, in this case, that the time at which the trailer tool starts to cut will be influenced not only by the wear on the cutting tool but also by the mechanical properties of the material investigated, such as ductility, drag on the tool, etc., which need not necessarily have an important bearing on the wear of the tool, but will show up on the trailer. No doubt the author has considered this factor as well as the variation due to spring and radial displacement of the tool resulting from the chip's pressure.

It would be interesting to know in this connection what reductions in the machined diameter of the various test pieces were necessary to make the trailer tool cut and also what the thickness of the chip removed by the trailer tool was in each case. The writer would expect that on some materials there would be a slight burnishing action from the trailer tool before it "bit."

---

[14] Director, Department of Engineering Shops, Colleges of Engineering and Architecture, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[15] Western Electric Company, Hawthorne Works, Chicago, Ill.

During some tests, it has apparently been found that the wear on the cutting edge of 0.001 to 0.002 in. coincided with the complete breakdown of the tool comparable to that experienced with heavy cuts in rough turning. Comparisons between the results of tests with shallow and roughing cuts seem, in this case, justified.

As far as comparisons are concerned between tests with shallow cuts where the tool life was based entirely on the time when the trailer tool started to cut, and roughing tests, where the complete breakdown of the tool was used as a basis for tool life, it may be that the inconsistency in the results is partly due to a fundamental difference in the two testing methods.

It is interesting to note that the author has also made an attempt to grade the finish and to correlate it with the material's machinability. The author has made reference to the phonograph method described by Mr. R. E. W. Harrison in one of last year's papers, which is intended as a mechanical means for grading the finish of ground surfaces. Certainly it is desirable that further research be done to find a satisfactory grading method which eliminates the subjective factor and is based entirely upon electrical or mechanical principles. The work already done by Mr. Harrison may point to a step in the right direction. Personally, the writer has not abandoned hope that the method employing reflected light will prove practicable. It seems quite reasonable to him that machinability studies involving finish should use a predetemined change in finish rather than tool wear to indicate the end point.

The term machinability as used by the author is taken to mean tool life measured either with the trailer-tool method or the breakdown test. In both cases a definite point has first to be reached before a test can be evaluated.

As noted by the author, a number of investigators have measured the cutting pressure on the tool for a definite set of cutting conditions and used the results as a measure of machinability. Others have used the increase in cutting pressure during the cutting action of the tool, since this increase bears a definite relationship to the tool life. The first method is misleading, since it does not disclose all the characteristics of a material which tend to wear out the cutting edge of a tool. The second method is basically correct, but has in its practical application in most cases suffered through the inadequacy of the measuring devices, usually consisting of hydraulic gages which, due to their sluggishness, do not register all the details of the cutting action. Suitable rigidity of the tool mounting is difficult if not impossible to obtain, and it is questionable whether any worth-while improvements can be made in devices of this type.

The Western Electric Company has overcome the greater part of the above-mentioned difficulties in a device which permits the measurement of all three components of the tool pressure. The device makes use of the piezo-electric property of quartz crystals when subject to pressure in certain directions. Electrostatic charges are created which within a wide pressure range are directly proportional to the pressures. On account of the relatively high natural frequency of the mechanical system comprising the crystals and tool mounting, the charges follow very closely all changes in the applied pressures. A record of the amplified charges in connection with calibration curves will therefore give a clear picture of the cutting action. The writer expects that it will be possible to report on the device and some of the results obtained at the next annual meeting.

The tests conducted by Mr. Digges have shown a certain consistency between tensile strength and Brinell hardness on one hand and tool life on the other hand, if one and the same material is considered. Where different materials were compared, a change in the order of machinability was found in some cases for various tensile strengths. This seems very confusing. The results of the tests, together with those obtained in previous tests by Mr. Digges and other investigators, make it seem as though we are far from a general solution of the problem of machinability and that only through a competent correlation of all the work done so far and cooperation on a national or even international scale can we hope to make satisfactory progress. There are an infinite number of variables, and the Bureau of Standards would render a splendid service by compiling a list of them and if no more than on a "guesstimate" basis indicate their relative importance.

The matter of chemical composition alone is obviously of tremendous importance, and the writer appreciates very much the author's contribution to the subject.

AUTHOR'S CLOSURE

The word "machinability" is in every-day use, and it now occupies a permanent place in our vocabulary. It is therefore unfortunate that so much confusion exists from the use of this term. As Professor Boston has pointed out, this confusion is due to the various criteria used by different investigators and machinists to evaluate machinability. Probably in the near future some one will define machinability so that its meaning will be clear to all concerned and will set aside the existing confusion. Until such a time one can only use the term for a specific application.

It is indeed gratifying to have Mr. Geschelin's and Mr. Huson's remarks on the value of the results to the production men.

Professor Boston's word of caution in regard to the application of the test data is important. The application of the results to conditions differing widely from those used in the tests are likely to be misleading. The order of superiority in machinability of the different steel forgings would probably be different if, for example, the tools had been of the new cutting material, cemented tungsten carbide. Reference has been made to the results of tests with roughing cuts, presented in an earlier report. It was felt that it would be needless repetition to include these results in the present report.

In reference to Mr. Bouvier's discussion, when the test conditions are such as to permit the tool to cut for a long period, the trailer method does not always give an end point corresponding to a complete failure of the tool with roughing cuts. In the majority of the tests here reported, the end point coincided with a complete breakdown of the tool.

It is believed that the variation in size of the forgings used in the cutting tests had no influence on the time at which the trailer tool began to cut. The design of the tool holder was such as to eliminate errors due to the mechanical properties of the materials investigated, spring of tool, etc. No attempts were made to measure the thickness of the chip removed by the trailer tool, and no burnishing action from the trailer tool was observed in the cutting tests.

The author is looking forward with considerable interest for the presentation of Mr. Bouvier's report of his experiments in measuring the forces on cutting tools with quartz crystals. Some Japanese investigators also have made use of the piezo-electric properties of quartz crystals in measuring the force on cutting tools. Some data on this subject are contained in a report by M. Okochi and M. Okoshi, Scientific Papers of the Institute of Physical and Chemical Research, Vol. 5 (No. 84), 1926–1927, p. 261.

MSP-54-5a

Small Tools and Gaging for Interchangeable Manufacture

By E. J. BRYANT,[1] GREENFIELD, MASS.

To secure interchangeable parts in continuous production, proper gaging is necessary. The author describes the specifications by which the design of the correct gage can be greatly simplified. The methods by which the manufacture of reamers, taps, threading dies, drills, etc., can be held to uniformity, within proper tolerances, are covered in the paper.

ONE of the first, and probably the most important, requirements before proceeding with the manufacture of an interchangeable product is a set of drawings of the parts which have been dimensioned to give working tolerances on all dimensions, with particular emphasis on the fact that all dimensions should have a tolerance. The less important dimensions can be satisfactorily covered by standard or printed specifications on the drawing form, which gives a tolerance for all dimensions for which the tolerance is not given between the dimension lines. Each engineering department can vary this fixed limit according to the product with which it has to deal.

These general specifications or tolerances should cover only those dimensions that designate unmachined surfaces, such as the general dimensions of castings or forgings. The machined surfaces should be dimensioned with the limits permitted for that particular dimension. The practice in the way of designating these limits should be standardized; as a matter of fact, it would be highly advantageous if the practice in this regard could be standardized throughout the world. Certainly there is no reason why all of the drawings originating from one engineering department should not be consistent in this respect, but it is very rare that they are, the reason being that different draftsmen brought up in different organizations have different methods of designating tolerances.

Thorough engineering practice in dimensioning the drawings with tolerances will bring to light many points in construction and possible interferences that might otherwise be overlooked until much time and material have been wasted by incorrect machining. This is not a theory—the case has been proved time and time again to the sorrow of many.

In bringing out a new product it is highly desirable and economical to have some parts made to the maximum metal condition and other parts made to the minimum metal condition, and to have these parts tested in actual performance before proceeding with the designing and making of tools for producing the parts. Reasonable tolerances should be allowed on all dimensions. It is well to emphasize "reasonable" rather than "maximum" or "liberal," because an excessive amount of tolerance—that is, tolerance beyond that required for ordinary careful workmanship—has been found to lead to more spoiled work through carelessness than is the case where reasonable tolerances are used. As a matter of fact, present-day production is demonstrating that so-called "close" tolerances take no more time to produce and result in less spoiled work, and in general better product, than would be the case if the maximum functional tolerance is allowed on the product.

Of course, the value of interchangeable product is not only from the economy in assembling, but in service to the consumer in being able to supply replacement parts, and this is, in most industries, an absolute necessity.

In the case of thread sizes, it is desirable for the engineering department to adopt a list of preferred sizes to be used on all product. The individual engineer in designing his product should use no other sizes except in the case of an absolute necessity, in which case the necessity for their use should be decided by the chief engineer or by a board. Economies resulting from this procedure will result in very material savings, as it materially affects inventories and availability of production tools.

Fixtures and Jigs

The next consideration after the specifications and models or sample parts is the necessary jigs and fixtures. The author will not touch on this, as his subject covers small tools and gages, and he does not interpret this to include jigs and fixtures.

The general principle in this field was well outlined by Joseph W. Roe in his contribution to the Machine Shop Practice Division at the Annual Meeting on Dec. 3, 1928.

The author only emphasizes in this connection the importance of working from one locating or registering point on the product, the necessity of clamping the work directly over a supported surface, and also that the jigs be so designed that their own clamps do not distort them. There is no metal that is being worked with in any of the industries today that is not flexible to a far greater extent than is generally realized, which results in many inaccuracies that are difficult to account for. One should provide for ample chip clearance and easy cleaning.

Gages

With the proper specifications, the designing of proper gages for the part is greatly simplified. Usually it is only when it has been decided to put limit gages on the job that serious consideration is given to the tolerances that can be allowed. A large percentage of the drawings received with instructions to supply limit gages do not have sufficient information from which to set the proper limits, so either general practice must be applied or the job be delayed until more information in regard to the functional requirements of the part are obtained. Gages answer the workman's question regarding the accuracy to which he must work.

[1] Manager, Gage and Reamer Departments, Greenfield Tap and Die Corporation. Graduate machinists' apprentice, Brown & Sharpe Mfg. Co., Providence, R. I. Supervised construction of machines and parts for several years and was general foreman of Small Tool Division for four years. With Taft-Peirce Mfg. Co., Woonsocket, R. I., for approximately ten years, inaugurating and managing their Small Tool and Gage Division. Mem. A.S.M.E.

Contributed by the Machine Shop Practice Division and presented at the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

With the drawings properly dimensioned and gages made to these dimensions, no time is wasted by the workmen or foreman in guessing at the accuracy required for the particular dimension of the part on which he is working. The author cannot refrain from emphasizing this fact, because he knows from experience that in thousands of shops the management does not insist on the necessary time being taken to produce proper drawings and tools before proceeding with production, and they never know what their final losses are from this procedure. These losses are continuous from the time the incomplete drawing leaves the engineering department until the shop has discontinued the manufacture of the part to that drawing. The sum total of losses from this procedure runs into millions of dollars a year.

The general subject of gaging is covered by Prof. Earle Buckingham's paper contributed to the Machine Shop Practice Division at the Annual Meeting on Dec. 2, 1929.

The author would emphasize the recent trend of general practice, which is the very general use of class 2 and class 3 specifications for screw-thread work. Class 2 specifications meet the requirements of general thread assemblies, and the tolerances are as liberal as are necessary for nearly all classes of work, and with the possible exception of some of the small numbered sizes for which class 1 is more practical. Class 3, which was originally designed for the better grade of automotive work, has proved to be generally applicable to all of the better grades of screw-thread requirements.

The economical production of threaded holes to class 3 specifications has been made practical by the general use of ground thread taps, which can now be obtained in all sizes. External threads are generally produced with adjustable tools, either adjustable dies or thread-milling machines, and there is no loss of production involved in holding these parts to reasonable limits. In many instances this member can be held to class 3 specifications where it is desirable and economical to produce the hole to class 2 specifications. The combination of class 2 and class 3 assembly naturally makes a better or closer condition than the application of class 2 to both members, and it is an economical solution of many problems.

It is not economical to check too many dimensions with one gage. Gages are designed to disclose that the product is within the specifications, and except in the case of receiver gages, which check the relation of all of the important dimensions of a part, it is desirable that the gages should check the individual dimensions, as the operator has the tendency to overlook or miss some point that is outside of the gage dimension.

Automatic and semi-automatic gaging machines with electrical indicating and selecting devices are being more generally used. This type of gaging equipment requires a very large volume of production to justify the outlay involved, but where the production is continuous it results in important savings.

In closing the subject of gages, there should be emphasized the importance of a periodical inspection, not only of the gages used on the product, which of course may be subject to inspection at intervals or as they are put into use, but inspection of the master or reference-gage equipment of the factory, as a necessity for good production.

REAMERS

Reamers for interchangeable manufacture can be obtained in adjustable designs for most of the large sizes of the more expensive reamers, thus permitting the reamer to be kept well within the tolerance. Smaller sizes, of course, are used in the solid type, and must be discarded when worn below the limits of the particular job on which they are used.

The hole tolerances set up by the General Motors organization, as outlined by Mr. D. W. Ovaitt in his articles in *American Machinist* of June 5 and 12, 1930, provide a practice which can be economically used in many factories, as when the solid or non-adjustable tools of these small sizes are worn below the limits for one class, they can still be used for other classes. The establishing of the classes of limits for plain holes is now before the Sectional Committee on Allowances and Tolerances for Cylindrical Parts and Limit Gages, and undoubtedly classes of fits embodying the principles outlined by Mr. Ovaitt will be considered by this committee.

The increased efficiency of grinding permits of the more economical production of holes to closer requirements, also the use of the new steel alloys for reamer blades has increased the life of reamers, and gives economical production of holes to close limits in large quantities. Cemented tungsten carbide can economically be used for reamer blades in some cases.

It has been interesting to note the change from spiral to straight and then from straight to spiral flutes in reamer designs. The old straight fluted reamers were generally superseded by the spiral fluted to prevent chatter and give smooth holes. With the adoption of staggered spacing, the straight fluted reamer came again in vogue, as the straight fluted reamer will always produce a straighter hole than will the spiral fluted reamer; and now, probably because of better machine alignment and machining, the spiral fluted reamer is in more general use than the straight fluted reamer, although the fact still remains that the straight fluted reamer will produce a straighter hole.

TAPS

Probably one of the most troublesome problems in the past of interchangeable manufacture has been the thread parts, particularly the tapped holes. The ground threaded tap has reduced the trouble along this line to the minimum, and today ground thread taps of high-speed steel are available that are made more accurately than the old cut thread taps. They are correct for lead and form, and are within the same pitch diameter specifications as the cut thread tap. Their cost is no greater than was previously paid for the cut thread tap. These taps are generally suited to produce holes to class 2 tolerances. Then for the close specifications, such as the class 3 tolerances, the close-limit ground thread tap is available and at a very reasonable price. Both types of taps are available in various styles. The so-called hand tap of the plug type is the one most generally used in production. The various forms of the so-called "gun" tap, which curls the chip ahead of the tap, are very popular for machine tapping, particularly for through holes or where the hole can be drilled deeper than the depth of thread required. This type of tap requires considerably less power, and is used to advantage on the multiple tapping machines, automatic tappers, and when tapping with electric motors.

Ground taps can be obtained with different types of relief, and special taps with interrupted threads are a necessity for economy production of threaded holes, particularly on the tough, stringy metals, such as tubing.

The length of chamfer on a tap has an important bearing on the production, not only in the size of hole produced, but also in the life of the tap. One length of chamfer will not produce the best results in all materials under all conditions. In general, the short chamfered tap has more tendency to free itself—that is, cut oversize—and the long chamfered tap cuts closer to size. In cast iron and brass, the short chamfered tap—that is, a tap with one to two thread chamfer—is the best. On steels a longer chamfered tap is usually desirable and frequently a necessity. The alignment of the machine—that is, the alignment of the spindle with the hole—is an important feature, several production engineers going so far as to assert that the major part of the tap breakage is due to this defect. The producing of a good thread in most tough tapping jobs is usually obtained with a combination of the correct chamfer, cutting hook of the tap, and the use of the proper lubricant.

The necessity of the proper lubricant cannot be overemphasized. Where the very best possible design of tap is used, it is at times impossible to obtain anything like a decent thread or only a very limited number of good holes, until the proper lubricant is used. This means in most cases that a special lubricant adapted to the work must be found. There are some on the market at the present time that are especially adapted for the tapping of holes in tough material. Another known effect of lubricants is on the cutting size of the tap. Lubricants with a high sulphur base will cause the tap to cut considerably over in size.

The actual size that a tap will cut is controlled by a number of different conditions. This fact is not generally appreciated by the purchaser of taps, but the fact is that the size of the holes produced by a tap will vary all the way from one or two thousandths of an inch under to several thousandths over the actual size of the tap used. Of course, the undersize condition is due either to shrinkage of the metal or distortion after the tap has been removed, but as this is a condition that is frequently encountered it must be taken into consideration. Under average conditions, in steel and iron, a tap does not cut closer than 0.001 in. over its own size, and frequently it cuts from 0.002 to 0.003 in., or even more, larger than itself due to conditions under which it is used.

THREADING DIES

As previously pointed out, the threading dies used on production manufacture can nearly always be adjusted or set. This is true of the round die, spring die, "acorn" die, self-opening die, as well as thread milling. Efficient production of these tools is mainly dependent on the correct grinding of the chamfer and its proper cutting angle. The cutting angles are usually established by the maker for the class of work for which the die is recommended. This varies from radial for cast brass to a very acute cutting angle for copper, with other grades of metal ranging in between.

The proper clearance at the throat of the die is one thing that most affects the production life of the die. The chamfer of the throat should be ground with just sufficient clearance and provide the fullest amount of support to the cutting edge. If the cutting edge is not supported, it will chip when the die becomes a little dull.

DRILLS

The drill is called on to do a great deal of work in production. Little is said about it in general, but there has been a great deal of improvement made in it, and today this company is obtaining far more production from its drills than ever before. Undoubtedly most of this is due to improved steels supplied by the steel maker and to better heat treatment, but to some extent to the improvements in the design and manufacturing methods of the drills. Drills today are more accurately finished than ever before. The credit for this should go to the developers of the centerless grinding process.

INSPECTION

One of the most important phases of interchangeable manufacture is the set-up for inspection. In general the inspection should be under the management and not under the production control. The primary purpose of the inspection should be to assist the production to produce acceptable parts.

The so-called first-piece inspection method, which required the first piece produced on any given operation to be passed by the inspector, and the continued inspection or provision for the continued assurance that the work being produced by the machine is correct, rather than waiting until all of the parts have been completed, is usually the most satisfactory and economical inspection method to pursue.

Here, again, the importance of correct specifications from the engineering department results in substantial saving of time and material. Where the product is to go to a consumer who has his own inspection for material purchased, it is highly desirable that the consumer and producer get together on their inspection methods. Much time is wasted and much money spent in shipping rejected material where the chief difficulty is that the inspectors are not checking in the same manner. Producers are as anxious to make material that passes the consumer's inspection as the consumer is to have it pass his inspection, and rejections are usually the result of misunderstandings or misinterpretation of specifications. When the user finds out the particular inspection requirements and methods of the consumer, his troubles are usually eliminated.

Present-day inspection for interchangeable manufacture calls for a continuous inspection program from the time the raw material is received—and in some cases even an inspection before the material is shipped; that is, at the source—and through all the production operations. Heat-treated parts today frequently are receiving 100 per cent inspection on each operation. All of this has been found economical to insure the proper production of an interchangeable finished product.

Discussion

JOHN GAILLARD.[2] The writer would like to say a few words with regard to the question of unilateral and bilateral tolerances raised by the previous speaker. In fact, there is something in the historical development of the art of fitting which has caused an evolution from bilateral to unilateral tolerances. In the early stages of industry when handicraft was supreme, the craftsman would take care of each fit individually, removing metal until the fit was correct. He did not know about tolerances. When the rate of production increased and some degree of interchangeability between parts became necessary, an effort was made to hold individual parts to "exact" dimensions. For example, as it has just been said, "a one inch shaft was supposed to measure one inch." An "exact" dimension being something ideal, it was soon realized that it could only be aimed at and this resulted in giving a permissible plus and minus variation. Thus bilateral tolerances were established. In the course of time, however, it became evident that unilateral tolerances were preferable for a general system of tolerances as they secure the maximum degree of interchangeability in general, combined with greatest ease of visualization for the designer.

It is significant that the British Engineering Standards Association as far back as 1906 adopted a national system of fits based on bilateral tolerances, and in 1924 revised this standard to the effect that unilateral tolerances are recommended as the best practice. If you look up the British standard, you will find that bilateral tolerances are still given in addition to unilateral tolerances, as an alternative. However, it is stated that this is simply a concession to those manufacturers who had adopted, in the period between 1906 and 1924, the bilateral tolerances given in the original standard. To those who still have to adopt a system, the British standard explicitly recommends unilateral tolerances.

In addition to the British standard, eleven other national standards on fits between cylindrical parts have been established in the course of the last ten years, including the American Tentative Standard B4a-1925. All of these standards are based on unilateral tolerances.

---

[2] Mechanical Engineer, American Standards Association, New York, N. Y. Mem. A.S.M.E.

In the fall of 1929 somebody well acquainted with the automotive industry called my attention to the fact that some production men in that field had not felt inclined to adopt the American Tentative Standard because commercial stock reamers would not economically produce holes with unilateral plus tolerances. This is due to the fact that the present commercial stock reamers are made with a small plus tolerance on the nominal size. For example, a 1-in. reamer may be held between the limits 1.0000 and 1.0003 inch. Such a reamer wears down pretty soon to a point where it begins to produce undersize holes, and these, of course, are not acceptable, according to the American standard. Those criticizing the standard on this account, would therefore prefer bilateral tolerances which permit one to go on using the reamer for a time after it has begun to produce undersize holes. Reasoning along this line, some organizations have gone one step further, such as General Motors, by adopting hole tolerances extending *downward* from a constant reference line, instead of *upward* from the nominal size, as the American standard holes do. The General Motors system has been explained in *American Machinist*, June 5 and 12, 1930 by Mr. Ovaitt, and I discussed this system in *American Machinist* of November 6, 1930. As the chairman has mentioned, this question has been brought to the attention of the sectional committee on Allowances and Tolerances for Cylindrical Parts and Limit Gages, which no doubt will give it due consideration, and I would not have mentioned this question again, if reference had not been made to it in Mr. Bryant's paper, where it states that in the General Motors system reamers may be used subsequently for different grades of holes. In this connection, I want to call attention to the fact that such subsequent use of a reamer can also be applied to American standard holes if only the new reamer is held to a larger size. The reamer may then be used first for the hole with the largest tolerance, and as the reamer wears down, it is subsequently transferred to the production of holes with smaller tolerances.

The only thing I wanted to emphasize is that the essential requirements of a system of fits, such as general interchangeability of mating parts and clarity to the designer, are much more important than the reamer question, especially as a slight change in the present commercial reamer sizes would make it possible to combine such advantage as is claimed for non-standard systems as referred to above, with those presented by the American standard system, or in general, by unilateral plus tolerances on the holes.

W. S. Huson.[3] This paper enters quite fully into the manufacture of present-day reamers, taps and threading dies and the better results obtained by intelligent selection in these cutting units of those best accepted to the work in hand. In the past there were few small tools that could stand the abuse of those in question and while some endeavor was made to analyze the best forms little was done until the advent of quantity production to size compelled closer attention and longer life to the shapes and cutting qualities; so vital, where threading is involved, to interchangeability. The paper is a desirable addition to data already at hand and of which the author has taken note and used in its preparation.

In one part he says "the management does not insist on the necessary time being taken to produce proper drawings and tools before proceeding with production." This is being overcome in the realization that as machinery is designed, preliminary considerations must be given to the tools involved, their bearing on the final production in cost and uniformity. In other words the question of tools for interchangeable products is being taken from the tool-room and placed upon the drafting department. This is, as it should be, done in a department where the correlation of parts, often having a bearing on tooling equipment, can be studied and the best solution formed at the start. It may be said that more ingenuity is sometimes displayed in the inception and design of suitable fixtures and tools than is needed for the parts themselves. This is brought out in the instance given in Mr. McLaren's paper, "Conventional Gages and Their Application to Duplicate Manufacture" to be presented at this session, in the gage for hook and hook needle, the accuracy of which is the measure of the ability of tools to produce the work within the limits demanded.

The cost of making fixtures, etc., for production and inspection runs, often deeply, into money and there is at times hesitancy as to the advisability of incurring it; nevertheless there is an intrinsic value, which should not be overlooked, in the satisfaction that comes from the present methods of duplication, inspection and repairs servicing. This bears on the closing paragraphs of the paper where the importance of correct specifications from the engineering department is manifest in time and material savings.

The preliminary and auxiliary means are a legitimate charge in processes of production where exactitude is of prime importance.

L. D. Burlingame.[4] The author refers to the classes of screw thread work which have become standard American practice, and calls attention to the fact that under some circumstances economy of manufacture and satisfactory fits can be obtained by combining different classes of fit. He says:

"The combination of class 2 and class 3 assembly naturally makes a better or closer condition than the application of class 2 to both members, and it is an economical solution of many problems."

In his oral presentation of the paper Mr. Bryant goes further in pointing out that class 4 fit of the N.S.T.C. Report is materially closer than class 3, allowing very little for wear of gages and of tools, and states that the matter is under consideration of either liberalizing the tolerances for class 4 or of establishing an intermediate class between 3 and 4.

The question may be asked why the same plan as suggested for use between classes 2 and 3 is not applicable here also and that by making one of the mating parts to class 3 and the other to class 4, and using the class 3 tolerances for the part where difficulty of maintaining the close limits is greatest, may not give conditions practically equivalent to establishing intermediate sizes suggested and without a change from present adopted standards and without the addition of new sizes.

This suggestion would be applicable to gages as well as to the finished work, and would tend toward making the product in high-grade work more nearly interchangeable, and thus reduce not only the cost but also the requirements for selective fits.

G. A. Bouvier.[5] The writer is in general agreement with Mr. Bryant that it is good engineering practice to dimension drawings with tolerances. However, if any of the younger engineers get the idea that this is an ideal solution to the problem of attaining complete interchangeability, they are due to be bitterly disappointed. Theoretically, of course, if a part is properly dimensioned, interchangeability should result. The difficulty is that we cannot dimension everything, which has an effect on interchangeability. It is generally impracticable to specify on a drawing a tolerance for the amount of out-of-roundness and straightness of a hole, and the exact character of the surface. Holes supposed to be parallel are never exactly parallel, but I have seldom seen any tolerances for parallelism. I don't blame the draftsmen though, because it is difficult to determine the amount and direction a hole is out of parallel. Drawings on almost all the parts made in a shop depict right-angled surfaces, but we seldom see any limits for these angles.

[4] Legal Technician, Brown & Sharpe Mfg. Co., Providence, R. I. Mem. A.S.M.E.

[5] Western Electric Company, Hawthorne Works, Chicago, Ill.

Picture an automatic screw machine spindle and the spindle shoulder against which the thrust is taken. This shoulder must not only be square with the axis of the spindle but in addition its surface must be flat. We all know how difficult it is to obtain flatness in a small block, let alone attempt its attainment in the case of a shoulder on a shaft. When we couple this with the necessity for having the surface at right angles to the axis of the shaft, we have a problem on our hands. It is unfortunate that most draftsmen who dimension their drawings assume that the factors mentioned are perfect. However, these factors and many others naturally will have an effect on the quality of the final product. Obviously, the more complete the information given in specifications and drawings, the more intelligently will the shop be able to produce what is required, but I feel that for some time to come, we are going to have to depend on the process or method used, and upon the cleverness and skill of the craftsman, to produce a satisfactory product.

Mr. Bryant has said that present-day production has demonstrated that so-called close tolerances take no more time to produce and result in less spoiled work than would be the case if the maximum functional tolerances were allowed. I cannot agree with a literal interpretation of this statement. I am quite confident that with proper planning, more liberal tolerances would result in greater outputs. However, I believe I understand the intent of Mr. Bryant's remark to mean that the close tolerance often forces concentration on a job which otherwise might not receive proper attention. As a result better methods are used, there is more respect for the job, and carelessness and indifference are eliminated. In other words, close tolerances compel and insure good management, and in this sense most of us know of reductions in cost which have resulted from closer tolerances.

W. H. Gourlie.[6] There is no question that the points raised by Mr. Bryant and Mr. MacLaren are to the point and desirable to bear in mind on this important subject of gages. The writer would like to supplement their comments, grouping such remarks under three general headings, all of which pertain to gages: (1) Design, (2) use, (3) measurement.

It is important, even absolutely essential, that the gage be designed in the light of the requirements of the piece it is to check. The component is the important thing, and the gage must be made to best accomplish the purpose desired. At the same time there is more and more effort being made in the standardization of gage design, with the object in view of lowering the cost of gages of the simpler types where standard designs answer every need of the job. The writer refers particularly to the work of the American Gage Design Committee. Standards have been adopted by that committee, and since by the leading gage manufacturers, for thread plugs, thread rings, plain plugs, and plain rings, in the popular sizes. If the engineer will use, in so far as practical, the standard length of blanks, or standard handles, or other parts of the design, considerable saving will result in a user's gage cost. It is well worth while to bear this in mind.

There are many who use gages, and there are many who abuse them. Sometimes the distinction between use and abuse is a question of the cost of properly cleaning the piece preparatory to gaging. It costs money to clean a piece properly, and in some cases this expense is greater than the saving which would be effected by longer gage life. The writer has in mind an incident that came up just a few days ago of a thread gage used for checking tapped holes in a windshield pillar. The pillar was made from stainless iron and was highly polished after tapping, but before gaging. An appreciable amount of the polishing compound lodged in the threads, resulting in rapid gage wear, and in some cases chipping. After a thorough investigation it was found that the addition of a longitudinal chip groove, which cleaned out the bulk of the lapping compound, was the most economical solution, even though gage wear was much more rapid than would result were it possible and practical to thoroughly clean the thread before checking.

Precision gage blocks are another type of gage frequently abused because of misunderstanding of their proper use. Frequently improper cleaning of blocks before wringing results in a scratch and burr on one or two blocks. Failure to remove these will result in the scratching of additional blocks as varying combinations are made up. The writer has known of a new and complete set of blocks being scratched in just this manner, the set being less than two weeks old. When properly used, blocks will last for months, but when abused their life is short. These same principles are true in all types of gages. When used properly, gages will have a long accurate life. As abuses are permitted, life is cut down and cost of gages is increased. The user must balance cost of gages against cost of properly preparing parts for gaging. He cannot expect minimum cost with maximum accuracy unless proper precautions are taken when preparing the parts for gaging.

Methods of measurement of gages must be clarified, and set, in order to duplicate measurements to the accuracy demanded by present-day conditions by inspectors at various and sundry points throughout the country. It is comparatively easy to measure a plain cylindrical plug gage, 1 in. diameter, to 0.0005 in. A micrometer in the hands of most skilled mechanics will easily repeat to a figure well within that. When the tolerance is reduced to 0.00005 in. the story is entirely different. Temperature assumes importance of the first order. Measuring pressure is a factor, and hardness and stability of the metal in the gage must be considered. There is comparatively little dispute in such cases, however, as those manufacturers requiring such fine accuracy recognize the difficulties which must be overcome and are equipped to overcome them.

The measurement of screw threads and thread gages is an entirely different proposition. Almost every one manufacturing threaded products uses gages, and most users endeavor to measure them. Most inspectors feel that their readings are accurate within 0.0002 in., and yet the equipment used varies from a hand micrometer with wires 4 or 5 years old to the latest in measuring machines with pressure control. It is no exaggeration to say that variations in the same gage on pitch diameter are as great as 0.001 in., according to the different methods and skill of the user. The gagemaker is equipped to properly measure under suitable conditions, and the writer knows from having carried on some experiments that the leading gagemakers and the Bureau of Standards tie in very closely with measurements of pitch diameter. It is necessary, therefore, that users of gages who wish to measure to ten-thousandths on the pitch diameter of new or used gages, have a suitable measuring machine with pressure control, and wires which have been calibrated at the proper pressure, crossed over a cylinder 0.750 in. in diameter, as recommended by the Bureau of Standards.

It must be remembered, too, when discussing the measurement of pitch diameter, that that is the simplest element of the screw thread to measure. It is probably for that reason that most users check that single element, paying little attention to lead and angle. The gagemaker, on the other hand, checks all three, and maintains them within tolerances commensurate with the product tolerance.

Conventional Gages and Their Application to Duplicate Production

By THOMAS F. MacLAREN,[1] PROVIDENCE, R. I.

The attainment of greater accuracy in present-day machines has necessitated improved gaging facilities. This article briefly treats of some important considerations in the design of gages, a description of a few special applications, and the need for standardization in gaging methods relative to machine-shop practice.

THE need for interchangeable, duplicate parts is now generally appreciated by manufacturers, and the benefits derived are shared alike by consumer and manufacturer. Parts that fit accurately in an assembly give better service and longer wear. This materially decreases assembly and repair costs.

No two things are the same, but machine parts may be duplicated to within very small tolerances in every dimension. This attainment becomes increasingly difficult with increased production rates and closer tolerances.

Duplicate production in large quantities has necessitated a revolution in methods of inspection especially with respect to inspections performed by the machine operator. Frequently the time allotted for the gaging process is limited by the schedule of machine operations, and a delay in any part of the schedule for one piece might result in considerable lost time.

The shop practice of 20 years ago in many plants was to have but one accurate measuring apparatus, and it was usually placed in a special room. Today in order to facilitate production and provide accurate work and machines, it is necessary to have accurate gages and tools in the hands of the operator. The older machines were not so accurate as those of today, and it was of little value to have gages with a degree of accuracy which could not be approached by the machines. Today, as machines are more accurate, it is necessary to produce more accurate test tools. Every forward step in accuracy by the machine manufacturer is a challenge to the gage maker.

The machine of 20 years ago which would duplicate work to within 0.001 in. has been superseded by the machine which will duplicate to within 0.0001 in. in less time. Likewise the gage department which considered 0.0001 in. to be the last word in accuracy is now measuring to a much greater degree of accuracy and with less difficulty.

In duplicate manufacturing the degree of accuracy which it is possible to attain and maintain is limited by the gages and test tools employed in the manufacturing and inspection processes. In much of the duplicate work being done at the present time, however, the accuracy demanded is not so great that the inspection need be considered as precision work. The accuracy required in the work is merely another consideration in the design of the gage.

The importance of correct design in gages and test tools cannot be overemphasized. It is of course impossible to formulate any complete list of rules which will suffice as an infallible guide to the designer. Apart from the comparatively few standard instruments for measuring, such as micrometers, vernier calipers, height gages, etc., individual gages must frequently be developed for each piece or operation. It has been said that the secret of good gaging is the faculty of seeing clearly "how big a little bit is."

For shop use it is impractical always to provide an absolute measuring device for each job, and for duplicate production plants the cost of the time required to operate the more accurate precision measuring instruments is prohibitive. It is then necessary to provide for the mechanic a dependable tool—precise, if precision is required, simple, durable; a tool with which he can carefully check his work with a minimum expense of time and effort.

The accuracy of the shop gage is dependent upon the precision desired, and it should be remembered that the most accurate gage is not necessarily the best for the job. If the gage controls the work to a tolerance less than is required by the design of the piece, with a resulting decrease in production and increase in costs, the gage is not well designed. The nature and number of pieces to be tested are factors which should determine the nature of the design with reference to the durability of the gage.

Different metals have different abrasive qualities. Aluminum is apt to wear a steel gage more rapidly than cast iron. For large productions of many thousand pieces it would be necessary to make the gage points of metal which can be heat-treated to stand the wear to which they will be subjected, while for small productions a less durable grade of metal can be used. The problem, then, is to find a steel which will have the combined features of maximum durability and lowest cost.

The gage points should be easily accessible to facilitate the gaging process and the detection of any foreign matter which might cause an error. Losses due to an interference at the gage points may amount to hundreds of dollars in a few minutes. Trick designs should be avoided. Generally speaking, the gage which is simple to operate is easier to manufacture. Too often the gage designer forgets that while it is a simple job to place a straight line on paper, it may require a difficult machine operation to reproduce it on the gage. A straight line demands accuracy, where a liberal limit might be permissible.

The gage maker's tolerance should be placed on the "wear side." Every gage is in error to some extent. Where the gage maker is given a tolerance, commercial gages should be so designed that as much metal as possible may be left on the gage points. If reliable data regarding the wear of a gage under certain conditions can be obtained, it is permissible to use smaller tolerances in its manufacture to allow for this wear, but such a

[1] Brown & Sharpe Mfg. Co. Mr. MacLaren, after receiving his high-school education in Nova Scotia and the Providence high schools, served his machinist's apprenticeship course at the Brown & Sharpe Manufacturing Company. He afterward attended the Massachusetts Institute of Technology, where he took the regular course in mechanical engineering. Mr. MacLaren joined the Brown & Sharpe sales department in June, 1930.

Contributed by the Machine Shop Practice Division and presented at the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

procedure should be authorized only when the dimension limits are relatively large and the proposed use of the gage is limited.

Fig. 1 shows a sewing-machine hook and hook needle, with a gage which is now being used to test the composite piece. This gage is one of over 30 gages of similar design which are used in the machining process of over 60 operations required by this part. Several other methods of testing have been resorted to in an attempt to reduce the manufacturing time, but in each case the results were no better than those obtained with the present gage. A projector type necessitated too many holding devices, and a gage with fixed gage points gave no indication of the magnitude of the error. It is true that for many jobs the plunger or finger type gage is obsolete, yet until another proves to be superior in every instance it cannot be discarded. In the department where this gage is used there are hundreds of similar gages which give better service than any other types which have yet been tried. The dimensions for the piece are distributed in many planes, and practically the entire contour of the hook end is held to close limits. Each of the plungers is brought up against its mating surface in turn, and the final one *A* has a standard plug which must be in alignment with the hole in the hook needle. In gages of this type the error is indicated by the relation of the outer ends of the plungers to the outside surface of the gage, and if a limit of 0.0005 or more is permitted, the outer end of the plunger is made with a high and a low side. If the piece is correct, the high side will extend above the gage surface and the low side will be below the surface. This can be detected by passing the finger over the surface.

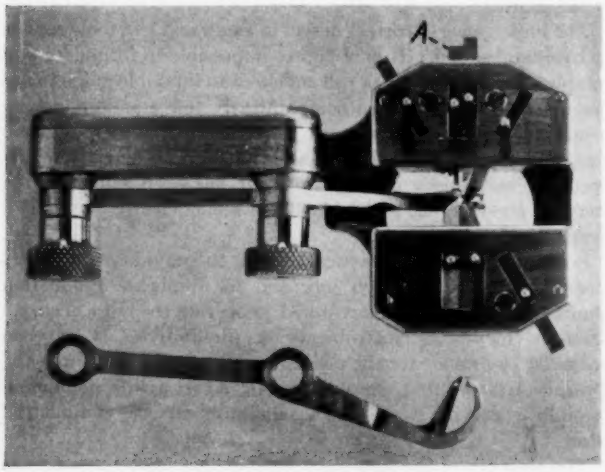

Fig. 1 Finger or Plunger-Type Gage With Seven Gage Points Used on Hook and Hook Needle

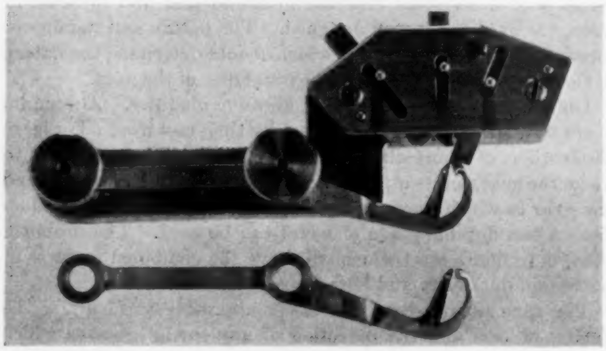

Fig. 2 Finger Gage for Use on Sewing-Machine Hook and Hook Needle

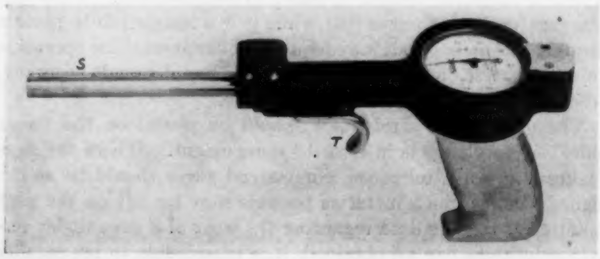

Fig. 3 Comparator Gage for Internal Measurements

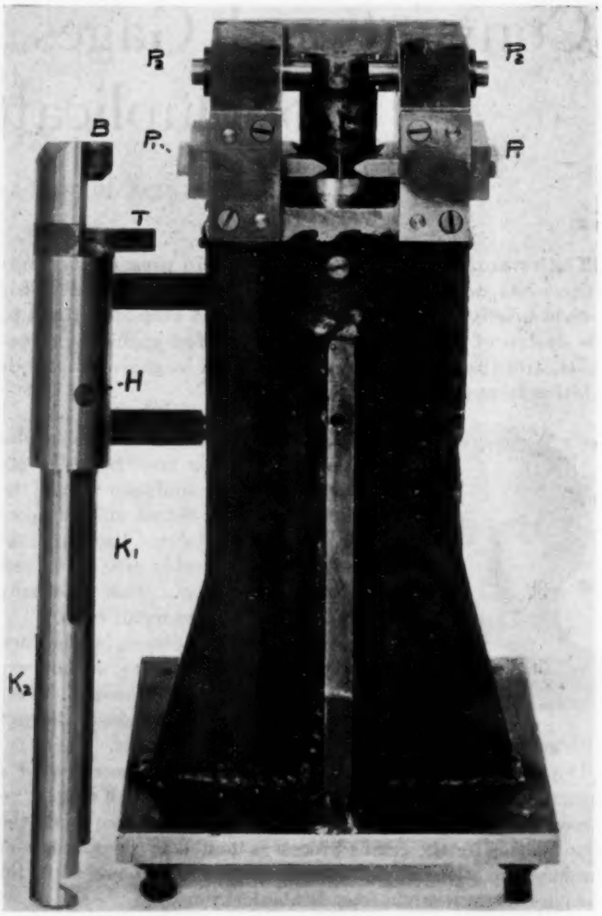

Fig. 4 Control Shaft and Rear View of Gage

Fig. 2 shows another gage which is used on this same piece. With many gages, where the gage surface is kept smooth and well polished, limits of 0.0005 are being held on jobs similar to this.

Selective assembly methods have opened a field for two types of gages which resemble the regular plug and snap gages in principle, but which have adjustable gage points. Fig. 3 shows a gage used for gaging the diameter of a hole or similar dimensions. The spreaders *S* in the shaft are controlled by the trigger *T*, and when the gage shaft is inserted in the piece to be gaged the trigger is released. The spreaders expand, and this motion actuates the dial indicator which indicates the deviation of the piece from a master.

A gaging device similar in principle to the one just described is used for external work to good advantage in many jobs. It

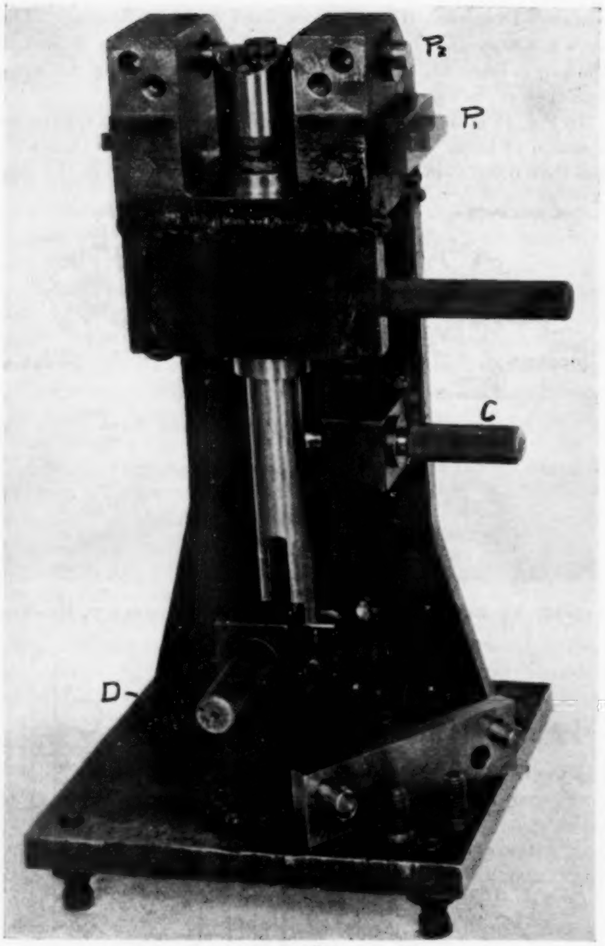

Fig. 5 Front View of Control-Shaft Gage, Showing Locating Pin and Keyway Plungers

consists of one fixed jaw and one floating jaw, the motion of which actuates a dial indicator. When the trigger is released, the jaws close on the piece to be gaged, and by comparing the reading with that of a master, any error is easily noted.

For each of these gages provision is made for their use over a wide range of sizes.

Arc welding is now being extensively used in the manufacture of gages, with a resultant saving of time in many instances. The gage used for testing the control shaft (Figs. 4 and 5) was constructed from boiler plate. As can be seen from the outline of the piece (Fig. 6), it is a type of gage which is adaptable to a large percentage of machine-shop work. The shape of the arrow- or carrot-shaped tooth *T* and its relation to the reamed hole *H*, the two keyways K_1 and K_2 and the knob *B* are most important. Fig. 4 shows the two sets of plungers. The lower set P_1 mates with the contour of the "carrot" *T*, and any deviation over 0.0001 in. can be seen with the naked eye. The size is checked by the high and low sides on the plungers. The knob form does not have to be as accurate as the "carrot," and is checked for size by high and low sides of the two upper plungers P_2.

The two keyways are checked by the keyway plungers *C* and *D*, which gage for size as well as location with reference to the "carrot." The hole is not necessary for the operation of the assembled machine, but it is drilled for use as a locating point in the jigs, fixtures, and gages used in the manufacturing and inspection operations.

In many operations used in duplicate production it is desirable to check work to less than 0.0005 without removing it from the machine. Several devices have been manufactured to do this with varying degrees of success. One micrometer on the market has incorporated in the frame an indicator which has a constant-pressure spring actuated by a floating anvil. By adding or subtracting the reading of the indicator dial from the reading on the thimble it is possible to gage to 0.0001 in.

Another micrometer designed to read to 0.0001 in. is shown in Fig. 7. To obtain the size, it is necessary only to add the reading of the small auxiliary thimble to the reading of the main barrel. The small thimble turns independently of the main thimble and does not affect the spindle movement. With this micrometer and similar measuring devices where the graduations are widely spaced, it is possible to estimate to parts of a ten-thousandth, a valuable feature in many instances where an accuracy greater than that afforded by many standard measuring tools is necessary.

In many machine operations in which there is a relative change in the location of the cutting member and its work, it is desirable to have a gage which will make it possible to note this change.

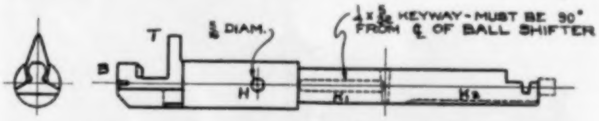

Fig. 6 Outline Sketch of Control Shaft

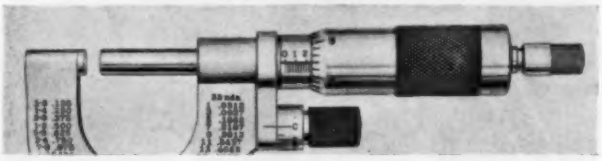

Fig. 7 Micrometer With Auxiliary Thimble for Reading Directly to 0.0001 In.

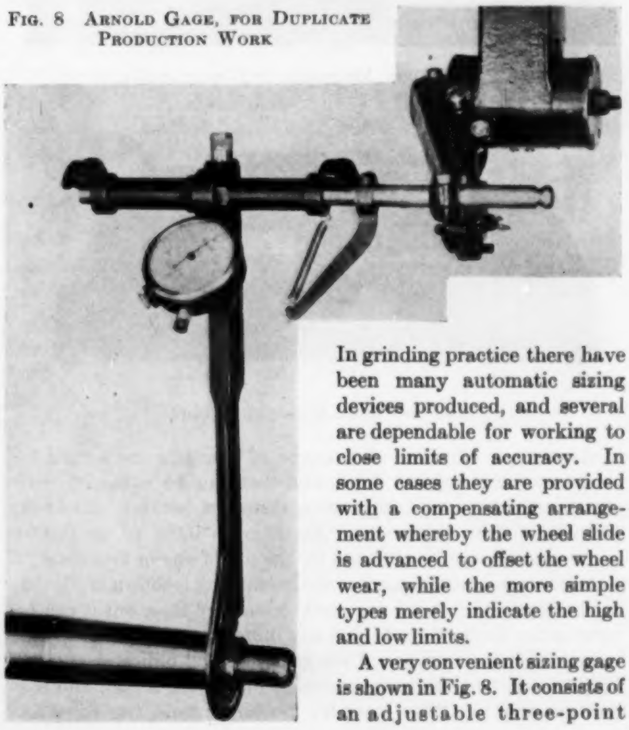
Fig. 8 Arnold Gage, for Duplicate Production Work



In grinding practice there have been many automatic sizing devices produced, and several are dependable for working to close limits of accuracy. In some cases they are provided with a compensating arrangement whereby the wheel slide is advanced to offset the wheel wear, while the more simple types merely indicate the high and low limits.

A very convenient sizing gage is shown in Fig. 8. It consists of an adjustable three-point spreader, with two of the points fixed and the third floating against a plunger, the motion of which is recorded by a dial indicator. It does not read to size directly and is in reality a comparator rather than a measuring tool. One piece of work is ground correctly, and the gage is then set to the high limit with the dial at zero. Fig. 9 shows a similar gage mounted on a grinding machine. When the grinding operation is completed, the gage is conveniently swung clear to permit the operator to change the work unhindered. Diamond or Carboloy points on the spreader of these gages eliminate the danger of changing the setting by wear or of injuring the finish, and they can be equipped with attachments for measuring tapers, distances between shoulders, and many other dimensions. Readings to 0.001 in. or 0.0001 in., as desired, can be obtained by the use of one or two dials.

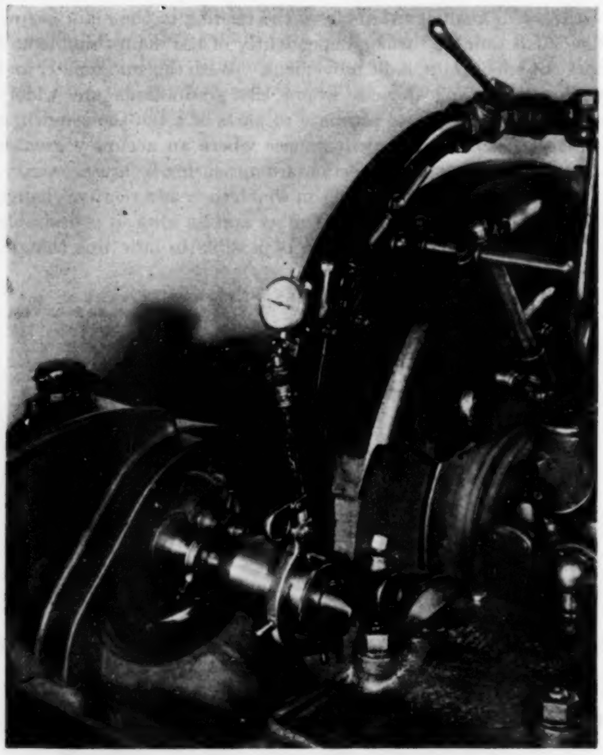


FIG. 9 PRATT GAGE, MOUNTED ON GRINDING MACHINE

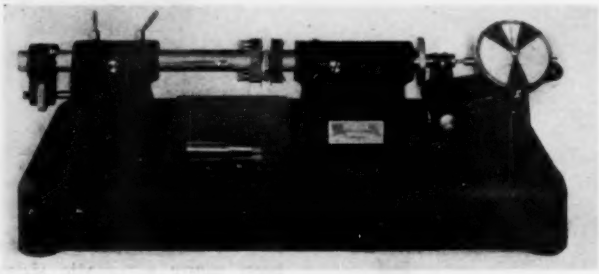

FIG. 10 WIRE-MEASURING GAGE

A convenient bench gage for wire measuring is shown in Fig. 10. In the illustration it is being used to measure taps, but it can be used on bar stock, threads, and any dimensional work which will come within the capacity of the gage. A dial indicates any deviation, and two blinds are provided for setting a high and low limit, as shown. When used for measuring taps, two wires are suspended between the jaws, one fixed and one floating. The jaws are separated by a lever located under the dial indicator, the tap is inserted, and the jaws are released, forcing the wires into their correct position.

In Fig. 11 is shown a gage which was manufactured for the inspection of hubs. So accurately was this gage made that with less than 0.00025-in. tolerance in the keys or keyways in the plug or ring, it is possible to insert the plug in any one of the 16 possible ways. This gage illustrates an item in the cost of gage manufacture which must be considered by the designer, since in order to check a gage of this type it is usually necessary to make a mating gage which may require more time to build than the original.

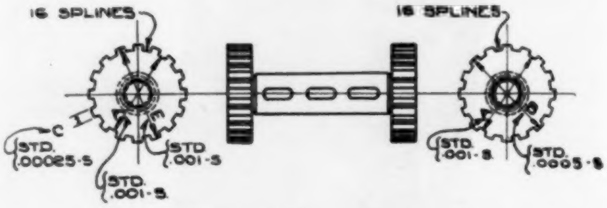

FIG. 11 GAGE FOR TESTING SPLINED HUBS

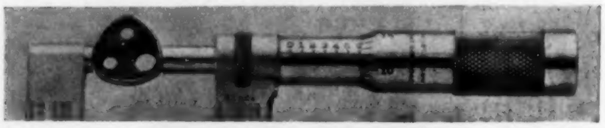

FIG. 12 ECCENTRIC WHICH GIVES CONSTANT MICROMETER READING

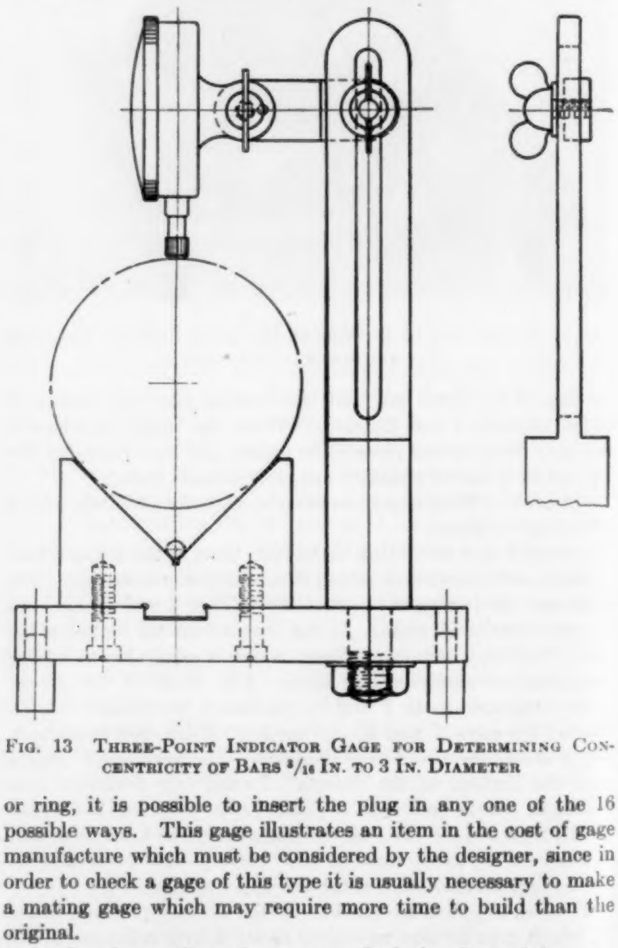

FIG. 13 THREE-POINT INDICATOR GAGE FOR DETERMINING CONCENTRICITY OF BARS $^{3}/_{16}$ IN. TO 3 IN. DIAMETER

A misunderstanding of proper methods for determining concentricity has resulted in many inferior machine tools. In order that machine operators may not be misled, it should be understood that a micrometer, vernier, or any similar two-point measuring instrument is not adaptable for measuring or establishing the concentricity of a bar. If the bar is round, the two-point measuring tool will not indicate otherwise. But it is possible to secure duplicate readings at intervals of small increments over the entire periphery of the bar with the micrometer spindle and anvil surfaces tangent to the bar, and yet be able to tell with the naked eye that the piece is not concentric. An exaggerated illustration of this is shown on Fig. 12. This piece will give duplicate readings on the micrometer as long as the gage surfaces are tangent to the piece at the gage points.

In order to determine the concentricity of a piece, the ideal measurement would be from the outside to the plane center of gravity. If the work has accurate centers, this measurement can be made by rotating the piece on centers using a dial indicator. In centerless grinding work, however, it is not convenient to use this method, and some different but equally satisfactory method must be used.

Fig. 13 shows a simple design which will overcome this difficulty. The same principle can be used in a variety of ways with a varying degree of precision. By revolving the piece in the V-shaped base, any eccentricity will be noted on the dial indicator. Micrometers have also been manufactured with a V-shaped anvil for the purpose of measuring cylindrical stock.

It is impossible to list the many gages on the market. Comparator blocks have displaced many devices, and frequently they are less expensive and have a wider range of application than the gages displaced. Fluid gages, optometers, many types of comparators, and other new gaging devices are being produced to meet the demand of modern production methods.

The need for standardization in gaging is becoming more and more essential in many branches of shop work. Perhaps in no phase of the industry is there a greater natural opportunity for variation in practice of design, manufacture, and inspection than in gearing, and along this line Mr. F. W. England, chairman of the inspection committee of the American Gear Manufacturers Association, has edited a most valuable paper, in which he recommends in exact detail a code of inspection for the member companies of the association. With his discussion he has included descriptive drawings and photographs of many testing devices which are giving good service in the inspection of splines, tooth parts, and all dimensions which are common to the manufacturers of gears and their customers. Similar codes of gaging practice might well be adopted by other engineering organizations.

For practically every job there is more than one gage, but there is one which is superior. The limitations and adaptability of the gage, coupled with the design of the piece, the dimensions to be checked, and the accuracy required, will determine which is the gage for the job.

Discussion

[Note: Discussion of this paper jointly with that of E. J. Bryant, by W. H. Gourlie, will be found following the latter paper.]

W. S. Huson.[2] Accuracy in gages, leading to accuracy in sizing and inspection, is well brought out in this paper, for inspection has often been handicapped because of lack of testing tools properly designed and made and held in exact consonance with the gages and tolerance allowances used in production. There is more than just a modicum of truth in the author's remark, "Every forward step in accuracy by the machine manufacturer is a challenge to the gage maker," for while skill can be shown in the making of intricate gages, the use for convenient testing is sometimes lost sight of, and perhaps because of cost, limitation to the opportunity for a gage to test to the fullest extent is overlooked. There is a practical side to testing as well as to other tools, in that the cost to make them fully efficient is incurred but once, whereas if they fall short of all that could be done, there is continuing expense in the need for additional gages or the like as well as more time required. The realization that work can be produced to close limits cheaper than otherwise has not penetrated fully into manufacture, but as papers like this one are put forward the reluctance to grasp the value of sizing to fixed standards is breaking down in sensing that it has become the modern way of doing and proving work economically.

The illustrations show examples of gages that bear out the facility with which gaging can be done. The increasing use of arc welding for making jigs, fixtures, and testing apparatus has been a material help in enabling them to be made more efficient, because castings cannot always be as fully made, as there may be molding limitations. The welded tool may not look as pretty perhaps as a casting, but if it can be more efficient that is the main point. Figs. 4 and 5 show this and are worth studying by any who have work where a keyway is the locating unit.

This paper ties in well with the companion paper by Bryant; they are somewhat parallel in import and should be read into each other. The importance of what is set forth is emphasized by the paper by C. R. Reiman (Trans. PI-52-10) setting forth the sizes and tolerances for metal fits and graphically showing by charts the practical use in every-day production of shafting made and held to very close limits.

Improved Device for Recording Instantaneous Tool Pressures in Machinability Studies

By O. F. GECHTER[1] and H. R. LAIRD,[2] CHICAGO, ILL.

O. F. Gechter

The device described permits the measurement of the three tool-pressure components during the machining of short test pieces. The advantages of the device as compared to similar devices used in the past are outlined. It is shown that the use of the piezo-electric pressure-measuring method makes possible a rigid tool mounting and the recording of relatively sudden pressure changes. The mechanical and electrical limitations are discussed, and improvements are suggested. A discussion of some of the test results illustrates the value of the device for machinability studies.

H. R. Laird

THE device described in this paper is the fundamental part of equipment being employed in one plant of a large industrial concern[3] to determine the relative machinability of die-cast aluminum alloys. The results of the tests, together with those of an investigation of rates of corrosion, adaptability to casting, and other physical and chemical properties, will be used to select the alloy most suitable for the manufacture of the case shown in Fig. 1. The tests are being made on parts cast in blank form in order to obtain results which will, as far as possible, reflect the properties of the alloys as encountered under actual manufacturing conditions.

The complexity of the problem of machinability is well illustrated by the fact that, in spite of the large amount of research already devoted to the problem, no method has been developed which makes it possible to draw conclusions regarding all the phases involved. It is true that attempts in this direction have been made. E. G. Herbert,[4] for instance, measured the hardness in various sections of the chip, the tool, and the material cut, and as a result has expressed the opinion that the only true measure of machinability is the hardness of the chip. F. Schwerd[5] took high-speed cinematographic records of the chip formation during the cutting action of the tool and expects that a procedure along this line will finally solve the problem. Both methods require further research to be of practical value.

The mechanical grading of the finish of machined surfaces, one phase of the problem of machinability, has in recent years been brought closer to solution by a number of methods. Promising examples, in the opinion of the authors, are a phonographic finish-measuring instrument described by R. E. W. Harrison[6] and a photoelectric device developed by F. Firestone,[7] and used in one case for the detection of objectionable flaws in wristpins.

The major part of research in connection with the problem of machinability has been based on tool life and tool wear. This is logical, because these two quantities play an important part in the economic manufacture of machined products. The method most widely used is probably the standard tool-life test originated by F. W. Taylor.[8] This type of test gives results that are especially applicable to roughing cuts. The trailer-tool method used by T. G. Digges and H. J. French[9] compares the machinability on the basis of actual tool wear rather than ultimate tool life and corresponds therefore to modern manufacturing requirements with their close dimensional limits.

It may be interesting at this time to mention the results of tests conducted by A. Wallichs and H. Opitz[10] on automatic screw ma-

chines. These tests have apparently proved that interrupted cuts, such as performed on automatic screw machines, and continuous cuts will result in the same tool life as long as the tests are made under otherwise identical conditions. This conclusion was verified by roughing tests made both on a planer and a lathe.

In view of the relative importance of removing metal with the least amount of energy, it is only natural that the problem of chip pressure received early attention. Some investigators have even gone so far as to use this pressure as a measure of machinability. It has been repeatedly pointed out that this procedure is misleading because it does not take into account various factors, such as abrasive action of the material, etc., which result in a shorter tool life, but which may not affect the tool pressure in a way conducive to the measurement of machinability.

The true value of tool-pressure measurements has been demonstrated by tests conducted by Schlesinger[11] and others. It was found that especially the radial and feeding components (P_1 and P_2, respectively, in Fig. 4) increase as the tool wears, and become abnormally high at the point of complete tool failure. Obviously, the conclusion could be drawn that tool-pressure measurements represent a means for determining wear and life of a tool. Similar results were obtained in more recent tests, during which the tool temperature was measured by using the contact point of tool and material as the hot junction of a thermocouple.

In deciding upon a suitable method for measuring the machinability of the die-cast aluminum alloys, it was considered advisable to deal separately with the problem of grading the surface finish. Main consideration was therefore given to the following points:

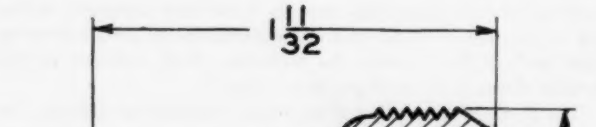

Fig. 1 Die-Cast Aluminum-Alloy Case on Which Machinability Tests Were Made

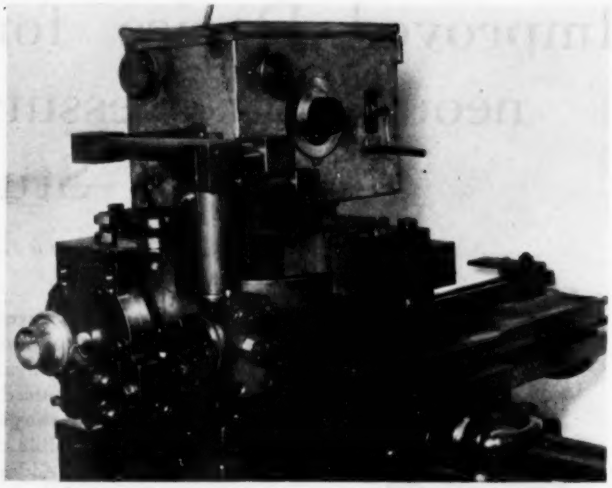

Fig. 2 Tool-Shank Mounting, With Pressure Units and Shielding Box for Special Vacuum Tube

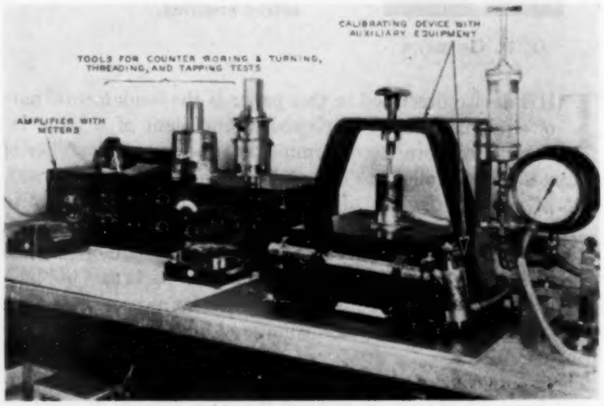

CALIBRATING DEVICE WITH AUXILIARY EQUIPMENT
TOOLS FOR COUNTER BORING & TURNING, THREADING, AND TAPPING TESTS
AMPLIFIER WITH METERS

Fig. 3 Amplifier and Calibrating Device for Tool-Pressure Measuring Device

It was desired, first of all, to obtain as much detailed information as possible regarding all those properties of the alloys which affect tool wear and tool life. It was felt, for instance, that comparative data on the hardness and uniformity of structure of the individual parts and of parts of the same and of different alloys would be of great value. These properties cannot be detected with ordinary tool-life tests, which measure only an accumulative effect. Their knowledge is helpful, however, as an indication of one of the causes of tool wear and of casting qualities.

The form, the number, and the material of the test pieces also were taken into consideration. The form excluded the possibility of using the trailer-tool method of Digges, since the total length of cut during the turning tests amounts to only $^7/_{16}$ in. The number and the material of the test pieces made it highly desirable to select a method that would require the least number of parts for one test in order to be able to vary the cutting conditions as much as possible.

A device of the type to be described, which permits the measurement of the three components of the tool pressure, was finally considered as best meeting the requirements. It was expected that tool-pressure measurements would considerably shorten the duration of the tests by permitting a comparison of the machinability of the alloys on the basis of the increase in tool pressure or the trend in this increase during the machining of a fixed number of parts rather than on the basis of ultimate tool life. It was further assumed that any changes in the uniformity of the parts and the alloys could be detected by the necessary resulting changes in the tool pressure. An important factor was also the desire to investigate the relationship between tool pressure, cutting angles, tool life, coolant, and other variables. We have in mind in this connection especially the investigation of the problem as to whether, for a definite set of test conditions, the tool with the least cutting resistance will show also the longest life.

FIG. 4 TOOL-SHANK MOUNTING OF CUTTING-PRESSURE MEASURING DEVICE

It was realized that the device, in order to give satisfactory results, would have to avoid the disadvantages common to practically all similar devices used in the past. An investigation was therefore conducted with the purpose of finding or developing a method of measuring pressure that would permit a rigid tool mounting and the recording of relatively sudden pressure changes. From the description of a simple test set-up[12] used for recording the tangential component of the cutting pressure on a lathe tool, it appeared that the piezo-electric method would best meet the demands. This method was therefore adopted. It is based on the property of quartz crystals to produce electrostatic surface charges when subjected to pressure in certain directions. The charges produced are proportional to the applied pressures and can therefore be used for pressure measurements. These charges appear or disappear practically instantaneously as the pressure is applied or removed.

DESCRIPTION OF THE DEVICE

The mechanical part of the device consists of a tool shank with holder plate mounted in ball bearings and between balls in such a way that the three components of the tool pressure are transmitted to three separate quartz crystals. The electrostatic charges produced on a given crystal by the corresponding pressure component are collected on electrodes of copper foil and allowed to charge a condenser. The voltage produced across the condenser by these charges is impressed on the grid of a special vacuum tube having a very high input impedance. The output of this tube is amplified sufficiently to be read on a rugged milliammeter or recorded by an oscillograph. The meter readings are calibrated directly in terms of applied pressure by the use of a hydraulic device and a dummy tool.

---

[12] J. Kluge and H. E. Linckh, "Piezo-Electric Measurement of Compression and Acceleration Forces," *Z.D.V.I.*, Sept. 14, 1929.

Fig. 2 shows the tool-shank assembly with pressure units and the metal box containing the condenser and special vacuum tube mounted on the turret of a No. 6 Brown & Sharpe hand-screw machine. This machine was selected for the cutting tests on account of its availability and rigidity. It was modified to give a maximum cutting speed of 800 ft. per min. for the large diameter of the test pieces. Fig. 3 shows the amplifier and the hydraulic calibrating device.

Fig. 4 is a diagrammatic sketch of the tool-shank assembly which illustrates how the pressure components are transmitted to the crystals with the minimum amount of frictional resistance. The mounting block for the outer race of the front bearing is located vertically between steel balls housed in cups with approximately $^1/_{64}$ in. clearance. The location sideways is fixed between one steel ball which rests against a pressure disk in the front housing and another ball which transmits the radial pressure to the quartz crystal C_R. The bearing housing is clamped to the machine turret.

The rear end of the shank is mounted in a single-row open-type ball bearing. This type of bearing was selected because it permits slight angular and longitudinal movements of the inner race. The outer race of this bearing is clamped in a housing mounted on the machine turret. The inner race is clamped to the shank. The shank is located longitudinally between the shoulder of the outer race and a pressure ball which transmits the feeding pressure to the quartz crystal C_F.

The magnitude of the tangential pressure component is determined by measuring the torque produced on the tool shank. A torque arm is mounted on the shank for this purpose which transmits the pressure to the quartz crystal C_T. The radial location of the torque arm and therefore also the shank is fixed between one ball, bearing against a pressure disk in the machine turret, and another ball which transmits the resulting torsional force to the quartz crystal C_T.

All quartz crystals are mounted between hardened and ground holder plates in pressure units of identical construction. The design of these units can be seen in detail from Fig. 4. The adjusting screws provided in each one of the units are used to preload the crystals to an extent which insures elimination of all static play in the pressure transmission members.

Before assembling the device all housing cups for the pressure balls were filled with grease. Great care was then taken to mount the shank in such a way that all pressure balls were in proximity to their correct location in relation to the pressure pins, to avoid binding.

Fig. 5 shows a schematic drawing of the electrical circuit and also the orientation of the crystal axes relative to the applied pressure. The pressure is applied along the neutral axis of the crystal, and the electrostatic charges are collected from the surfaces perpendicular to the electric axis. The precautions necessary when dealing with other electrostatic measurements must be taken care of here. Hence, all the connections between the quartz crystals and the grid of the pressure tube, as well as this tube itself, are electrostatically shielded. Furthermore, all of the insulation in this part of the circuit must be of the best, red sealing wax and hard-rubber blocks having been found suitable. The pressure-detecting tube itself must have a very high input impedance. The tube used here has an input impedance of the order of 10^{16} ohms. Insufficient insulation in this part of the circuit will cause objectionable drifts in the pressure readings.

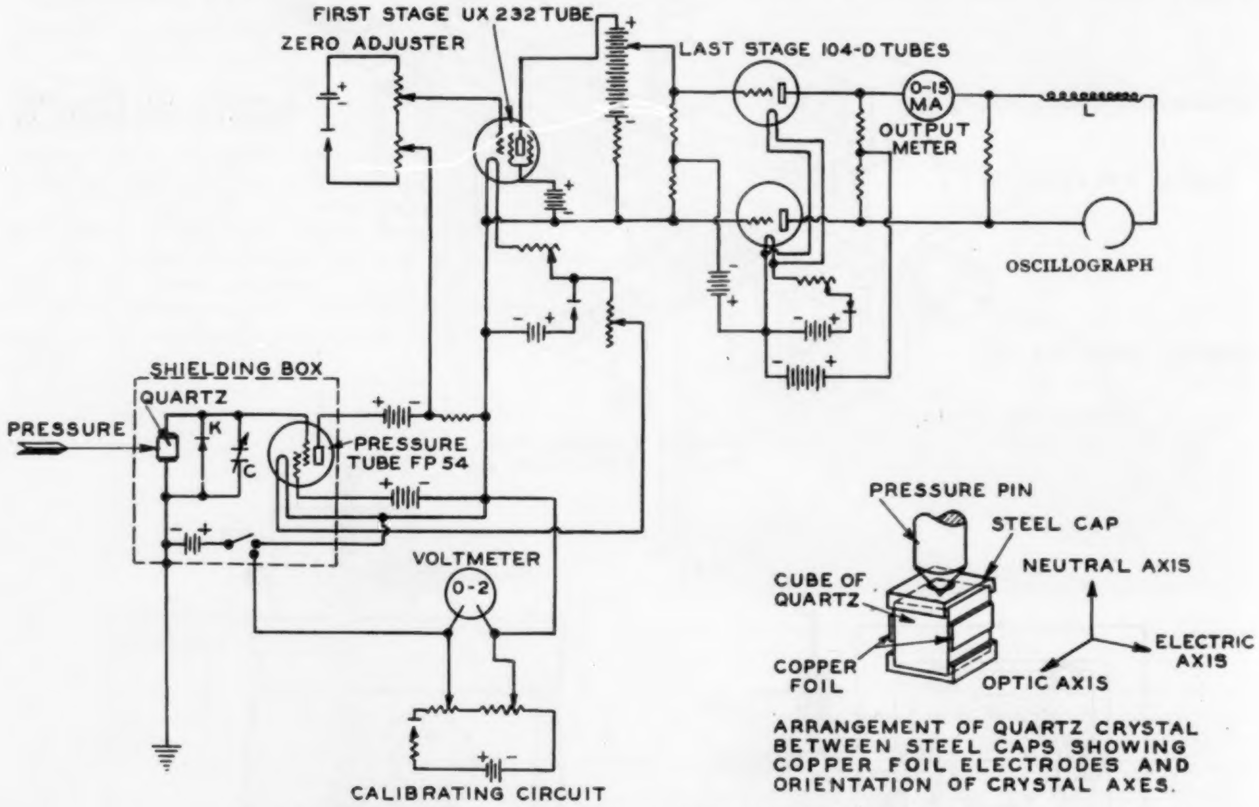

Fig. 5 Schematic Wiring Diagram for Piezo-Electric Pressure-Recording Device

The values of the drifts here were negligibly small. The effect of the actual numerical values of the circuit and tube leakage resistances on these drifts will be discussed farther on.

In Fig. 5 all parts of the circuit which must be shielded are shown as included within the shielding box. This is true of all except the crystals and leads from the crystals, which are all mounted in separate shields. A switch (not shown) is also mounted in the shielding box, which allows each crystal to be connected singly to the condenser and pressure tube. A grounding key is provided which places the grid of the pressure tube at the definite bias of —4.5 volts before starting a series of measurements. This key must of course be open when pressures are being measured.

The variable condenser *C* allows the sensitivity of the output of the amplifier in relation to applied pressure to be varied as desired. This is evident from the following considerations. With a given amount of charge, corresponding to a given applied pressure, the voltage produced across the condenser varies inversely with the condenser capacity. Since, as will be shown farther on, the output of the amplifier is proportional to this condenser voltage, it follows that the output for a given applied pressure will also vary inversely with the condenser capacity.

In the device as described the change in the grid bias of the pressure tube, or ΔEg, for maximum output is approximately 0.8 volt. The total charge produced on the side of a cube of quartz of any size is 1.04×10^{-11} coulombs per lb. of total force. This was calculated from the relation $Q = d_{11}W$, where Q is the total charge in electrostatic units and W the total force in dynes, using the value 69×10^{-9} for the piezo-electric coefficient d_{11}. (See Sosman,[13] pages 559 and 560.) The available charge, due to the electrodes not covering the whole of the side of the cube, is 0.65×10^{-11} coulombs per lb. Hence, from the relation that voltage equals the ratio of charge to capacity, the pressure values required to give 0.8 volt for different capacities may be calculated. These pressure values will then give the maximum output for the corresponding capacities. Such pressure values, for the maximum and minimum capacities obtainable with the condenser used here, are as follows:

Pressure value, lb.	*C* (micro-micro farads)
130.0	1060
9.9	80

The amplifier for the output of the pressure tube is two-stage and resistance coupled. The first stage utilizes the screen-grid UX-232 vacuum tube, and the last stage two 104D vacuum tubes connected in push-pull. A zero adjuster, working on the grid bias of the first stage, is provided to retain the zero of the output milliammeter against slow changes due to battery-voltage variations. An adjustable voltage source and voltmeter inserted in the grid circuit of the pressure tube make it possible to calibrate the output in terms of the voltage supplied by the crystal. A switch is provided to cut out this calibrating circuit when measuring pressures. This provision was made because the long leads from the shielding box to the meter, even though encased in a grounded metal sheath, picked up electrical disturbances caused by the starting and stopping of electric motors. These disturbances, while producing no appreciable effect while the grounding key was closed, caused large permanent changes in output when the key was open.

By the use of the push-pull circuit in the last stage and suitable choice of the operating ranges of the grid voltages of the pressure tube and the first stage of the amplifier, the output has been made linear with the grid voltage of the pressure tube from 1.0 to 9.0 milliamperes, these outputs corresponding to grid voltages of —4.5 and —3.7 volts. A typical calibration curve is shown in Fig. 6, where "output" *MA* or ΔMA is plotted against positive voltage increments applied to the grid of the pressure tube. By "output" *MA* is meant the reading in excess of 1.0 *MA*, since 1.0 *MA* is taken as the zero point. During use the sensitivity of the amplifier decreases slowly, about $^1/_4$ per cent per hour, and this may be instantly checked when desired by applying a single known voltage increment to the grid of the pressure tube. This decrease is mainly due to changes in B-battery voltage. The sensitivity recovers on standing for a few hours.

STATIC CALIBRATION OF DEVICE

In order to be able to convert the output of the amplifier into actual pressure in pounds the calibration device shown in Fig. 3 has been designed and found very practical. It permits a complete calibration of all three pressure components in approximately 30 minutes.

The device consists of a hydraulic pressure generating unit, a portable hydraulic unit connected to the former by flexible metal hose, and auxiliary equipment for applying the calibration pressures to a dummy tool. Light mineral oil is used as pressure medium. The hydraulic cylinder of the generating unit is mounted on the platform of a 200-lb. scale. A pressure screw used to apply pressure to the piston of the cylinder is mounted in a bracket above the scale. In calibrating, the desired pressure is set on the beam of the scale in the customary manner. The approximate adjustment of the pressure is then made by means of the grease gun and the manometer. The accurate adjustment is made with the pressure screw. The portable unit, consisting mainly of cylinder and piston, is applied to the dummy tool in the directions of the three components of the cutting pressure by means of suitable back stops.

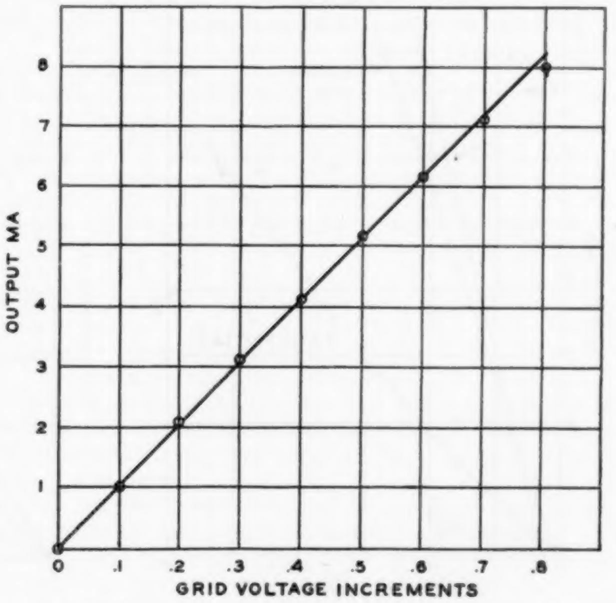

FIG. 6 VARIATION OF OUTPUT WITH GRID VOLTAGE OF PRESSURE TUBE

The accuracy of the calibrating device has been found to be within a fraction of 1 per cent at high pressures, while at low pressures it is less.

This calibration does not take into account the simultaneous action of all three components of the cutting pressure on the cutting tool, since the frictional resistances produced during the cutting action on the ball bearings and balls by the two pressure components not being calibrated, cannot be duplicated. To do this, three complete calibration units would be required. The error in the calibration is so small, however, due to the small coefficient of rolling friction, that in this case it can be neglected for all practical purposes.

---

[13] Sosman, "The Properties of Silica," Am. Chem. Monograph Series, no. 37.

In Fig. 7 are shown calibration curves of the variation of "output" milliamperes with tool pressure for each of the three components. Two sets of curves are shown—one for the condition of maximum sensitivity which is obtained with the minimum condenser capacity and the other for the condition of minimum sensitivity which is obtained with the maximum condenser capacity.

On close analysis it was found that these calibration curves consist of two portions—a portion in the lower pressure range which will be referred to as *A* and one in the higher pressure range which will be referred to as *B*. The portion *A* corresponds to the range in which, as the tool pressure is being increased, the tool shank moves gradually away from the back stops, and thus the preloading pressure is continuously being decreased. The actual increments in crystal pressure therefore correspond to the difference between the increments of tool pressure and the decrements of preloading pressure. For this reason the slopes of the *A* portions depend upon the magnitudes of the preloading pressures. Furthermore, there may be a slight curvature to the *A* portion, since the back stops are balls, and hence their elastic deflections are not strictly linear with pressure.

The *B* portions extend over the higher pressure range from the tool pressure values at which the preloading pressures are just removed. Here the increments in crystal pressure correspond to the increments in tool pressure. This portion of the curves, therefore, is always straight, and the slopes over this portion are independent of the magnitudes of the preloading pressures. The slopes would be the same for all three components if it were not for the fact that the ratio of tool pressure to crystal pressure is different for each component.

In adjusting the preloading pressures it is desirable to keep them as low as possible and still remove all static play. Such procedure will result in the slopes of the *A* portions of the curves being only slightly less than the slopes of the *B* portions. This will prevent the noticeable bend upward or increase in slope which occurs at the point where the preloading pressure is just removed in case this pressure is excessive. In Fig. 7 this point occurs at about 20 lb. pressure in the case of the radial component, where a slight bend upward can be seen. In the case of the feeding component the bend cannot be distinguished, while in the case of the tangential component only the *A* portion of the curve is shown, the bend occurring at a pressure of more than 200 lb.

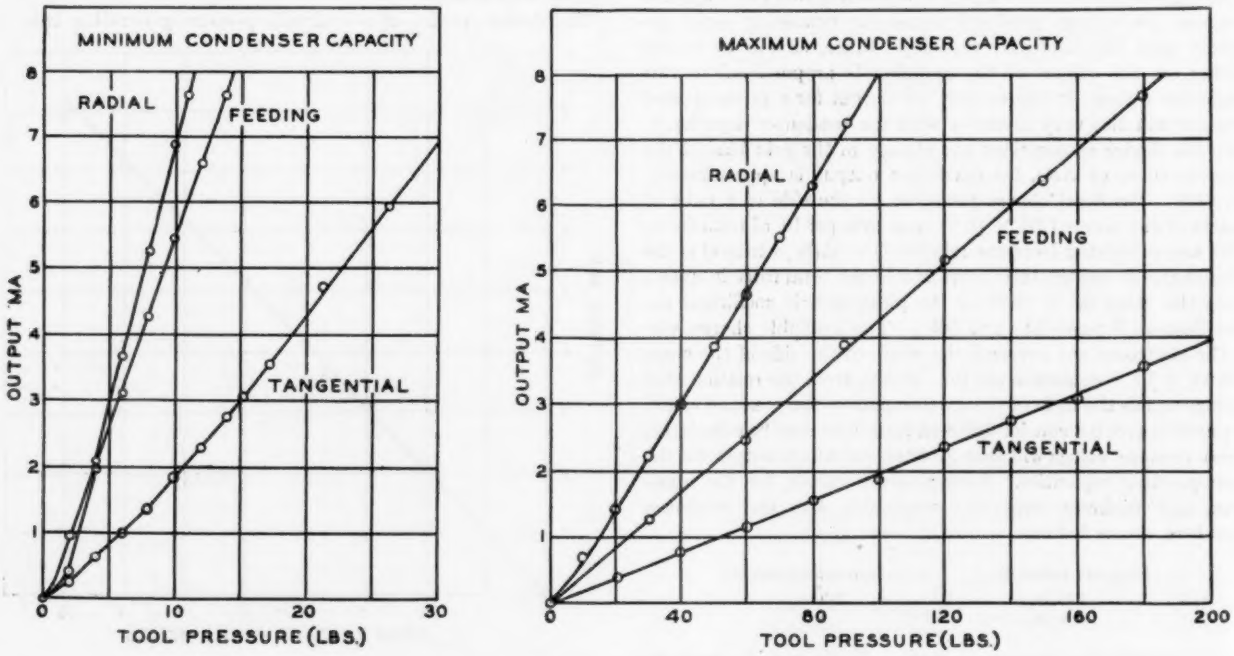

FIG. 7 VARIATION OF OUTPUT WITH TOOL PRESSURE

DYNAMIC BEHAVIOR OF THE DEVICE

In general, in order to record the fluctuations of any quantity without distortion, the recording instrument must have a natural frequency several times as great as that of any pulses or vibration trains occurring. If this condition is satisfied, the damping of the recording instrument is not important. The damping is of importance, on the other hand, when the natural frequency of the recording instrument is as low or lower than that of some of the pulses encountered. In this case an insufficiently damped instrument will overshoot and exaggerate the magnitudes of the fluctuations, while a critically damped instrument will, if anything, underestimate them.

In order to get an idea of what frequency of fluctuations of cutting pressure this device is capable of recording, it is necessary to know the natural frequencies of vibration and also the damping of the mechanical system comprising tool-holder plate, shank, balls, and quartz crystals. From computations on the device it was found that the elastic vibrational frequencies corresponding to deformation of the tool shank, torque arm, etc. due to forces applied in the directions of the three components of cutting pressure were much higher than the frequencies of vibration of the shank assembly considered as a rigid body, with the balls which transmit the pressure to the quartz crystals acting as restoring springs. Hence the natural frequencies corresponding to the application of forces in the directions of each of the components had to be computed on the latter basis.

These frequencies were computed in this manner, from the moments of inertia and the masses and the forces corresponding to unit displacements in these three directions. These forces were determined both by measurement and by computations on the compressibility of steel balls, both of which lead to the same values. The natural frequencies were also determined experimentally by taking oscillograms of the vibrations of the tool shank produced by suddenly released forces applied in the directions of each of the three components.

It was found that the vibrations of the tool shank were damped exponentially corresponding to viscous damping, and the values of k corresponding to the tangent exponential curve e^{-kt}, were determined from the oscillograms.

These experimental values of frequency n and damping k are as follows:

Pressure component	n (cycles per sec.)	k
Tangential..................	190	44.0
Radial......................	145	149.0
Feeding.....................	160	91.0

These experimental values of n agree with those computed, as described, within 5 to 10 per cent. With these values of the damping factor k, 5 to 15 vibrations of the tool holder occur on sudden release before they are damped down to a negligible value, so it is seen that the damping is far from critical.

If the device were used to record steady harmonic vibrations of a particular frequency, even with this insufficient damping, the response would not be exaggerated badly up to frequencies of 75 to 100 cycles per sec., although above these frequencies resonance would cause considerable exaggeration. However, the fluctuations in cutting pressure occur as an entirely irregular series of impulses. Hence we are interested in the behavior of the device under transient rather than steady state conditions.

The transient behavior is best illustrated by considering the response of the device to a force which rises from zero to maximum value in a given interval T, after which the force remains constant. If the interval T is several times greater than the natural period, the device will respond correctly and reproduce the actual pressure-time curve. If, on the other hand, the interval T is less than the natural period, the device will overshoot and execute its own damped vibration about the constant value.

Thus it is seen that when subjected to an irregular series of sufficiently rapid impulses such as the cutting pressure, the device will respond with a series of its own damped vibrations interrupted at irregular intervals. Actually the response is further complicated by impulses transmitted to the tool-shank assembly by the vibration of the lathe itself. It is obvious that oscillograms taken of the cutting pressure under these conditions will considerably exaggerate the magnitude of the pressure fluctuations.

The most satisfactory solution of this problem would be the critical damping of the tool shank for all three of its motions. This would cut out the overshooting and the bringing in of the natural vibrations of the tool-shank assembly.

However, the critical damping of such a heavy vibrating member appeared to be a problem of considerable magnitude. As a compromise, it was decided to retard the action of the oscillograph so that the time taken for it to reach full deflection was of the same order as that required for the oscillations of the tool holder to damp out. It was felt that this would in the main prevent it from following the natural vibrations of the tool holder, and hence smooth out these vibrations from the cutting-pressure oscillograms.

This result was accomplished by the use of a choke in the shunt circuit of the oscillograph which, by its inductive action, retards the rate at which the current rises to full value. Oscillograms were then taken, both of the vibrations produced by the sudden release of the tool holder and of cutting pressures. In all cases the natural vibrations of the tool holder were practically smoothed out, and other fluctuations were then apparent.

TEST PROCEDURE

The turning tests are being conducted with high-speed steel tools of the type indicated in Fig. 4. These tangentially cutting tools can be ground accurately and cheaply and therefore have an advantage as compared to radially cutting tools usually employed during machinability studies.

It is intended to investigate the suitability of the alloys for threading with chaser tools.

An objection may be raised against the use of tangentially cutting tools on account of their cutting action, which is somewhat different from that of radial tools. It should be kept in mind, however, that tangential tools are quite frequent in screw-machine work and are successfully applied in a number of commercial threading tools. One expects of course a fundamental difference in the life of both types of tools. This difference will be determined for similar test conditions by a series of tests with radial tools. It has no bearing, however, on the ultimate purpose of the tests—namely, the determination of the comparative machinability of the alloys.

The procedure during the turning tests is as follows. The parts are chucked on the small diameter and trued to a fixed dimension on the large diameter by means of a side tool. During the test cuts readings with a milliammeter are then taken alternately of the electrical output produced by each pressure component. The curves plotted from these readings represent a true picture of the changes in the pressure components due to tool wear and are used for the determination of the comparative machinability of the alloys. Indicative values of the cutting pressure in pounds per square inch of chip section are recorded on charts by means of the calibration curves.

Oscillograms are taken at various intervals to obtain a comprehensive picture of the cutting action. They are also used to determine the relationship between milliammeter readings (which are of course average output values) and the instantaneous output values of the records.

The machined diameters are frequently checked. Chip samples are also taken at fixed intervals for later reference.

Mechanical calibration tests are made about twice every week. Electrical calibration tests are made more frequently.

Visual records of the wear of the tools after each test are obtained by means of a Hartness screw-thread comparator. These records are used for a comparison with the results obtained with the cutting-pressure measuring device.

RESULTS OF TESTS

The authors do not, as yet, consider the tests sufficiently complete to give detailed information on the behavior of the individual alloys under various test conditions. They present therefore only the following general results, which were obtained during turning tests made without a coolant:

1 Oscillograms of the three pressure components gave a good indication of the uniformity of the material. It was found that the large-diameter section of the test pieces was invariably softer in the middle than at the ends. This condition showed up best in the records of the radial pressure and seems to indicate that this component best reveals any non-uniformity of the material. (See Fig. 8.)

2 A comparison of pressure curves of the three tool-pressure components verified the findings of previous investigators already referred to—that the tool wear affects the radial and feeding pressure much more than the tangential pressure. This is illustrated by the curves shown in Fig. 9 of the tool pressures during the dry machining of 250 parts of four alloys.

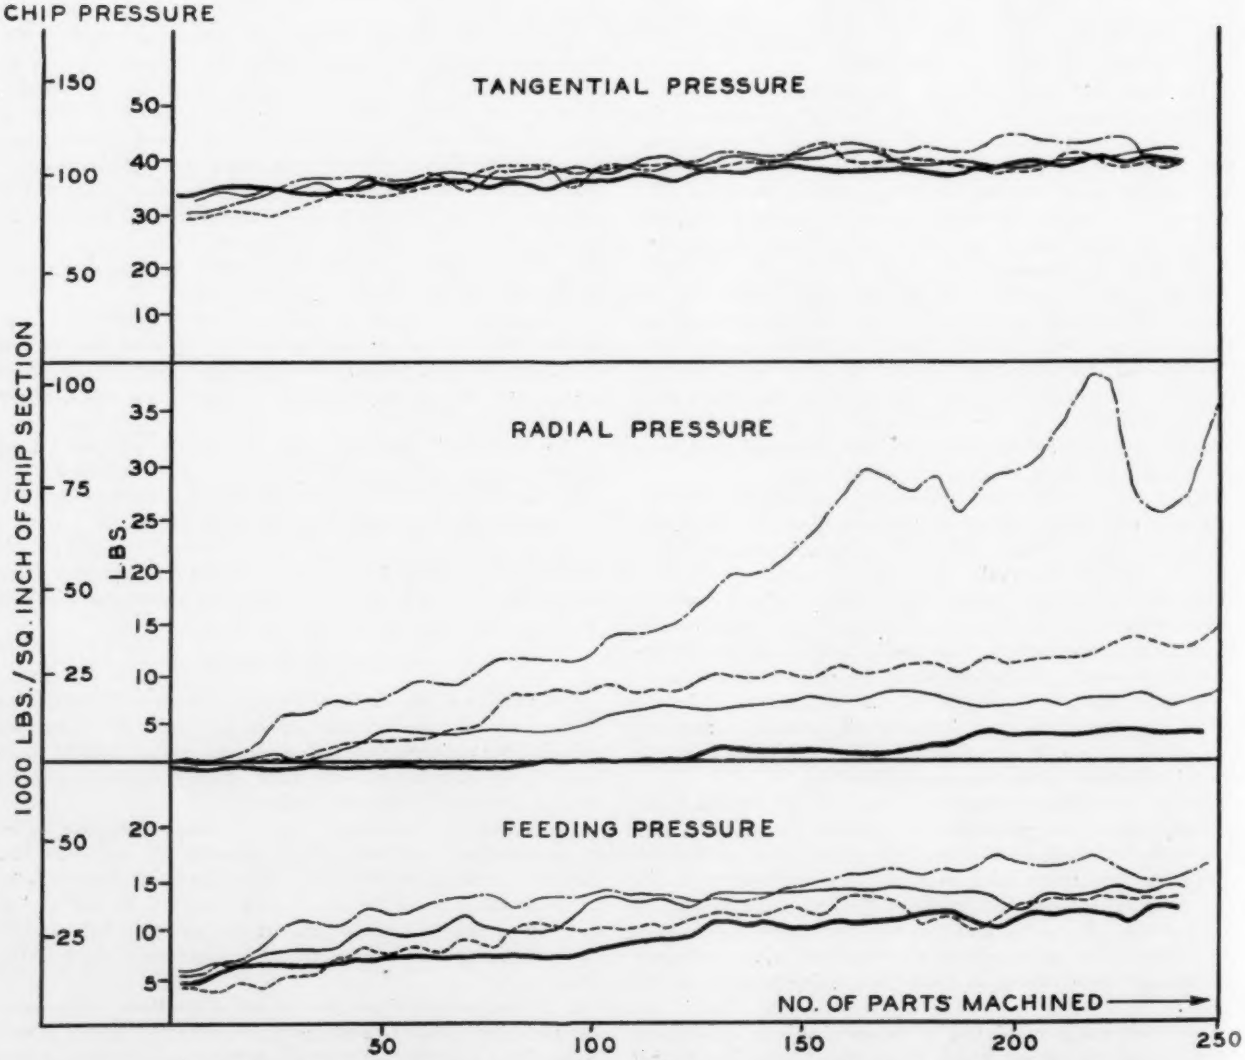

FIG. 9 VARIATION OF THE THREE COMPONENTS OF TOOL PRESSURE WITH NUMBER OF PARTS TURNED

(Heavy line: No. 8 alloy, 95.5 Al, 2.25 Ni, 0.75 Si, 1.5 Cu. Broken line: No. 5 alloy, 87.0 Al, 13.0 Si. Light line: No. 6 alloy, 95.0 Al, 3.0 Si, 2.0 Cu. Dot-and-dash line: No. 11 alloy, 90.0 Al, 8.0 Si, 2.0 Cu. Cutting conditions: Tool used, tangential 50-deg. cutting angle, material high-speed steel. Cutting speed, 765 ft. per min. Feed, 0.012 in. per revolution. Depth of cut, 0.031 in. No coolant used.)

3 The pressure curves of the radial and feeding components permitted a fair comparison of the machinability of the alloys for dry cutting conditions. (See Fig. 9.) For some of the alloys results were already obtained after machining 250 parts. For other alloys with apparently similar machining qualities the tests had to be extended.

4 A comparison of corresponding values of the tangential pressure during the machining of 250 parts each of two alloys, one with high and the other with low silicon content, under various test conditions, demonstrated that this pressure, usually referred to in a general way as cutting pressure, is in itself no conclusive measure of machinability. It was found that at the beginning of the tests the high silicon alloy required less pressure than the low silicon alloy, whereas at the end of the tests this condition was just reversed. It is obvious that wrong conclusions would have been reached if the machinability of these alloys had been based on the starting values of the tangential pressure and not, as had been done here, on the increase in the radial and feeding components of the tool pressure.

5 The starting values of the tangential cutting pressure ranged from approximately 75,000 lb. to 105,000 lb. per sq. in. of chip section for cutting speeds of 500 to 750 ft. per min., 0.012 in. feed per revolution, 0.031 in. depth of cut, and cutting angles of from 35 to 50 deg. The corresponding radial pressures amounted in most cases to only a few thousand pounds per square inch and were sometimes even negative. The corresponding feeding pressures ranged from approximately $^1/_4$ to $^1/_8$ of the magnitude of the tangential pressures. The end values depended upon the wear of the tool.

WORKING LIMITS OF THE METHOD AND OF THE DEVICE ITSELF

Applications of the piezo-electric property of quartz have been made by many in the field of the measurement of rapidly changing pressures. Work has been done along this line by Karcher[14] in measuring peak pressures, and more recently by Webster[15] and also by Kluge and Linckh[12] in measuring instantaneous pressure values. The work of Webster was on the high pressure produced by the firing of a gun, while that of Kluge and Linckh was on lower pressures, such as tool pressures and the vibration of a stretched wire.

The device that has been just described was designed along similar electrical lines to that of Kluge and Linckh, but has been improved from the standpoint of electrical leakage and also in that the output is linear with crystal voltage. Mechanically it represents the application of this method to the special problem of measuring the three components of cutting pressure during the machining of the short test pieces available. By providing suitable tool holders, it can be used for tests on practically any type of tool, such as turning tools, drills, etc.

The following is a short discussion of the controlling factors that enter in to determine the range of usefulness of this method as it might be applied to the measurement of other types of instantaneous pressures, and also of the device as described.

(1) *Lower Pressure Limit.* Even with more amplification than used here, there is an electrical limit to the lowest pressure that can be satisfactorily measured. This is because even with the best obtainable insulation in the circuit comprising the crystal, condenser, and grid of the pressure tube there will be a small leakage current which will produce a drift in the reading of the meter indicating the pressure. This drift may be divided into two parts:

(*a*) The drift due to the grid current of the pressure tube.

(*b*) The drift due to leakage over the quartz crystal and over the insulation of the condenser, grounding key, etc.

The first of these drifts has the same value whether the reading is at zero or full scale and is in the direction of increasing pressures. In the device as described this drift amounts to 0.03 lb. per min., corresponding to a grid current of 3×10^{-15} amp.

The second drift is back toward the zero reading with constant applied pressure. This drift varies with the magnitude of the pressure reading and amounts to a certain percentage of the reading. This percentage is proportional to the sensitivity of the device as determined by the condenser value. The greatest percentage observed was 0.5 per cent per minute, this being with the highest sensitivity—namely, full scale for 9.9 lb. crystal pressure. This value of drift corresponds to a leakage resistance over the insulating surfaces of the order of 10^{14} ohms.

For the work done here both of these drifts were sufficiently small. They amount to about $^1/_{20}$ of the drift present in the apparatus of Kluge and Linckh. It is probable that the tube drift could be cut down to 0.01 lb. per min. by special drying of the glass surface, since the manufacturer states a grid current corresponding to a drift of this magnitude. Special precautions might produce an improvement in the other insulating surfaces also. As it was, it was found necessary to put a drier consisting of calcium chloride in the compartments containing the quartz crystals. This was done because the shellac used to cement the foil to the crystals was quite hygroscopic, and caused a large leakage current without the drier present.

From the mechanical standpoint, the main point in determining the lowest pressure that can be satisfactorily measured is the friction on the members transmitting the forces to the quartz crystals. With the device as described, with the greatest sensitivity, a full-scale reading was obtained with the following values of the three components:

Tangential......	34.0 lb.
Radial..........	11.5 lb.
Feeding.........	14.5 lb.

There were no appreciable errors traceable to friction. As mentioned previously, due to different leverages and preloading pressures, these are quite different from the actual pressures on the quartz crystals.

(2) *Higher Pressure Limit.* There should be no upper limit electrically to the pressure that can be measured by this method. The shunting condenser can be made large enough to keep the working voltage of the correct magnitude. The pressure-charge relationship has been found linear up to 12,500 lb. on a crystal of the size used here (computed from Karcher's[14] data). It may be well to mention here that the piezo-electric constant is practically independent of temperature in the range from 0 deg. cent. to 100 deg. cent. (See Sosman,[13] pages 565 and 566.)

With the device as described, the full-scale reading with the maximum condenser value was for 130 lb. crystal pressure, the values for the three components being somewhat different due to leverages and preloadings. By substituting a larger condenser the range could be easily extended.

From the mechanical viewpoint, considering the quartz itself, the crushing strength of a $^1/_2$-in. cube such as is used here amounts to 75,000 lb., as calculated from data given on page 481 of Sosman.[13] The linear compression of such a cube amounts to 15 $\times 10^{-6}$ inches for 100 lb. or about twice that for a steel cube. This was calculated from Bridgman's value of the linear compressibility given on page 465 of Sosman.[13] The upper limit of the method as far as the working stresses are concerned would then depend on these figures as well as on the stresses produced in the steel balls and the other parts of the tool-shank mounting.

[14] J. C. Karcher, "A Piezo-Electric Method for the Instantaneous Measurement of High Pressures," Scientific Paper of Bureau of Standards (1922), 18, pp. 257–264 (No. 445).

[15] R. A. Webster, "A Piezo-Electric Gage and Amplifier," Franklin Inst. Jour., vol. 211, no. 5, May, 1931, pp. 607–616.

The upper pressure limit will also depend on the maximum displacements at the cutting point of the tool which can be tolerated as far as the limits of accuracy of the particular turning operation are concerned. For the device as described, the approximate displacement for an applied tool pressure of 100 lb. in the three different directions are:

Tangential....	0.0010 in.
Radial........	0.0018 in.
Feeding.......	0.0005 in.

These deflections were found to be largely due to the compression of the balls used to transmit the pressure to the quartz crystals and were considered not excessive for the work in hand. The use of rollers instead of balls is now being considered for transmitting the pressures to the crystals. This construction will require a much greater accuracy of the working parts than the present design to make it successful. However, as computations show, it will reduce the deflections of the tool point considerably.

(3) *Rapidity of Response.* In applying any method for measuring instantaneous pressure values occurring in any mechanical system it is essential that the building in of the recording device does not materially change the mass or the rigidity of the system, or the vibration characteristics of the system will be changed. Due to the high modulus of elasticity of quartz, this method is especially suitable for application to mechanical systems of high rigidity.

In applying any method to the problem of measuring instantaneous tool pressures, it is necessary for distortionless recording, as mentioned previously, that the system comprising tool, tool holder, and measuring device have a natural frequency several times that of any pressure pulses that will be encountered. To satisfy this condition, the masses must be kept to a minimum and the rigidity to a maximum.

The desire to be able to measure all three force components necessitated the design of a tool holder and mounting of rather larger mass and lower rigidity than otherwise would have been the case.

The device as described would satisfy these requirements if no pressure pulses corresponding to a frequency of more than 50 cycles per sec. were encountered. As the maximum frequencies corresponding to chip formation under the conditions of the tests appear to be over 5000 cycles per sec. (by chip size and surface speed), even the added rigidity of rollers, which would raise the natural frequencies of the device considerably, probably would not be sufficient. Hence, to prevent undue exaggeration of the response to pressure fluctuations, damping of some kind is necessary, and that which is in effect produced electrically, as described, appears at present the most practicable. Under these conditions the records obtained are reliable in every respect except for fineness of detail in regard to rapid fluctuations.

ACKNOWLEDGMENTS

The authors wish to acknowledge their indebtedness to Mr. G. A. Bouvier, under whose direction and supervision this work was done. They further wish to acknowledge the suggestions of Mr. R. J. Beavers during the earlier work and the assistance of Mr. F. J. Bigler in the carrying out of the tests.

Discussion

R. Poliakoff.[16] The authors rightly mention the importance of the problem under their investigation as based on tool life and tool wear. The methods used, however, by various experimenters are limited practically to roughing cuts, whereas finishing cuts still wait to be given at least part of the attention given to roughing cuts.

The writer would therefore refer to a method of studying the wear and life of finishing cuts used by him as far back as 1913, a description of which is given in the "Report on Past Experimental Work on Cutting Tools" of the Tool Steel Research Committee of the Manchester Association of Engineers (England), published in 1916. The method was favorably commented upon, also, in the "Proceedings of the Institution of Mechanical Engineers," London, 1913, p. 1150.

The principle employed was to work with the tool until it reached a predetermined bluntness. The latter was observed as the tests progressed by means of an indicator fixed in the rest immediately below the tool. (See Fig. 10.) The indicator was set to zero at the commencement of the cut, and it pressed against the bar so that as the tool became blunt and lost its cut, the radius of the bar increased by a like amount, and this was shown by the indicator. The indicator was graduated in 1/2000ths of an inch and the degree of tool bluntness decided upon for the particular test was 3/2000ths of an inch, i.e., about 25 per cent of the depth of the cut. The method, when proper instruments are used, affords a very accurate way of studying wear of finishing tools.

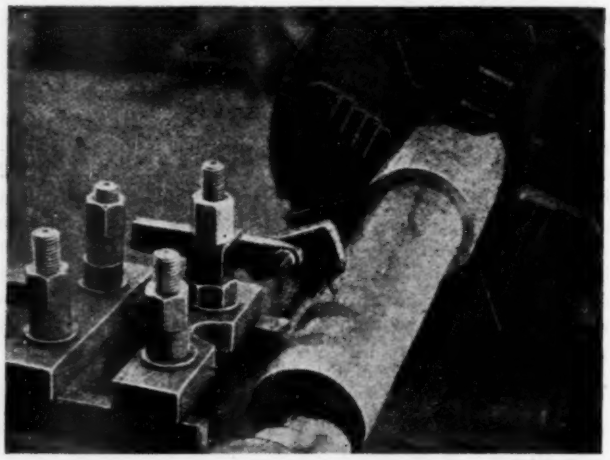

Fig. 10 Indicator in Position for Measuring Wear While Cutting

The writer cannot agree with the authors' statement that the problem of chip pressure received early attention in view of the relative importance of removing metal with the least amount of energy. It is important to study chip pressures, as they affect many elements both in the tool and the machine, but even with great chip pressures the amount of energy necessary to remove the metal can be very small and of minor importance, both in itself and as money expense. This, of course, is particularly true in the cases of problems which the authors had under investigation, where the chips removed were not heavy.

O. W. Boston.[17] The device described for recording instantaneous tool pressures is obviously the result of painstaking efforts of a high scientific order. The application of the quartz crystal seems superior to the hydraulic type of dynamometers because of the rigidity introduced in the measuring mechanism. The use of a liquid to transmit pressure of such high frequency as suggested would undoubtedly introduce additional difficult calibrations due to the tendency on the part of the liquids and containers to absorb and delay the transmission of the high-frequency forces.

[17] Professor, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

The use of this device to measure pressures in order to anticipate the degree of tool wear and tool life for the different materials machined is unique. It is not new in principle, but does indicate great possibilities. A complete relation between the cutting force and tool wear must first be determined carefully in order that tool life may be based on tool wear. As the tool wears, the force may actually become less and remain less until the point of tool failure, due to the cupping action of a chip on high-speed-steel tools, as when cutting ductile steel. On the other hand, the tool wear may be by abrasion on the flank below the cutting edge, as when cutting cast iron with high-speed-steel tools or when cutting steel with carbon-steel tools. The various die-casting alloys studied in the paper might react differently in this respect on a given tool.

The writer is not in a position to comment intelligently on the influence of the dampening effect of the heavy vibrating member which carries the part being machined. It appears that this is a problem, as the authors have stated, of considerable magnitude and one requiring careful calibrations. The authors make the statement that the fluctuations in cutting pressure occur as an entirely irregular series of impulses. The writer has found[18] that most metals when removed by the cutting edge of a tool are formed into small laminations which group themselves into elements of unequal size. On the other hand, on some metals, such as free-cutting screw-stock brass and free-cutting steel, the sections formed are quite equal. When viewing the formation of the sections through a microscope as the chip is being formed at very slow speeds, it was found that these sections occurred regularly at, say, every 0.015 in. of tool travel for certain cutting conditions. Presumably, the die-casting alloys being studied fall in the group which give chip sections of unequal size, producing the irregular series of impulses. It might be of help to study these impulses by trying to machine a free-cutting brass or free-cutting steel, such as those which have been found by the writer to give regular impulses.

The writer is interested in the statement made in paragraph 1, under the heading of "Results of Tests," that "It was found that the large-diameter section of the test pieces was invariably softer in the middle than at the ends." He would like to ask, Does this mean softer as measured by a hardness-testing machine or does it cut easier, that is, with lighter pressure?

In paragraph 2 under the same heading the statement is made that tool wear affects the radial and feeding pressure much more than the tangential pressure, as illustrated by the curves in Fig. 9 of the tool pressures during the dry machining of various parts. Inasmuch as these die castings will probably eventually be machined by the assistance of a coolant, it seems only reasonable that data should be obtained confirming this statement when cutting with a cutting fluid. The writer has found that the wear of a tool, particularly drills, is influenced by the nature of the cutting fluid.

It is of unusual interest that the radial and feeding pressures indicate more pronouncedly the increase in cutting force because of tool dulling than does the tangential pressure. Presumably, one conclusion is that the tool is failing by abrasion of the flank reducing the clearance angle below the cutting edge to zero, rather than by the cupping method. The writer has experienced this same condition when cutting cast iron and semi-steel with high-speed-steel tools.

Fig. 9 would indicate that the tool pressure when cutting a No. 8 alloy (the heavy line) is negative for the first 80 pieces produced. If this interpretation is correct, might this be due to the fact that the back-rake angle of the tool for this material is such as to cause the tool to dig in and take deeper cuts?

It is hoped that the authors will find it convenient to present the results of machinability. Certainly that part of the report dealing with instantaneous pressure is interesting and may throw considerable light on compositions with irregular impulses and tend to minimize or completely eliminate chatter.

The writer is looking forward anxiously to further progress dealing with this interesting study.

M. Stone.[19] Although the ultimate aim of the work undertaken by the authors is not the development of a dynamic-pressure-measuring instrument, this occupies the major part of the paper, and is of general interest as well.

In the field of instruments for measuring very small vibratory motions and forces, the writer has had much to do with the application and improvement of dynamic extensometers of the variable-coupled transformer (magnetic) and carbon-pile types. These instruments have very desirable accuracy, down to 0.00001 in., and have provided means for investigating a number of dynamic phenomena that otherwise could have been investigated only inappropriately—such as measurement of instantaneous and vibratory torque in Diesel drives, short-circuit forces and motions of turbo-generators, variable stresses in oil-pumping mechanisms, acceleration of railway-truck parts, etc. One reservation always has been present, however, and that concerns the inertia of the instrument to exceedingly rapid motions.

In this respect, the piezoelectric pressure-measuring device provides something that takes us far above the range of natural frequencies that other types of devices have. The fact, too, that the front of this device is merely a flat, parallel-faced crystal allows it to be used in places where other types of instruments would be decidedly disadvantageous, due to their size. In making up their instrument, however, the authors were not able to take advantage of the first property apparently because of the relative flexibility of the mounting carrying the crystals. Concerning the second, however, the reason for their compact instrument is made possible only through the small size of the crystals.

The crystal measuring device that the authors have followed in their design is that of Kluge and Linckh at the Technische Reichsanstalt in Berlin, and rightfully so. Although they were not the originators of the idea of using piezoelectric effects for mechanical measurement, these two men have perfected the application of this device to several types of measuring instruments. The writer recently had the opportunity of discussing with them several possibilities of its further use. At the beginning it was thought that the care necessary in measuring the exceedingly small electrostatic charges would hinder its being successful, but this has been to a large extent overcome by careful shielding and the use of the tube voltmeter.

Due to its high natural period, this type of instrument can do two things probably more successfully than other instruments—(1) record impactive forces, of explosion rapidity, and (2) record even the highest harmonic existent in normal elastic structures, which escape the other types of instruments.[20]

The authors have furthered the application of this type of measuring device in an instrument designed for a type of work that has been little investigated in this country. This discusser agrees with the authors that it is only through the type of investigation that they are planning that any real knowledge on the relative machining characteristics of various materials and tools can be based.

[18] "What Happens When Metal Is Cut," Trans. A.S.M.E., 1930, paper MSP-52-11.

[19] Engineer in Charge of Development, Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

[20] See "Piezoelectrische Messung mechanischen Grössen," by Kluge and Linckh, *Forschungsarbeiten auf dem Gebiete des Ingenieurwesens*, 1931, p. 95, where high harmonics are shown in the measurement of the starting torque of a direct-current motor.

R. E. W. Harrison.[21] This contribution to knowledge regarding the stresses involved in the cutting of metal is valuable and of special interest at the present time. The availability of the apparatus described by the authors makes it possible for the designer of machine-tool and small-tool equipment to more thoroughly appreciate the stresses involved, and therefore to adequately take care of them in the designs which he produces.

The paper brings out a number of points of exceptional personal interest, inasmuch as the writer spent some years at the Manchester College of Technology, where the tests were made in England, which determined the relative merits of high-speed and carbon-steel tools.

It would seem, from the graphical records on the eighth page, that the piezoelectric pressure-measuring method is more complete, inasmuch as there does not appear to be the slight lag and rounding of the curves at the points of high and low pressures which characterize the graphs produced by hydraulic-pressure-recording devices.

The authors are to be congratulated upon the careful analytical thought which has been put into the design of their tool carrier as well as the complete calibration of the apparatus before the tests were run.

As a record of an extremely interesting investigation into methods of recording tangential, radial, and feeding pressures, it is doubtful if anything of a more reliable nature has been made available. However, on the general question of machinability—and it is understood that this was the major motive which actuated the experiments—the writer would suggest the desirability of further investigation into the processes through which the raw material is passed prior to the machining operations. The reason for this recommendation is that during the past year various phases of the problem of machinability have been presented, and the results obtained from a series of very careful tests indicate that in almost every case where difficulty is experienced in machining a particular object, the most complete and permanent solution of the problem can be reached only by going back to the chemical or metallurgical analysis of the material being worked on, and then following through by a most accurate control over subsequent heat treatments such as normalizing, annealing, etc.

In one case in particular which the writer has in mind, it has been proved that to secure reliable machinability it is necessary to revise all previous ideas regarding permissible variations in chemical analysis and permissible working range in pouring, annealing and normalizing, etc. The results of the tests show that there is every indication that the older and more generally accepted methods of testing for machinability with a file, with the drill point, with the scleroscope, and with the Brinell machine do not produce the full story. The detection of inclusions, hard crystalline formations, and laminations cannot be accomplished reliably by any of the older methods, and it has been shown that these defects can be most adequately brought to light by cross-sectioning and a deep and rapid acid etching. In the particular case in question the results obtained included:

(*a*) Increase in cutting speed of from 20 to 40 per cent
(*b*) Increase in tool life of at least 50 per cent
(*c*) Almost entire elimination of rejections due to unmachinability
(*d*) Overall increase in manufacturing efficiency with practically no increase in the cost of raw material.

This latter statement serves to illustrate the fact that it is many times possible to do the job rightly at no increase in cost over and above the cost of the wrong or what might be termed the wide-range method. Whether figures such as those quoted could be made applicable to the particular piece of work shown in Fig. 1, the writer does not know. However, it is hoped that they will serve to draw attention to the importance of the control of specifications affecting the material before it is presented to the machine.

It is to be hoped that the authors will continue their experiments, as it would seem that their apparatus is particularly well suited for the recording of the effects of laminations in forged-steel products, and further experimentation would undoubtedly bring to light a definite relationship between forging and annealing temperatures and tool life.

E. O. Waters.[22] Fig. 9 of the paper is an interesting commentary on previous measurements of tool pressures, in showing that the radial and feeding pressures, rather than the tangential pressure, increase during the use of a tool. Such being the case, it appears that, contrary to early surmises, there is no correlation between the energy of cutting and the life of a tool, at least within the limits of duration in Fig. 9. In other words, as long as the removal of metal is the only criterion, and surface finish is disregarded, it would have been possible for the machine to keep on running, producing pieces of the specified diameter, well beyond the "250 parts" which apparently terminated the tests. If roughing cuts only are being taken, what difference does it make if the radial and feeding pressures rise to extreme values, as long as the tool and the machine are strong enough to stand up against these pressures?

On the other hand, if a high quality of surface finish is desired, it may well be that a sharp rise in the radial-pressure curve can be associated with a dulling of the tool sufficient to make it unsuitable for finish cuts. Such a correlation, however, would have to be arbitrarily established before the pressure measurements would be of any value.

The foregoing is not offered as a criticism of the authors' work, but of tool-pressure measurements in general. The method of measurement described in this paper is noteworthy for its sensitivity and for the practical absence of motion in the parts being weighed. It should be studied attentively by all engineers who may have occasion to make pressure measurements of a similar order of refinement in other fields of research.

Authors' Closure

The indicator method referred to by Mr. Poliakoff for the direct measurement of tool wear during finishing cuts is comparable to the trailer-tool method used by Digges and French for the same purpose. The authors are sure that both of these methods can be used to advantage and will furnish good results in all those cases where the test pieces are available in comparatively long bars of fairly uniform structure. As mentioned in the paper, however, it was for their investigations considered important to obtain not only data on the machinability of the alloys as expressed in tool wear or tool life, but also as much information as possible regarding such causes contributing to tool wear as variation in the hardness of the parts, presence of blowholes, and other physical properties. This reasoning led to the adoption of the method described.

The authors admit that for most modern machine tools the problem of removing metal with the least amount of energy is relatively unimportant from the standpoint of expense for the power required. They can well imagine, however, that investigators, during the early stages of machine-tool design, were much concerned with this problem also from the point of view of keeping the stresses and the wear developed in the relatively coarse machine elements down to a minimum. From the broader aspect of tool-pressure measurements in general, the authors are certain that even today a more accurate knowledge of chip pressures for the various materials and machining operations is desirable.

[21] Engineering Sales Director, Cincinnati Grinders Incorporated, Cincinnati, Ohio. Mem. A.S.M.E.

[22] Associate Professor of Mechanical Engineering, Yale University, New Haven, Conn. Assoc-Mem. A.S.M.E.

The authors concur with the opinion advanced by Professor Boston that the relationship between tool wear and the change in the cutting forces must be established before tool-pressure measurements are used for machinability studies. This was realized, and visual observations of the condition of the cutting edge of the tools were therefore made with a Hartness screw-thread comparator at the beginning of the tests, to check this relationship. The results obtained were considered satisfactory.

The irregular fluctuations in the magnitude of the cutting forces referred to in the paper should be regarded in the light of the natural frequencies of vibration of the device. These frequencies, while being relatively high, were yet not high enough to permit the device to follow the very rapid pressure changes resulting from the separation of the individual chip laminations which, according to calculations, occurred in some instances at the rate of 5000 per sec. The oscillograms of the cutting pressures, therefore, do not reveal all the fine details of the cutting action, but are a record rather of such irregular occurrences as blowholes and hard and soft spots. It can easily be seen that, to bring out the details of the cutting action, the cutting speeds used would have had to be decreased to values far below any practical shop speed.

The statement made in the paper regarding the variation in the hardness of the middle and end portions of the large-diameter section of the test pieces referred to the hardness as it expressed itself in the magnitude of the cutting pressure. While it would probably have been more correct, as suggested, to speak of the ease of cutting rather than of hardness, it was felt that the use of the latter term was justified in view of the greater chilling effect of the die on the end portions as compared with that on the middle portion.

Concerning the use of a cutting fluid, it was the intention of the authors at the beginning of the investigation to conduct tests under both dry and wet cutting conditions. However, a number of tests, during which a coolant was used, indicated that the respective rates of tool wear would be so slow as to make it advisable to restrict the investigation to dry-cutting conditions.

The authors share the opinion advanced regarding the interpretation of the negative radial pressures at the beginning of one test with alloy No. 8. The radial component of the chip pressure against the back of the tool in the direction toward the axis of the work must, in this case, have been greater than the radial pressure produced at the contact point of tool and work against the front face of the tool.

The authors appreciate the comments made by Mr. Stone regarding the electrical aspects of the device. They regard, with high esteem, the work done by Kluge and Linkh in Germany in connection with a number of applications of the piezoelectric pressure-measuring method, and are satisfied if their own work tends to further the adaptation of modern electrical developments to purely mechanical research such as machinability studies.

The point brought out by Mr. Harrison regarding the importance of chemical and metallurgical analyses of the materials to be tested in connection with machinability studies is well taken. While the authors expected valuable information in this respect from a separate study conducted on the physical, chemical, and metallurgical properties of the alloys referred to, they were of the opinion that the testing method for the investigation of the machining qualities should, if possible, furnish data also on some of those metallurgical properties of the alloys, which, it was expected, would affect the machinability. This latter consideration was therefore one of the factors which led to the adoption of the method described.

Regarding Professor Waters' comment, the rates of increase in the radial and feeding components of the chip pressures were taken as an indication of tool wear on the basis of the results of tests by previous investigators and of preliminary tests during which the effect of tool wear on the three pressure components was investigated. From a general point of view the authors see no reason why the method described cannot be applied equally well to roughing and finishing cuts. They desire to call attention, however, to the fact that they regard the problem with which they were confronted as a special one, in view of the shape and character of the parts, and ask that the method adopted be considered partly in this light.

Belt Drives With Cast-Iron Pulleys and Paper Pulleys

By C. A. NORMAN[1] AND G. N. MOFFAT,[2] COLUMBUS, OHIO

C. A. NORMAN

This paper gives data on transmission efficiency of various types of belts on cast-iron and paper pulleys and goes thoroughly into the transmissive power of oak-tanned and rubber belts on such pulleys with varying contact angle, a subject of importance in view of the prevalence of short-center drives with large transmission ratio. It is found that commonly used formulas for the effect of contact angle on transmissive power are not dependable for all combinations of belts and pulleys.

G. N. MOFFAT

PREVIOUS tests at the Ohio State University have covered a great variety of belt materials and have given the comparative degree of slackness at which belts of these materials could be run.[3] Data were also given with regard to stretch. These tests were principally on cast-iron pulleys and sheet-steel pulleys. Belts were also run at very high speed on pulleys with wood rims, and conclusions were presented regarding the effect of centrifugal force on transmissive power. Data on transmissive power from tests on a static slip test machine were given for comparison with the data from running tests, and the relative applicability and value of static and running tests were discussed.

No data were given, however, on transmission efficiency, i.e., the ratio of output at the driven end to input at the driving end; and effective pulls in excess of 50 lb. per inch of width were dealt with only for pulleys of a diameter of 6 in. Many inquiries having been received regarding transmission efficiency, it was concluded that it might still be well to publish some data of this kind. Also it appeared that the tests on pulleys with diameters of only 6 in. gave an advantage to very flexible belts. It appeared desirable to investigate high effective pulls with larger pulleys, on which even somewhat stiffer belts might develop sufficiently intimate contact. Data are furnished herewith for effective pulls as high as 100 lb. per inch of width for both oak-tanned and rubber belts. While on 6-in. pulleys in the earlier tests only a certain mineral-tanned belt was found capable of carrying effective pulls of this magnitude, the tests here presented show that on 18-in. pulleys both oak-tanned and rubber belts are likewise able to carry such loads.

In the earlier tests, for rim speeds of more than 8000 ft. per min., wood-rimmed pulleys were used, but no thorough investigation of the transmissive power of other than cast-iron or sheet-steel pulleys was undertaken. Impregnated paper pulleys have, however, long been known as an extremely effective means of transmitting power, and they have been gaining increasing acceptance in many fields. It appeared of value to investigate their properties rather fully.

The investigation was carried out not only at 180-deg. contact angle, but at a variety of contact angles. This appeared of particular importance in view of the prevalence of drives with short center distances and large transmission ratios, i.e., small contact angle on one pulley unless an idler is used. It is well known that V-belts operate well under such conditions. It was of interest also to find out what flat belts might do.

Well-known formulas purport to make possible an allowance for variations in contact angle. These formulas are, however, based on the assumption of dry, solid friction between belt and pulley. Actually, with fillers, impregnations, and belt dressings in general use, the friction may well be of a semi-viscous character. Tests, for instance, by Friedrich[4] in Germany and the generally accepted influence of slip on friction render this highly plausible. Under such conditions the formulas in general use are not dependable.

APPARATUS USED

Tests were performed on the 40-hp. belt dynamometer set in the laboratory of the Mechanical Engineering Department of the Ohio State University. The set is shown in Fig. 1. The letter *A* denotes a motor, cradled so as to oscillate around its axis and mounted in a frame which rolls on ball bearings on a track *B*. This motor carries the driving pulley *C*. The torque is weighed on a platform scale *D*. The total pull of the belt, the sum of the tight-side and slack-side tensions, is carried from the frame of the motor through a wire rope and a bell crank to a platform scale *E*. The driven pulley *F* is mounted on an electric dynamometer *G*. The dynamometer torque is weighed on a scale arm *H*. The speed is measured by speed counters connected by means of flexible shafts *I* and *J* to the driving and the driven shafts. On the flexible shafts are two clutch couplings operated by electromagnets in series so that the speed counters can be coupled in and out at the driving and the driven end at the same instant. In consequence, speed differences and creep or slip may be determined very accurately.

For tests on the influence of contact angle a frame *K* and an adjustable idler *L* were added to this equipment as shown in Fig. 2. By moving the idler along the frame the contact angle could be varied from 90 deg. on the driving end and about 150 deg. on the driven end to 150 deg. on the driving end and 90 deg. on the driven end. The idler was carried on ball bearings and consumed a practically negligible amount of power.

The transmissive power of the belt is expressed as effective pull and as tension ratio. The effective pull is the difference between the tight and the slack tension, $T_1 - T_2$, where T_1 is the tight tension and T_2 the slack tension. Multiplied with the belt speed and divided by 33,000 it gives the horsepower transmitted. The same effective pull, however, may be transmitted with either a tight belt or slack belt. Evidently a belt capable of running quite slack has superior transmissive power. For any given effective pull, the tight tension T_1 is comparatively small and the belt is not very highly stressed. This should be conducive to long life and but little stretch. Moreover, the bending pull on the shaft is low and the load and friction in the bearings are low. The belt gives the most favorable and economical conditions of power transmission all around.

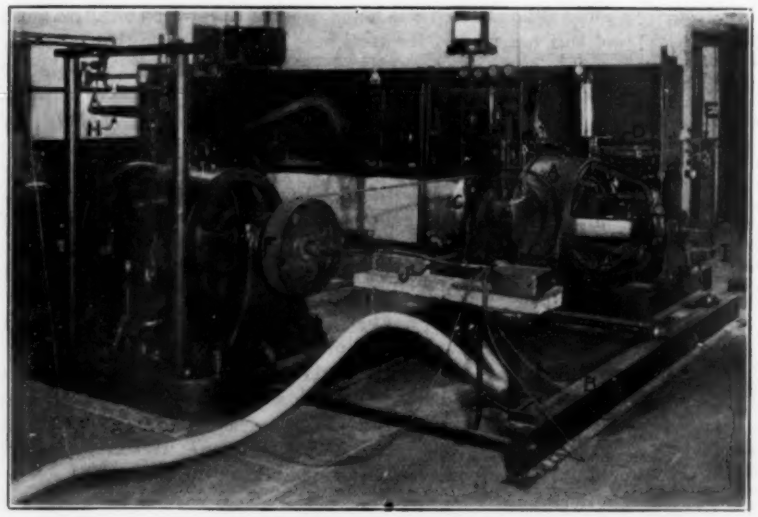

FIG. 1 40-HP. DYNAMOMETER SET

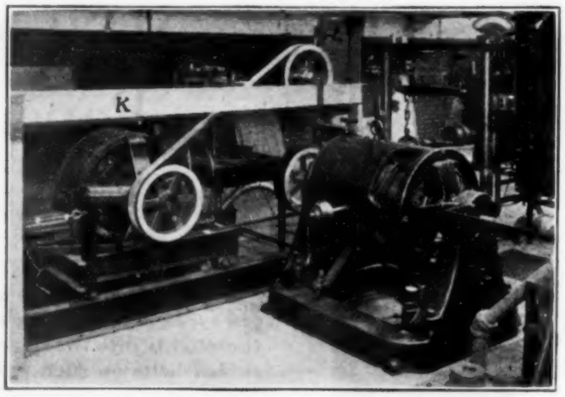

FIG. 2 DYNAMOMETER SET WITH FRAME FOR VARYING CONTACT ANGLE

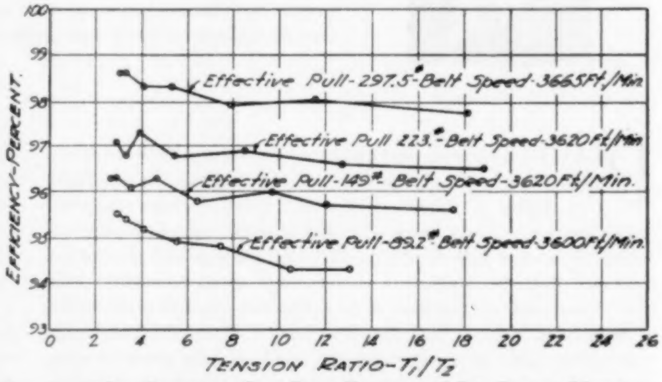

FIG. 3 18-IN. CROWNED CAST-IRON PULLEYS; 3-IN. SINGLE MINERAL-TANNED BELT; 180-DEG. CONTACT ANGLE

The best way to indicate condition of slackness seems to be by the ratio of the tight tension to the slack tension, i.e., by T_1/T_2. If T_1 is high compared with T_2, i.e., if the ratio T_1/T_2 is high, then the belt runs very slack, and if the slip is not great, it is an economical and efficient means for transmitting power. On the other hand, if T_1/T_2 is low, the belt is tight, and while it still may show a high transmission efficiency, i.e., a high ratio of output to input, yet it runs with comparatively high bearing friction, high shaft pull; it may stretch considerably and require frequent take-ups, and the life will not be as long as if it could be run slacker. For practical purposes a tension ratio of 2 may be considered indicative of a very tight belt, while a tension ratio of 10 means a quite slack belt.

To present transmissive power, tension ratio has been plotted against slip, i.e., the curves show to what degree of slackness the belt can be reduced before serious slip commences. In some cases serious slip commences suddenly; the curves break off sharply. In others the slip increases gradually. Before the belt is in danger of losing hold entirely, the slip becomes greater than can be permitted in a drive that is operating rationally.

It should be stated that the method of measuring speed has an influence on the extent to which slip readings can be carried. If speed measurements were instantaneous, one might get readings even if the belt was slipping very seriously. Revolutions were, however, counted over two minutes of time, and it was necessary to

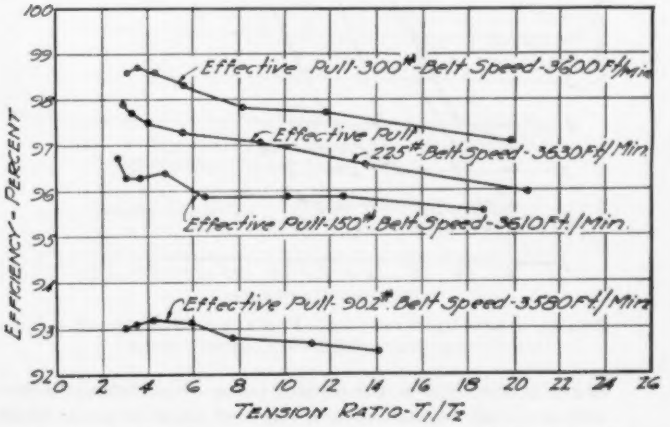

FIG. 9 18-IN. CROWNED PAPER PULLEYS *B*; 3-IN. FOUR-PLY RUBBER BELT; 180-DEG. CONTACT ANGLE maintain steady running conditions for this period. This meant that slip could not be carried to a point where the drive was not perfectly positive. An attempt was always made to get the last point on the curves as close to the point of serious slip as possible. In this connection it is well to remember that belts often behave rather erratically near the slipping point. Sometimes it is possible gradually to work up to a degree of slackness under which the belt could not possibly be started up under load, and one which could not possibly be reset after the belt has once begun to slip seriously. The final breakdown point of the drive is therefore one that cannot be stated with absolute exactness.

The ultimate points given on the curves are the last at which the observers could still get dependable torque and speed readings over two minutes of time.

Efficiency Data

The efficiency data are presented in Figs. 3 to 9, inclusive. They pertain to a mineral-tanned belt on cast-iron pulleys and to an oak-tanned belt and a rubber belt on cast-iron pulleys and on two kinds of paper pulleys, marked, respectively, *A* and *B*.[5] The leather belts were somewhat-used single belts, and the rubber belt a four-ply belt of a recent type brought out by a well-known rubber concern. All belts were 3 in. wide. All pulleys had a di-

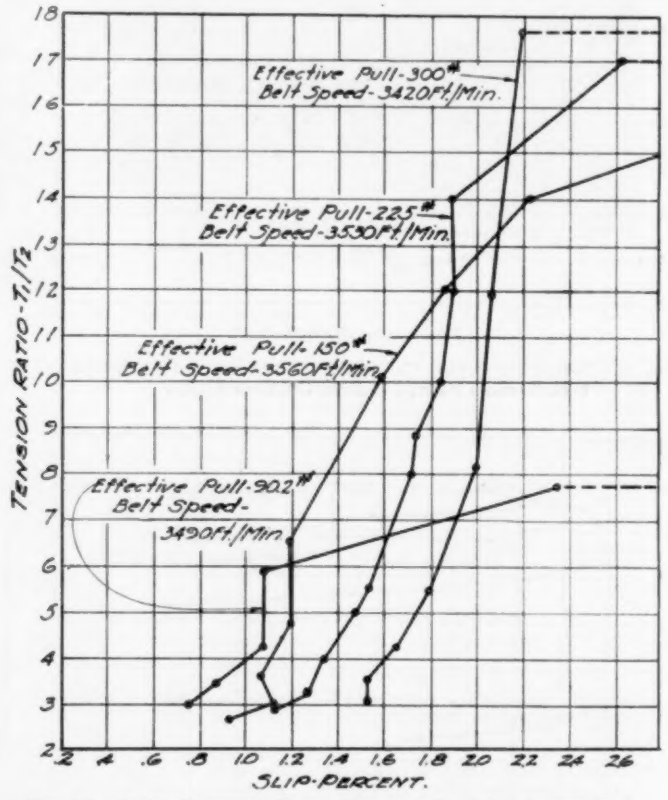

Fig. 12 18-In. Crowned Paper Pulleys *B*; 3-In. Single Oak-Tanned Belt; 180-Deg. Contact Angle

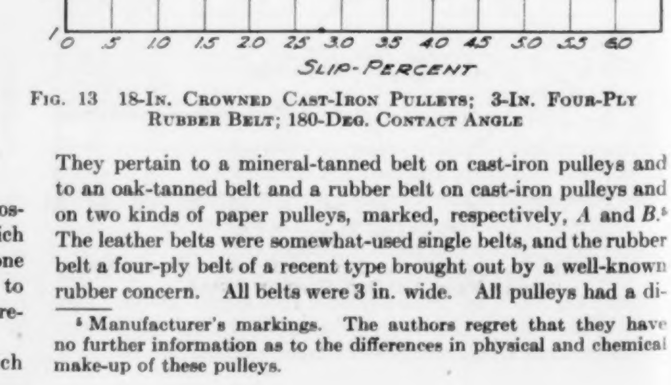

Fig. 13 18-In. Crowned Cast-Iron Pulleys; 3-In. Four-Ply Rubber Belt; 180-Deg. Contact Angle ameter of 18 in. and were crowned. The slack strand was run on top. The belt speed was approximately 3600 ft. per min. in all cases. It is given on the curves. So is likewise the effective pull. It will be seen that four different effective pulls were held. They are approximately 90, 150, 225, and 300 lb. total, or 30, 50, 75, and 100 lb. per inch of width. A normal effective pull for these belts would be about 50 lb. per inch of width. It may then be said that the loads were carried to 100 per cent overload.

---

[5] Manufacturer's markings. The authors regret that they have no further information as to the differences in physical and chemical make-up of these pulleys.

No attempt was made to smooth out the curves. The actual points obtained in any one test are simply joined together.

It will be seen that the efficiency values obtained vary but little from belt to belt. At a normal load of 50 lb. per inch of width the efficiency is about 95 or 96 per cent for all belts. As the load increases, the efficiency goes up, and reaches values around 98 per cent for 100 per cent overload. As the load drops, the efficiency drops. This is due to the fact that the power consumed in flexing the belt over the pulleys and the windage loss on belts and pulleys remain the same at all loads; consequently, these losses constitute a larger percentage of a small power input than they do of a large one. Naturally a flexible belt should show a somewhat higher efficiency than a stiff one, and this should show up particularly at light load. But to judge by the results here shown, the difference is not great on 18-in. pulleys. All told, there is little justification to discriminate between belts and between pulleys on account of differences in mechanical efficiency. All belts when rationally run and loaded are an efficient means for transmitting power. If any lesson is to be learned, it is that one should, as far as possible, avoid idling belts.

TRANSMISSIVE POWER

Data for transmissive power at 180-deg. contact angle are given in Figs. 10 to 15, inclusive. The data refer to the pulleys mentioned in the preceding section. Only oak-tanned and rubber belts are included, however.[6] On pulleys of 18-in. diameter both oak-tanned and rubber belting are shown to be capable of transmitting an effective pull of 100 lb. per inch of width, and this condition holds true on cast-iron pulleys as well as on paper pulleys. However, the degree of slackness, i.e., the tension ratios to which the belt can be carried, is much higher on paper pulleys, particularly of type *B*, than on cast-iron pulleys.

The possibility of running rubber belts at tension ratios as high as 14 to 15 should be of considerable convenience and importance. The necessity of running rubber belts tighter than leather belts on cast-iron pulleys has been held as a great drawback with rubber belting. The drawback may not be quite as serious, at least with sufficiently large contact angles, as has sometimes been stated. Nevertheless, pulleys giving a decided improvement in the tractive power of rubber belts should be welcomed.

A peculiarity shown by the tests is that with the lowest effective pull, 30 lb. per inch of width, the belts start slipping at much lower tension ratios than with higher effective pulls and do not attain nearly as high maximum ratios. The reason is to be seen in the stiffness of the belt. A low tension ratio with a very low effective pull means that there is not enough total tension to pull the belt snugly onto the pulley, the slack-side tension being very low and particularly lacking in this respect.

INFLUENCE OF CONTACT ANGLE

The results of the tests with varying contact angle are plotted in Figs. 16 to 27, inclusive. As above only oak-tanned leather belts and friction-surfaced rubber belts were used in these tests, and only two effective pulls, 50 lb. and 75 lb. per inch of width, were held. Even so, with four idler positions for each belt-pulley combination and each effective pull, the data gathered are somewhat voluminous.

The commonly used formula for connecting tension ratio with angle of contact and coefficient of friction is

$$T_1/T_2 = e^{fa}$$

where e is the basis of the natural logarithms, f the coefficient of friction, and a the contact angle.

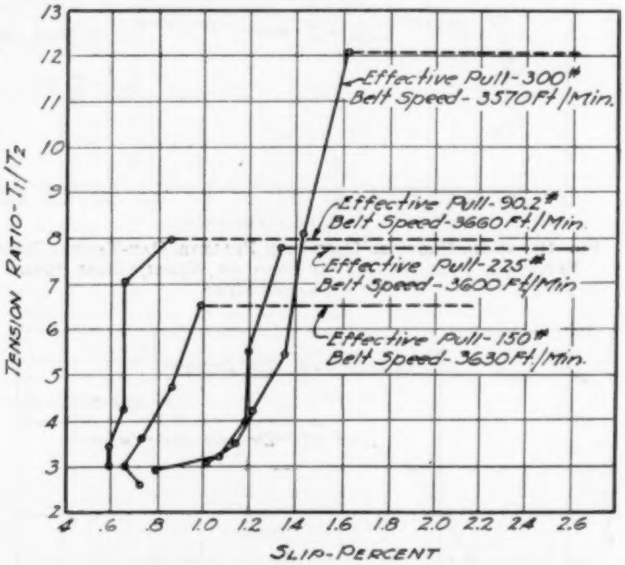

FIG. 14 18-IN. CROWNED PAPER PULLEYS *A*; 3-IN. FOUR-PLY RUBBER BELT; 180-DEG. CONTACT ANGLE

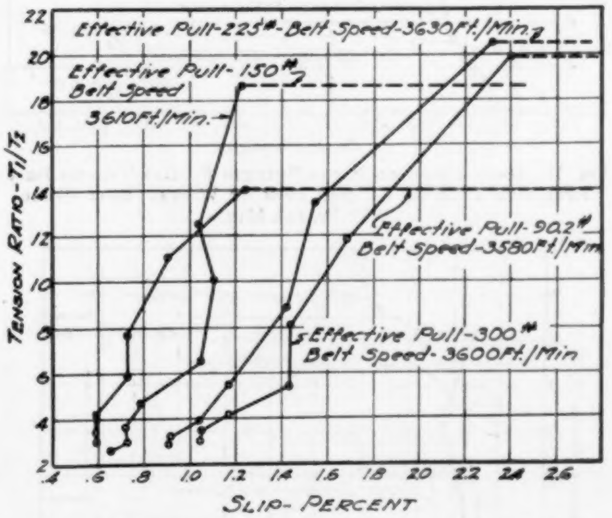

FIG. 15 18-IN. CROWNED PAPER PULLEYS *B*; 3-IN. FOUR-PLY RUBBER BELT; 180-DEG. CONTACT ANGLE

By means of this formula the coefficient of friction was figured for the maximum tension ratio obtained with 180-deg. contact angle. With the coefficient of friction so obtained, the tension ratios corresponding to angles of 140, 120, and 90 deg. were computed, and these theoretical values were plotted into the diagrams in Figs. 16 to 27 so that they can be directly compared with the experimental values obtained.

---

[6] Transmissive power of high-grade mineral-tanned belting was covered in Bulletin 41 of the Engineering Experiment Station of the Ohio State University previously referred to. It was there shown to be capable of transmitting an effective pull of 100 lb. per inch of width even on pulleys of 6 in. diameter.

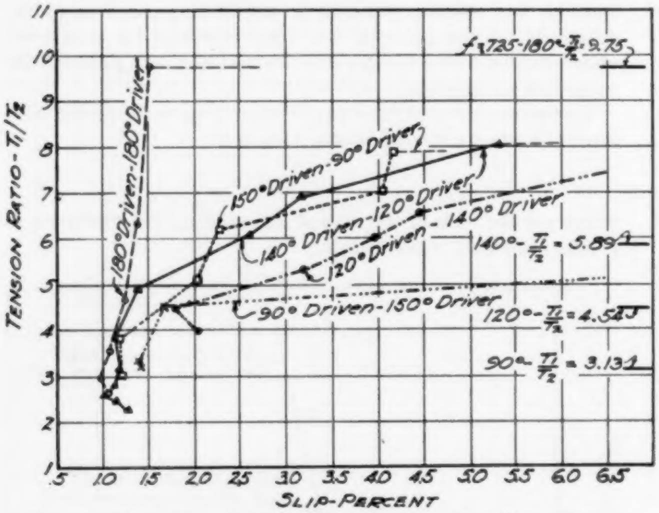

FIG. 16 18-IN. CROWNED CAST-IRON PULLEYS, OAK-TANNED BELT; EFFECTIVE PULL 50 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

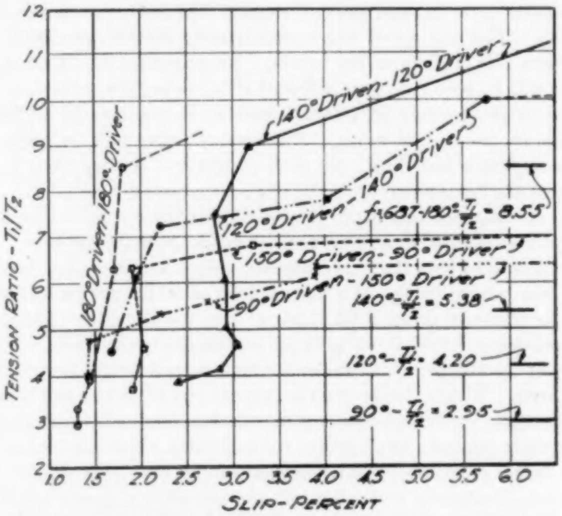

FIG. 17 18-IN. CROWNED CAST-IRON PULLEYS; OAK-TANNED BELT; EFFECTIVE PULL 75 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

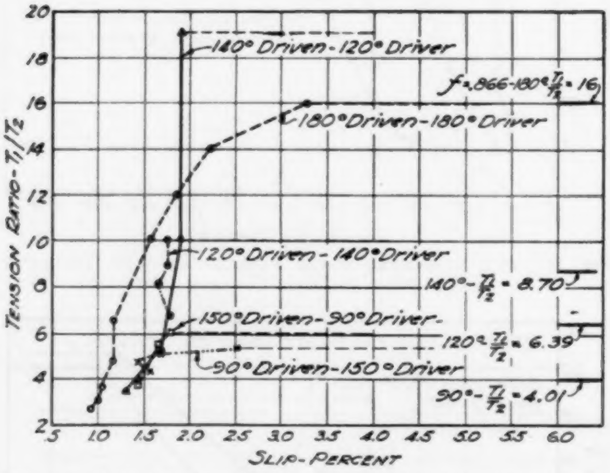

FIG. 18 18-IN. CROWNED PAPER PULLEYS *B*; OAK-TANNED BELT; EFFECTIVE PULL 50 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

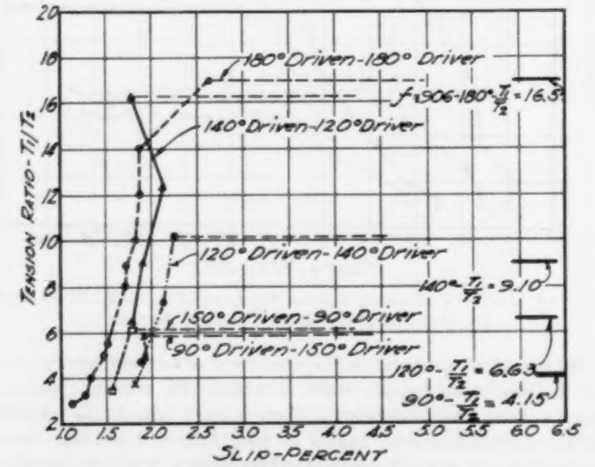

FIG. 19 18-IN. CROWNED PAPER PULLEYS *B*; OAK-TANNED BELT; EFFECTIVE PULL 75 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

Turning first to the classical combination—oak-tanned belt on cast-iron pulley—the results are given in Figs. 16 and 17. The fact is brought out very clearly that with reduced contact angle the transmissive power is as a rule improved by a certain amount of slip. The improvement is, however, quite irregular, and to be on the safe side, one should hardly assume a maximum permissible tension ratio of over 4 with an effective pull of 50 lb. per inch of width, and over 5 with 75 lb. The lower value with 50 lb. effective pull is due to the stiffness of the belt. As already explained, a certain total pull is needed to secure a sufficiently close contact between belt and pulley, and this necessary pull is a heavier charge against the lower effective pull than it is against the higher.

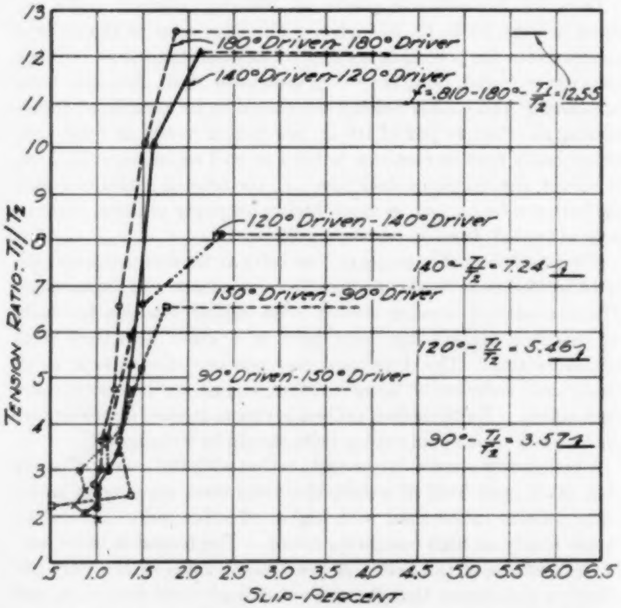

FIG. 20 18-IN. CROWNED PAPER PULLEYS *A*; OAK-TANNED BELT; EFFECTIVE PULL 50 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

The tension ratios obtained may be said to exceed those derived from the theoretical formula. However, the irregularity of the results is such that it would hardly be advisable to try to draw a curve to take the place of the theoretical relation. This is as might be expected for a belt the transmissive power of which depends in an intricate fashion on both solid and viscous friction. Particularly the latter would no doubt be influenced in a very complicated manner by temperature, humidity, slip, age, and stiffness of belt, etc. One would almost be tempted to suggest that for oak-tanned belts on cast-iron pulleys no attempt to correct for contact angle should be made at all, but that the minimum tension ratios found with 90-deg. contact angle should be made the basis for all belt calculations.

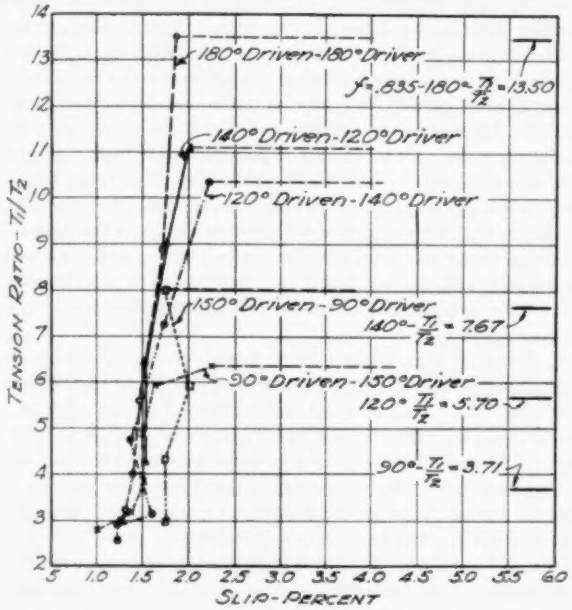

FIG. 21 18-IN. CROWNED PAPER PULLEYS *A*; OAK-TANNED BELT; EFFECTIVE PULL 75 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

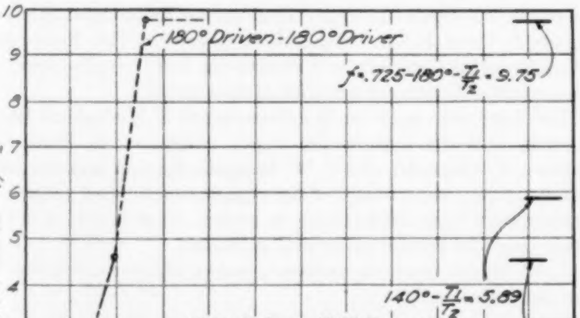

FIG. 22 18-IN. CROWNED CAST-IRON PULLEYS; RUBBER BELT; EFFECTIVE PULL 50 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

Substituting paper pulleys of type *B* for the cast-iron pulleys, a very different picture of the transmissive power of oak-tanned belting is presented. The data are given in Figs. 18 and 19. The friction coefficients with 180-deg. contact angle are higher, and there is a much more decided dropping off of transmissive power with reduced contact angle, the minimum values, however,

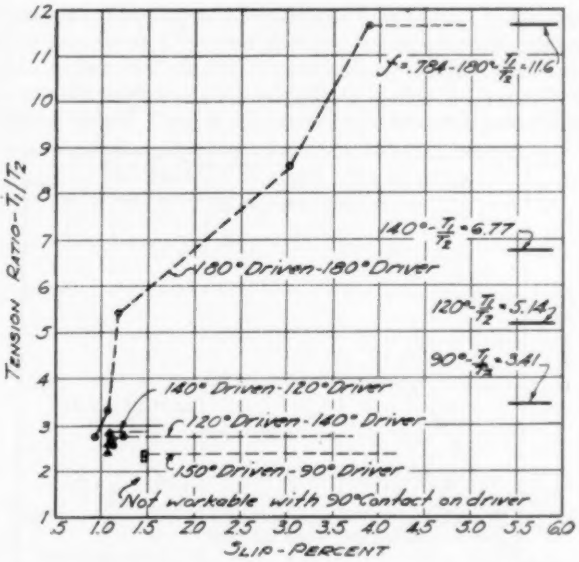

FIG. 23 18-IN. CROWNED CAST-IRON PULLEYS; RUBBER BELT; EFFECTIVE PULL 75 LB. PER INCH OF WIDTH, BELT SPEED 3800 FT. PER MIN.

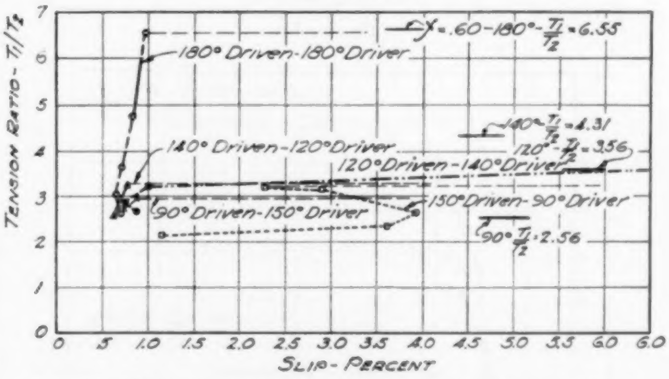

FIG. 24 18-IN. CROWNED PAPER PULLEYS *A*; RUBBER BELT; EFFECTIVE PULL 50 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

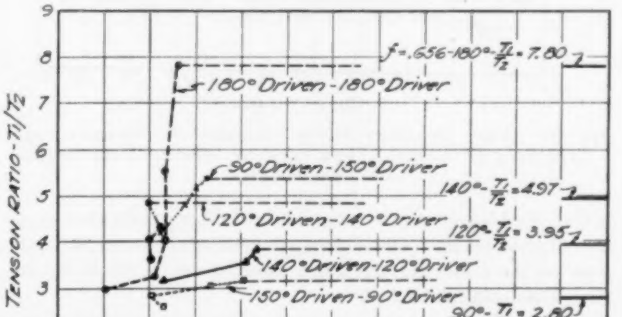

FIG. 25 18-IN. CROWNED PAPER PULLEYS *A*; RUBBER BELT; EFFECTIVE PULL 75 LB. PER INCH OF WIDTH; BELT SPEED 3650 FT. PER MIN.

remaining at least as good as with cast-iron pulleys and the intermediate values remaining decidedly better. A peculiarity is the abnormally high values obtained for both at 50 lb. and at 75 lb. effective pull per inch of width for a contact angle of 140 deg. on the driven pulley and 120 deg. on the driver. The probability is that the highest points were obtained after a somewhat excessive slip had set in. This slip may have developed a slight "tackiness" of the pulley surface, which asserted itself after the equilibrium was again established.

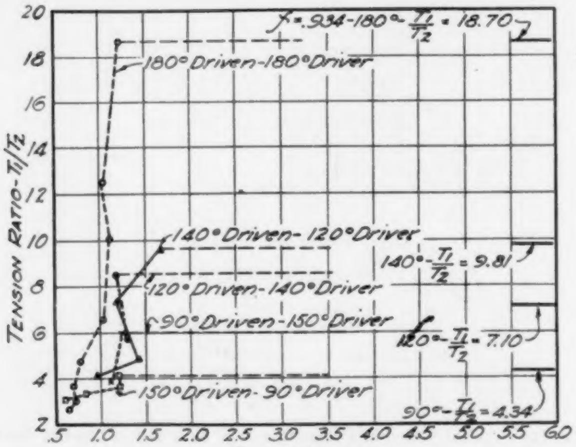

FIG. 26 18-IN. CROWNED PAPER PULLEYS *B*; RUBBER BELT; EFFECTIVE PULL 50 LB. PER INCH OF WIDTH; BELT SPEED 3770 FT. PER MIN.

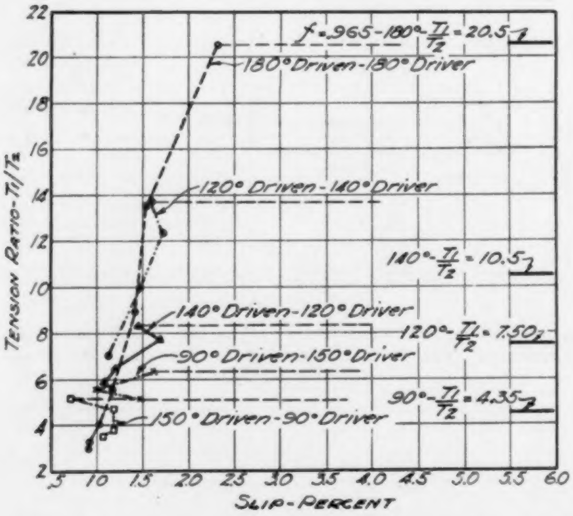

FIG. 27 18-IN. CROWNED PAPER PULLEYS *B*; RUBBER BELT; EFFECTIVE PULL 75 LB. PER INCH OF WIDTH; BELT SPEED 3900 FT. PER MIN.

A more regular behavior is displayed by paper pulleys of type *A* as shown in Figs. 20 and 21. The maximum values are not quite so high as with the type *B*, but the minimum values are as good. The actually obtained tension ratios with reduced contact angle are always higher than the theoretical ones, and the full transmissive power is developed with much less slip than with cast-iron pulleys. From the nature of the curves one would be tempted to say that neither tackiness of the pulley surface nor oiliness of the belt surface has anything to do with the favorable results obtained. In consequence, the conditions observed should be of an unvarying and dependable character.

For rubber belts on cast-iron pulleys the situation is as depicted in Figs. 22 and 23. With large contact angles, quite high transmissive powers may at times be obtained, but with reduced contact angles the transmissive power drops very seriously, and it is not much better at 120-deg. contact angle than it is at 90-deg. It should be remarked that the maximum tension ratios plotted in this graph are exceptional. They were obtained for several effective pulls in the series of tests with 180-deg. contact angle, which forms the basis of this paper. Such values were, however, not obtained in the tests published in 1928, nor were they obtained in check tests carried out late in 1930 and here published as Fig. 13. Maximum tension ratios of 4 to 5 are more likely than maximum ratios of 9 to 11. It is possible that these high ratios were brought out by stickiness caused by beginning slip. If lower ratios are used for maximum values, then the relative reduction in transmissive power with reduced angle is not so severe. However, the actual tension ratios at small angles will be no better than before, and the conclusion remains that with small angles of contact the combination of rubber belt and cast-iron pulley is not the best possible.

As shown in Figs. 24 and 25 an improvement is obtained by using paper pulleys of type *A*, particularly at fairly high effective pull (Fig. 25). However, as indicated in Figs. 26 and 27, to obtain really excellent ratios, paper pulleys of type *B* should be used. The reduction in tension ratio with reduced contact angle follows here rather closely the one derived from the formula, but even the lowest ratios are a considerable improvement over those obtained with rubber belts on cast-iron pulleys.

It would seem then that by a judicious use of paper pulleys the transmissive power both of oak-tanned and of rubber belts may be considerably improved.

ACKNOWLEDGMENTS

The investigations here presented were carried out as a project of the Ohio State University Engineering Experiment Station, of which Dean E. A. Hitchcock is director. The Rockwood Manufacturing Company, of Indianapolis, Ind., supplied some of the pulleys and defrayed a portion of the expense.

The tests were made in the Department of Mechanical Engineering, and the authors are under obligation to Professors William T. Magruder and F. W. Marquis, the past and the present chairman, respectively, of the department. They gratefully acknowledge their indebtedness to several other members of the department for helpful advice and assistance.

S. M. Marco, graduate assistant, was an efficient aid in testing and computation.

Editorial assistance has been furnished by Dr. K. Y. Tang, Department of Electrical Engineering, F. W. Marquis, and J. M. Weed, assistant director of the station.

Discussion

J. C. LINCOLN.[7] As to power transmission by belts, the speed multiplied by the difference in tension between the tight and slack sides equals the power transmitted. Consequently, the higher the belt speed the greater the power transmitted with a good allowable tension. The maximum tension which can be held with long life can be determined with reasonable accuracy, and consequently the only method of increasing the power transmitted is to increase the speed. The effect of centrifugal forces will be to decrease the pressure between the pulley and the belt, especially on a small pulley; with a given belt speed the centrifugal force decreases as the diameter of the pulley increases. Thus, at 5000 ft. per min. belt speed the centrifugal force on the

---

[7] The Lincoln Electric Company, Cleveland, Ohio.

6-in. pulley is twice as great as it is on a 12-in. pulley; consequently to transmit the maximum amount of power, the pulley sizes should be as large as possible.

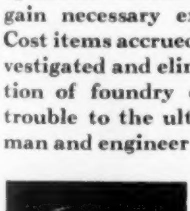
AUTHORS' CLOSURE

Mr. Lincoln is correct in stating that the centrifugal force reduces the pressure between belt and pulley. This reduction is, however, not dependent on pulley diameter, but only on belt speed. The mass of the belt on the pulley increases in direct proportion to the pulley radius, and the centrifugal force increases in direct proportion to the mass. On the other hand, the centrifugal force with unchanged mass decreases with increased radius. The two effects neutralize each other, and the formula for the centrifugal force on a belt is simply wV^2/g, where w is the weight of the belt per unit length, V the belt speed, and g the acceleration due to gravity.

Correlation of Casting Design and Foundry Practice

By ALEX TAUB,[1] DETROIT, MICH.

Correlation of design and foundry is a necessary part of any sound engineering program. However, it is quite often neglected, adversely affecting the ratio of the result per dollar. In considering the foundry the fact that individual foundry practices vary must be borne in mind. Castings are virtually assembled in the liquid state within the mold, and this principle must be borne in mind, but not overdone. Open-mindedness on the part of the designer is essential. Foundrymen must be urged to express new foundry ideas, since in new designs provision might be made to permit the use of new foundry development. Machine-made green-sand coring is a new practice being successfully used. The true bulk of a design is in the flask, not in the individual casting. Wall thickness is a general target on weight reduction. This is bad practice. Weight must be eliminated by design. The designer can help in obtaining clean castings by providing ample space for cores. Driers are a necessary evil, and the design should eliminate them wherever possible. Elimination of fins still requires development on the part of the foundry. A large proportion of foundry and engine-operation difficulties can be traced to improper determination of engine length quite often by a non-technical executive. Impatience on the part of engineers to see their designs in operation results in insufficient time for the foundry to gain necessary experience with experimental castings. Cost items accrued during productive periods should be investigated and eliminated from any new design. Elimination of foundry difficulties also means elimination of trouble to the ultimate owner. Therefore the foundryman and engineer are equally interested in the final result.



ENGINEERING and economics are quite often considered separate sciences. However, although economics is broad, standing firmly on its own feet, engineering cannot be so separated. Engineering in terms of pure research may sometimes be separated from economics, but as applied to a product engineering is merely the mechanicalizing of economics. Before a product is ready for manufacture it must include many economic considerations, the most outstanding yet most often neglected being that branch represented by the foundry. Designers have been notorious for their neglect of foundry consideration, and it is with the hope of improving these conditions that the following generalizations are presented.

The fundamental that must be borne in mind in correlating design and foundry is the universal law of "result per dollar." To meet the competitive conditions prevailing today, product change must be considered from the angle of progress. Is the change that is being contemplated an improved result? Will this result cost more than the improvement can be worth? Is it possible to obtain the desired result for the prevailing cost, or by simplification can the desired result be obtained with a lower cost?

The following considerations are in the spirit of "result per dollar." On new products or new designs consideration must be given, not only to known foundry practice, but to specific foundry practice available to the particular designer. Foundry practices vary. Some large institutions will readily consider the green-sanding of every possible part of a job, particularly if they are short of core-oven space. Other foundries that have an abundance of core-oven space will not give much consideration to green-sand coring, since they are able to produce their castings at satisfactory prices with the regular baked-sand process.

The designer must bear in mind that a casting, particularly such castings as automobile cylinder blocks, are virtually being assembled in the liquid state within the mold. The principle of liquid assembly must ever be borne in mind in the shaping of the design to insure that unnecessary projections, uneven sections, and uneconomic bulk shall be avoided.

It would seem a simple proposition, with the principle of liquid assembly in mind, to arrive at the maximum in economics if one arranges to assemble in the mold the maximum amount of material, including all brackets possible that are now being bolted on. The fallacy of this argument is obvious when one considers that quite often the inclusion of a bracket in a cylinder-block casting may easily raise the price per pound of the entire block. Increasing the price per pound of a block weighing 200 lb. becomes serious.

The price per pound of a casting is the true measure of the extent of designer-foundry correlation. The difference in cost between iron at the cupola and the cost per pound of the casting on the foundry floor is the final arbiter as to whether a job has been well done.

The designer does not always comprehend the foundry as an institution housing and using the sciences. It seems to be difficult for some engineers to get away from the idea that a foundry is a place where commercial mud-pie making is going on.

One does not expect a designer to be a foundry expert, since the foundry art is a lifetime's study. However, he is expected to know approximately how his casting should be made in order that his design may not create unnecessary cost-producing hazards. At least his design should incorporate the proper draft considerations and the fewest possible external cores.

The external cores are the first sign of design weakness. They must be tolerated where necessary, but forever remain a red-flag point to be eliminated at the first opportunity. Elimination or reduction of internal cores should be given consideration, but only with the cooperation of the particular foundry available to the designer, since, as stated earlier, an abundance of core-oven space may make the elimination of certain cores uneconomic.

---

[1] Research Engineer, Chevrolet Motor Company. Mr. Taub has been associated with the automotive industry since 1906. He was educated in England. He has been with General Motors Corporation since 1917. Mr. Taub has presented several papers before the Society of Automotive Engineers.

Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Cooperation of Departments

Open-mindedness on the part of the designer is a most important requisite. The foundryman must not only be heard and heeded, but quite often must be tempted to discuss his ideals. Perhaps a small modification might permit the development of new foundry practice. Such a practice may be awaiting just such an opportunity. The author knows of no better example of this than the recent practice of the Chevrolet foundry at Saginaw.

In Fig. 1 *a* indicates a casting used as a clutch housing. Such parts have been used in the industry for many years. At Chevrolet this design of clutch housing was preceded by a design as shown in the construction pictured in *b* Fig. 1. The casting portion of the *b* construction is obviously a simple open housing easily completely molded with green sand without the aid of any dry-sand cores. In fact, the construction is so simple that in this particular case two of these pieces were cast in one mold.

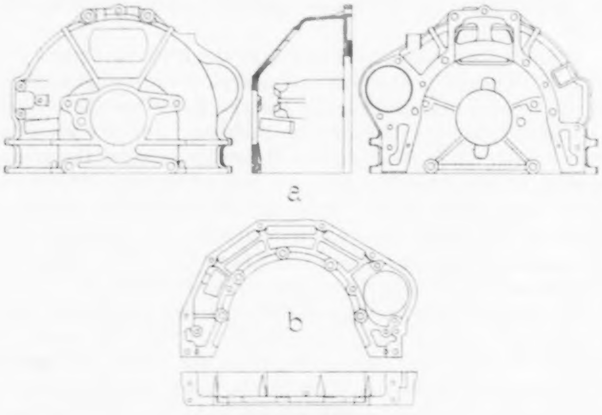


Fig. 1 Clutch Housing
(*a*, new design, requiring a housing; *b*, former design, cast two in a mold.)

When the construction was changed, it made necessary the use of a housing as at *a*. The question of cost immediately entered, since this housing was not suited to the casting of two pieces to the mold, and neither was it suited to complete green-sanding. Precedent dictated that the inside should be dry-sand cored. However, the Saginaw foundry thought differently, and advised the engineering department that if certain principles were adhered to they could completely mold this casting in green sand. Therefore the exact design as indicated was evolved—not all at once, but gradually, small changes being made continually as problem after problem confronted the foundry.

The inner mold of this piece was made of a special sand under fairly high compression, and is fitted into place within the flask without being removed from the molding machine on which it is made. The flask containing the impression of the inner back flange is then put in place, and the mold is ready for pouring. Note the direction of the various contours, the sharp corners representing the face of the mold. All of this detail was necessary to make this molding process a success. The success attained by this method has encouraged this organization to attempt its application to other and more complicated castings.

Due to the fact that the green-sand core under these circumstances is machine-located, the castings obtained by this process have been accurate and highly satisfactory. The price per pound of this casting undoubtedly was lowered considerably, due to the successful development of this method.

It must be remembered that it required the fullest cooperation and confidence of the engineering department in the foundry to complete this process. Due to the many difficulties encountered by the foundry, the project would have been put on the shelf had the engineering department objected at all to the many minor changes requested by the foundry. In fact, this is one instance where the foundry came very close to losing patience with itself before any signs of impatience had appeared in the engineering department.

In spite of the foregoing, it is well to bear in mind the over-ingenious foundryman, who will undertake to make anything. This type of individual is just as troublesome as the individual who will not cooperate. He permits his enthusiasms to carry him into the realms of impracticability, resulting in hazards for himself and unsatisfactory final cost to his customers. Designers do not realize that actual disaster may follow ill-considered designs of castings.

Recently a cylinder block that necessitated a complete dry-sand coring of the inside and outside was designed and put into production. So heinous an offense against progress could not have been perpetrated had the foundry been given any consideration or the slightest voice in the matter of design.

True Meaning of Bulk

Bulk to the designer may mean only the total size and weight of a given casting. The true bulk is the overall size of the flask necessary to make that casting. If the general dimensions of the casting are such as to require a considerable amount of waste sand, the molding equipment must be larger and therefore slower than necessary.

An example of this is shown in Fig. 2, which illustrates two types of exhaust manifold. The upper left figure and the upper right figure are, respectively, top and end views of the same manifold in the mold, and the lower left and lower right views are a redesign manifold, permitting a reduced volume of sand over that shown in the upper views. One requires a considerable amount of unused green sand in a large flask difficult to handle, therefore requiring heavier and slower equipment. The other requires considerably less sand; likewise is easier handled, and consequently lighter molding machines can be used.

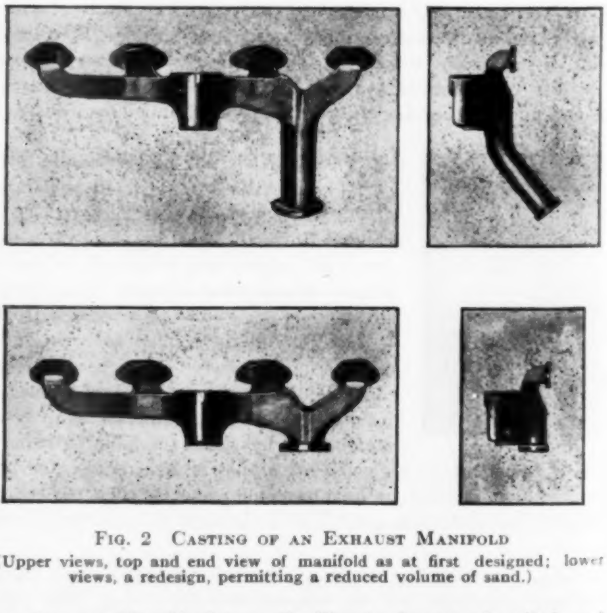

Fig. 2 Casting of an Exhaust Manifold
(Upper views, top and end view of manifold as at first designed; lower views, a redesign, permitting a reduced volume of sand.)

The principle of flask bulk should be borne in mind with every type of casting. Sometimes a projecting boss or point may require 2 in. or so additional flask, placing molding of the casting just outside the capabilities of a lighter and faster machine, thus increasing the cost burden of the final product.

IMPORTANCE OF WALL THICKNESS

Wall thickness is the haven for the designer who wishes to reduce weight; yet actually this is the one place where weight cannot be reduced unless the walls prior to change were thicker than good practice would dictate. Light walls breed every known type of foundry loss, and during the process of manufacturing quite often give trouble in handling. Further than this, light walls are the source of resonance under operation.

It has been said many times that "the more cast iron, the less brains," but it is obviously better to have 110 lb. of cast iron at 4 cents a pound than to have 100 lb. of cast iron at 5 cents a pound. The 10 lb. eliminated might be something for the engineer to be proud of, but it is nothing that the engineer can offer his customers with any degree of assurance that the customer will obtain more result for the money he is expending.

If weight is to be eliminated, it must be done by shortening walls and eliminating parts; in other words, by designing less weight into the product, using care that structure has not been impaired and that the machine shop has been interfered with in no way.

There is no casting in use today in any industry wherein walls have a more important function than in the cylinder and crankcase unit casting as used in the automotive industry. In this instance the walls are not used to cover space, but have the most important structural functions, and these walls must be thick enough to answer the purpose. They must be thick enough to be easily cast and thick enough to stand for rough handling of cleaning and fabricating.

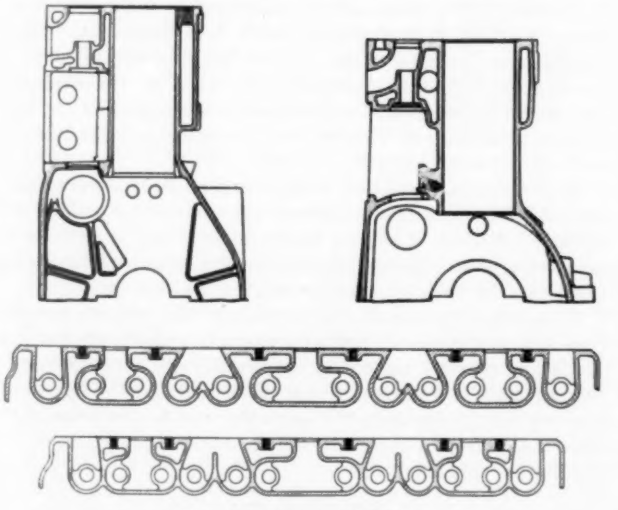

FIG. 3 CYLINDER BLOCKS
(Transverse sections at top—at left, design with little cooperation from the foundry; at right, design with fullest cooperation. Longitudinal sections at bottom—upper, good design; lower, poor design.)

CLEAN CASTINGS

The designer seldom feels that it is within his scope to aid with the matter of producing clean castings. He feels that this is the business of the foundry, and if the castings are not clean the foundry is at fault. There is no doubt that good foundry practice goes far in insuring clean castings; nevertheless, this ideal could be more easily attained if the designer would cooperate with the foundry in this matter. The foundry gives considerable thought in the method of molding to enhance this point.

Dirt has a tendency to float upward with the iron; therefore the most important part of the cylinder block is usually at the bottom of the mold when the casting is being poured. The dirt rises to an unimportant surface which is later machined, and the difficulty from dirt is more or less mitigated.

However, if core walls are very thin and small projections of sand are permitted to exist, there is always the possibility that such spots will easily wash away and the sand find a resting place in a critical location, causing the costliest kind of scrap. A cylinder block, for instance, might be almost completely machined before it is found that one of the bore walls is loaded with sand.

In considering sand cores and green-sand impressions, one should visualize a torrent of boiling iron rushing through this mold, which torrent has weight and therefore pressure, sufficient to break off corners and projections. One should consider where cores are thin and that there is molten iron on both sides of this thin piece of sand, and therefore there is a possibility of burning through. This may come in a spot not easily detected until the casting has been manufactured and delivered into the hands of a customer, who will be constantly annoyed by the recurrence of, perhaps, heating troubles that will baffle even a willing service station.

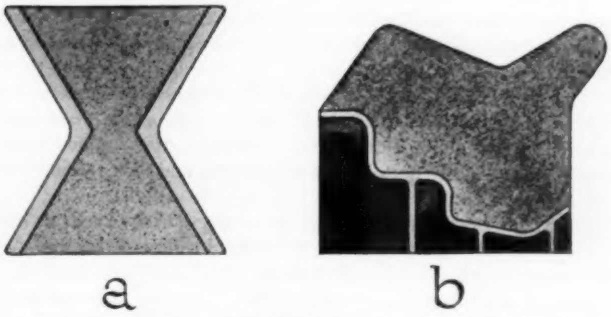

FIG. 4 UNSUPPORTED DESIGN THAT CANNOT BE MOVED
(*a*, hour-glass shape, with narrow neck that cannot support the upper body of sand; *b*, design with no supporting surface.)

Fig. 3 shows various critical sections of cylinder blocks. Good and poor designs are indicated in the longitudinal sections. Generosity at this location means the difference between good and poor operating engines and trouble or no trouble in the foundry. The transverse sections through the blocks indicate one design made with very little collaboration on the part of the foundry and the other design made with the fullest collaboration.

The cylinder block as indicated with the generous water space is still being used and is being produced in large quantities, whereas the other block has gone the way of many faulty designs and is no longer being produced.

Small water-jacket core holes may not appear small on the design, but when the designer considers the fact that supporting wires may be at the center of these small cores, then he will realize that his space is indeed small. The fundamental to bear in mind is that the size of the core must always be such as to insure the designer that space will always exist.

DRIERS FOR THE SAND

In the core making itself, the designer must be made to realize that a dry-sand core, though in itself capable of sustaining its own weight without bending, is baked into this condition, and before baking it is a loose, soft, oily pile of sand. Core-sand mixtures are such as to permit almost unbelievable overhanging of the sand. Nevertheless, there are limits to which wet core sand can be piled up and carried from bench to oven.

An obviously impossible design to produce and carry around unsupported would be an hour glass, such as shown in Fig. 4 at *a*. Evidently the narrow center neck cannot support the upper body of sand. Further, it is clearly impossible to carry a pile of wet sand that has been squeezed into the shape as shown in Fig. 4 at *b*. This shape allows no supporting surface to permit carrying from bench to oven.

Automotive foundries are asked to make cores of this type every day, and do so. However, it requires additional equipment in the form of driers, which are usually castings with the necessary impressions that are left in the wet sand until it is baked and hard enough to permit withdrawal. Driers are a necessary evil and can never be considered otherwise, and wherever possible the efforts of the designer and the foundryman should be directed toward their elimination.

Mobility for change has become an industrial necessity. All large organizations have learned that it is necessary that they be able to follow the trend by changes as quickly and as readily as possible.

With a casting which is being produced in large quantities, necessitating a considerable number of driers, engineering changes become tremendously expensive, and even minor changes become important.

Recently a minor change was made in the water jacket of a cylinder head. The changes in the pattern equipment were simple enough and not expensive. However, this simple change scrapped the driers used in this equipment, and this necessitated an expense of $25,000.

In the automotive industry the water-jacket cores in the cylinder block represent the most fruitful source of trouble and expense. Here one may find driers in abundance, small core sections, and every known evil of the foundry. This condition applies more particularly to the L-head type of cylinder block.

The overhead-valve water-jacket core is simple, and, as is the case with the present Chevrolet six-cylinder engine, with the proper design-foundry cooperation, can be made in one piece, thus positively eliminating fins from within the block casting.

Fins Are Troublesome

One of the most troublesome by-products of the foundry is the fin, particularly when these fins locate themselves in critical water passages, obstructing circulation. There is very little that a designer can do to obviate this nuisance, with the exception of providing ample space so that fins may not bridge across.

For the elimination of this evil the designer must rely mostly upon the skill and knowledge of his foundry associates. Fins usually occur where two dry-sand cores are pasted together, the iron penetrating the split, burning away the supposedly adequate seal. This is one point in foundry development that has been slow, and a point that is worthy of more serious consideration. Improvement in sealing of split cores would undoubtedly prolong engine-valve life.

Of course, the root of this evil is inadequate core or water space brought about mainly because engine length is quite often determined by front-office executives who know little of engine fundamentals, yet do not hesitate to state how long a given engine must be. The engineer endeavors to fit his engine length to the space allotted. Wheelbase having been placed upon a sacred pedestal and body space being a sales argument, there appears to be nothing to do but to crowd the engine.

Obviously, the only possible space within the engine itself that can be absorbed is core space, particularly since on the drawing board this core space is just space. The engineer quite often overlooks the fact that this space must first be sand and later water.

It has been said by an eminent radiator engineer that "One inch of wheelbase would cure most of our engine troubles, including the troubles of manufacturing and the foundry," and this is undoubtedly true. Wheelbase during the last three years, and even to the present, is being increased 3 to 4 inches at a time, for appearance or for competitive reasons. Yet there are few executives who would not condemn the engineer who had the temerity to request an inch more of wheelbase to permit the building of a better engine through the provision of an improved core space. It is certain that when executives realize that the fundamentals of engine success are irrevocably tied up with adequate core space, new progress will be made with foundry problems.

Overcoming Engineering Impatience

To obtain the fullest benefits of design-foundry cooperation, it is first necessary to overcome engineering impatience. Too often an engineer who has given every possible consideration to his foundry problems in his design considers his job done. He immediately hounds the foundry for sample castings overnight. These castings are quickly machined and converted into an experimental unit for development work.

This is a great mistake. First, the foundryman has not been given sufficient time to review the feasibility of the suggestions that they may wish to have incorporated in the casting. Further, they have had no opportunity to check even near-production methods for obtaining the casting. If the casting incorporates practice that is new to the particular foundry, they have not gained any experience that may serve at a later date when they are called on to determine how the product can be profitably produced.

It is important that the foundry be given opportunity to make a sufficient number of castings. This permits them to determine its peculiarities, so that castings submitted to the experimental department at least represent their best judgment. These castings should not be machined, but should be cut up, and the sections very carefully analyzed. In this way the engineers can determine whether wall thicknesses are as desired in their various locations and whether the core space and the internal contours are what they really expected.

Quite often such analysis brings out the fact that cores have shifted. This may be due to methods adopted for making the castings. Perhaps it may be due to faulty design of patterns or core boxes, or an important foundry fundamental may have been overlooked by both the engineer and the foundryman.

A careful going-over of such castings by the engineer and the foundryman together will bring the engineer nearer to the foundry ideals and create a respect in the foundryman's mind for engineering ideals. When a casting is cut up and found to be perfect in every way, a duplicate of this casting can be machined, with some assurance that the results obtained therefrom will represent the future product.

Cost Barnacles

In spite of the greatest care on the part of both engineer and foundryman, cost barnacles are bound to be found clinging to the ship of progress of castings. These cost barnacles are created by the things that have been overlooked and by changes made during the productive period. Unfortunately, a new crop of cost barnacles will find their way into the new product during its productive period. For that reason alone, the foundry is entitled to be rid of the old difficulties.

A most healthy practice for any engineering organization is to go through the foundry practice of the past product, isolating the various annoyances met with during the year and carefully eliminating them from the new product.

True progress can be measured only by tangible results that can be handed to the customer in the form of freedom from difficulty, increased life, quietness, or smoothness. We are too quick to congratulate ourselves for making a casting shorter or "getting by" with smaller core space, due to some clever trick on the part of the foundry. However, one cannot sell these things to a customer. It means nothing to a man who drives an automobile that his cylinder block is one-half inch shorter than it might be. It means even less if the core spaces are smaller than necessary. It is interesting to note, in the final analysis, that elimination of foundry difficulties means greater satisfaction to the ultimate owner.

The foundryman and the engineer are equally interested in the final results of their joint product. Alone their scope is limited; united their progress will be continuous.

Discussion

F. A. Melmoth.[2] While referring specifically to cast iron, the author's comments could with equal accuracy be applied to the steel branch of the founding industry—perhaps even with greater value, as higher temperatures and greater shrinkages being common to steel castings, the call for designer consideration and cooperation is even more imperative.

The author's statement, "Designers have been notorious for their neglect of foundry consideration," is unfortunately true, and in the opinion of the writer is due almost entirely to the fact that few designers have been given the opportunity to familiarize themselves with the fundamentals of foundry practice and do not possess a working knowledge of the solidification problems associated with the metal in which they are designing. In other words, the designer is likely to be merely one of form and shape, intent upon the evolution of a part to perform some mechanical requirement or to transmit so much power effectively, regardless of the fact that his conclusions are theoretical only until his design is available in a solid form in the metal required. The least result of such an attitude may be increased cost of production, owing to difficulty in the foundry. The most dangerous possible result is that the part, produced by an over-optimistic foundryman, may not be able to exhibit, even approximately, the theoretical strength values on which it was designed, owing to localized weaknesses arising out of unconsidered solidification factors due to design.

A sentence that is striking and apt is, "The designer does not always comprehend the foundry as an institution housing and using the sciences." Foundries as an industrial body are not good advertisers. They do not with sufficient insistence bring before the engineering industry as a whole the fact that the industry of metal casting is making a determined effort to utilize modern scientific knowledge applicable to its own product. Research to produce better steel castings and better malleable and gray-iron castings, not to speak of the multitude of non-ferrous products, is steadily going on within the industry. It is realized that to produce a representative casting of any design we must understand the constitution and behavior of the metal going to make it. Foundries are no longer dirty ramshackle places, content to be looked upon as more or less necessary evils, or the Cinderellas of the metal trades. They are literally becoming homes of practical applied science. But unless that applied science of the metals involved is also permitted to exert its influence on design, much of its effect is lost, and progress must be retarded.

The following quotation from the paper is also important, "Wall thickness is the haven for the designer who wishes to reduce weight." The development of alloy steels in the steel foundry is materially affected by this mental attitude. We know that at very small increased cost many steel castings can be made with greatly improved physical properties, by means of alloy additions allied to adequate heat treatment. Such steels are rarely more fluid than plain carbon steels, very often distinctly the opposite, at a given temperature. They are not less affected by liquid and solid shrinkage—again rather otherwise. Indiscriminate reduction of wall thickness, therefore, increases the hazard of production out of all reason, causes an increased likelihood of defects, and entirely prohibits the casting from manifesting that increased service value indicated by its higher cost per pound.

When castings are designed as castings, by men whose training involves an intimate familiarity with all that fundamentally goes to make a casting, they will quickly occupy their real place in the engineering industry, being produced more cheaply and without that degree of hazard which is the bane of the casting industry.

Finally, engineers might ponder the fact that were it not for design in the shape of the ingot, it would be impossible to produce a satisfactory steel forging. How much more so, then, does design affect the foundry, where an individual casting may and does contain a conglomerate of varying sections and contours, outside the control of the foundry, but defying every natural law of metal solidification if complete soundness is expected?

E. R. Glenn.[3] The author has covered the subject admirably for a plant having its own foundry. However, there are many plants requiring castings which are purchased from a jobbing factory. Our plant uses many carloads per year of light gray and malleable iron castings purchased from outside foundries.

We are also confronted with the problem of designing parts for the most efficient handling in the foundry. In many cases the engineering department can proceed on the basis of past performance where new designs are practically a duplication of other designs now in use. In other cases we submit either the drawing or an experimental pattern to the foundry for criticism. We find the foundries eager to assist us along this line.

One problem that we have periodically is in changing foundries and finding that our equipment does not meet with the approval of the new foundry, which may request changes in methods of gating, coring, etc. The fact that different foundries have different thoughts and requirements is one we cannot alter and must consider when we make a change.

Many of our castings are not machined and must fit to each other or to steel parts. We therefore must consider an allowance for rapping, swelling, core shrinkage, etc., requiring on the part of the engineering department a knowledge of foundry practice, inasmuch as it concerns what must be allowed in such cases.

In our plant the pattern shop is under the supervision of the engineering department. Close cooperation is possible in the making of the pattern as the engineering department and the foundry want it. Where such a connection between the engineering department and pattern shop is possible, it will be found to be most profitable.

At every opportunity the writer visits the foundries and spends some time with the foundry officials talking over foundry problems and checking on the latest developments in foundry practice. This not only keeps the department up to date on foundry practice, but makes for ideal cooperation of engineering department and foundry.

Mr. Schwartz.[4] The writer wishes to expand one of the ideas which the author presents in what appears to be in incomplete form. This is that "the price per pound of casting is the true measure of the extent of designer-foundry correlation."

It is the writer's conception that the object of correlation of design and production is not to produce a given article at the lowest pound price, but rather to produce an object of certain required properties for the least overall cost in the form in which it finds its final application. Thus the best cooperation in the manufacture of a cylinder block will have been secured when the cheapest cylinder block in its machined state and of acceptable quality is available for delivery.

[3] In Charge of Engineering, S. L. Allen & Co. Inc., Philadelphia, Pa. Assoc-Mem. A.S.M.E.

[4] American Foundrymen's Association, Chicago, Ill.

In the design of any cast part there are in general two subjects to be considered, both equally important—the physical characteristics of the metal out of which the object is to be made and the amount and disposition of this metal in the object. It is quite generally true that, in changing from one cast metal to another or from one grade of a given cast metal to another, foundry conditions change sufficiently so that changes of design may be imperative.

The material is usually selected from the viewpoint of certain known physical properties. Frequently the suitability of a material for a given purpose involves the selection of several physical properties which may be incompatible; for example, high strength and high ductility or shock resistance in the same steel castings may be attainable only by unusual alloys or heat treatments. In the case of malleable iron high machinability is desired in order to minimize fabrication costs, and yet certain minima of strength or ductility may be requisite to make the castings adequate for their intended use. Many metallurgists hold that machinability and strength are contradictory and that in such cases a suitable compromise must be made. Instances exist where for foundry reasons a sufficient decrease in cross-section to take advantage of an increased strength for a changed material is impracticable, and it may therefore happen that the substitution of a stronger material is of no merit since it involves no corresponding decrease in weight.

Again there are instances in which the substitution of a more expensive light metal for a denser cheap metal is practicable under circumstances where the accompanying reduction in strength is of no consequence or, as may perhaps be less generally true, the light metal will produce an equally strong object of a lessened weight sufficient to make up the difference in cost.

Apparently accurate data have been shown the writer by others tending to prove that of two grades of the same material the one of the stronger ultimate strength may not produce the stronger casting; this under conditions where the use of the stronger material involves increased foundry faults.

In conclusion the writer would urge that consultation with the foundry should always be had before the design has approached completion. It quite frequently happens that after the designer has determined upon details in themselves unimportant, it proves impossible to change these details on account of tool conditions or on account of assembly with other parts. If the foundry engineer be given an opportunity to advise regarding the design of a casting while these unimportant details are not yet fixed by such considerations as these, he will be in a much better condition to decrease the ultimate cost of the part in question.

Max Sklovsky.[5] Our experience has indicated that it is difficult to obtain constructive criticisms from operating foremen on matters of design prior to the completion of the design. Usually it has been found that the foremen hesitate to offer opinions, as they are uncertain as to whether they fully understand the designs, even if they are certain of the difficulties that may be experienced in production of the specifically designed patterns. Also there has been observed an unwillingness to take the responsibility for criticisms and an unwillingness to offer suggestions for corrections that would imply a final responsibility for manufacturing methods. Consulting on the part of designers on this basis has not therefore been totally satisfactory.

Another plan which was adopted a few years ago has proved highly satisfactory—namely, the plan of assigning to the designing department a man from the production department to act as consultant to the designers. Such a man, having in mind the available methods and knowing the specific difficulties, constantly reviews designs and advises of difficulties that may be expected in production in carrying out specific designs. The individual so assigned is responsible directly to the production manager and is kept on the payroll of the production department. This plan has worked out with eminent success and has removed considerable friction and the bulk of the difficulties that had been encountered.

It has been found that when such an individual is part of the designing department and on the payroll of that department, he is likely to be shifted to work, when emergency arises, other than that of consultant as to manufacturing methods. With such an individual acting solely as a representative of the production department, there is no object to utilize him to serve otherwise in the designing department and remove him from the chief function for which he has been appointed.

J. H. Lansing.[6] The author has made a valuable contribution to the correlating of casting design and foundry practice. His illustrations are of decided interest and well develop the points made.

Of comparable interest to engineers in the automotive and many other industries is the correlation of casting design and foundry practice in the case of malleable-iron castings. The writer will venture to outline some considerations involved in malleable-iron-casting design.

The writer does not wish to stress the problems of any individual foundry, so will not therefore consider this subject from the standpoint of foundry equipment, available core capacity, etc., but rather from the standpoint of producing the most satisfactory castings in the most economical manner, assuming, as the great majority of designers must, that the customary foundry equipment and facilities will be available in the foundry which is to produce their malleable-iron castings.

He wishes also to caution against unqualified application of the statement that "the price per pound of a casting is the true measure of the extent of designer-foundry correlation." Although in many cases this is true, there are also many instances where, by designer-foundry correlation, the weight of a casting may be so decreased that a higher price per pound is involved, at the same time decreasing the cost per casting or part and increasing its adaptability for the required purpose.

To follow the application of some of the recommendations which will be outlined, one must appreciate some few of the characteristics of the subject material. Malleable iron, in the preliminary white-iron form, may be cast in intricate shapes and within such close limits as to reduce machining to a minimum. It is nevertheless subject to contraction strains, which are harmful only when sufficiently severe to cause the casting to crack in the hard state, and therefore to be scrapped in the foundry. The more severe strains may be eliminated by proper design, and the less severe ones, as stated, are of no importance, due to the fact that, in the normal process of manufacture, the castings are heated to a high temperature, held there for a sufficient period of time, and slowly cooled, entirely eliminating all casting strains and producing a refined grain structure. The resultant malleable-iron castings are composed entirely of ferrite containing nodules of temper carbon, and therefore machine with the greatest ease of any ferrous product. Good-quality malleable castings have an average elongation of approximately 20 per cent, yield point of 36,000 lb., and utimate strength of 54,000 lb. per sq. in.

---

[5] Chief Engineer, Deere & Co., Moline, Ill. Mem. A.S.M.E.

[6] Works Manager, Danville Malleable Iron Division, Allith-Prouty Company, Danville, Ill.

In connection with some work for the American Foundrymen's Association and the Malleable Iron Research Institute, the writer has been working on the revision of "Recommendations to Designers of Malleable Iron Castings." Members of the former organization originated the rough primary draft of these recommendations, some having already appeared in the symposium presented at the A.F.A. and A.S.T.M. joint meeting in June, and several members of the Malleable Iron Research Institute have collaborated in the revision and clarification. Although their present form may not necessarily be considered final, they may well be outlined at this time to indicate factors worthy of consideration in the designing of malleable castings. The present draft is as follows:

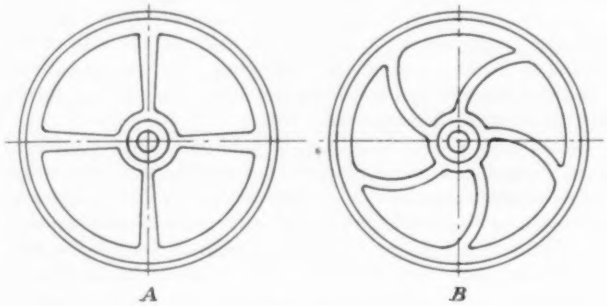

FIG. 5

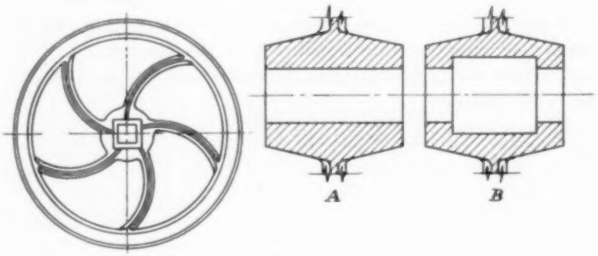

FIG. 6

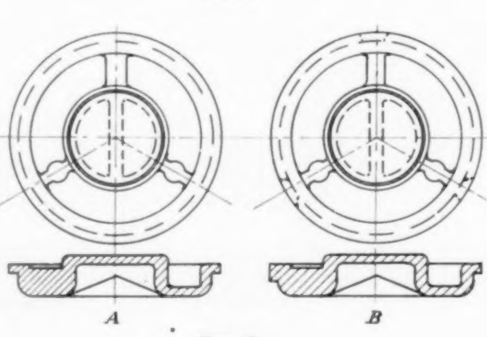

FIG. 7

1 To avoid unnecessary expense and delay, submit tentative designs to your malleable foundry for suggestions as to possible changes which, while not affecting utility, will aid in producing better and less expensive casting.

2 Thickness of casting should be as near uniform as possible, avoiding abrupt changes in section. Where it is necessary to vary metal from light to heavy sections, a gradual taper of the joint makes for greater economy in production and for greater strength. If this is impracticable, ribs of sufficient thickness to facilitate feeding may be placed on the light sections so as to connect with and feed into the heavy section or boss.

3 Where heavy sections such as bosses or lugs are located on the interior, it is desirable to have heavy sections of metal leading to feeding source.

4 The location and size of ribs should be such that they can be fed, or, if connecting light and heavy sections, they should be of such thickness that they can be used to feed metal through into the heavy parts.

5 Provision should be made of suitable place for attaching gates and feeders to heavy sections.

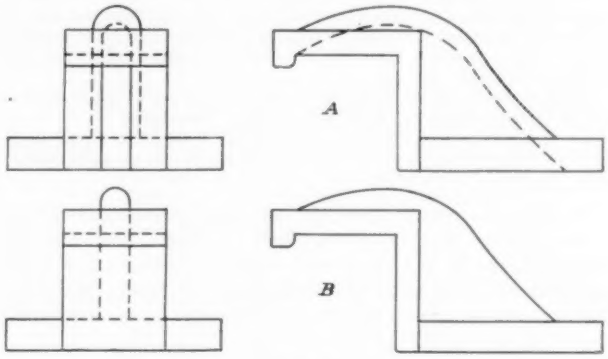

FIG. 8

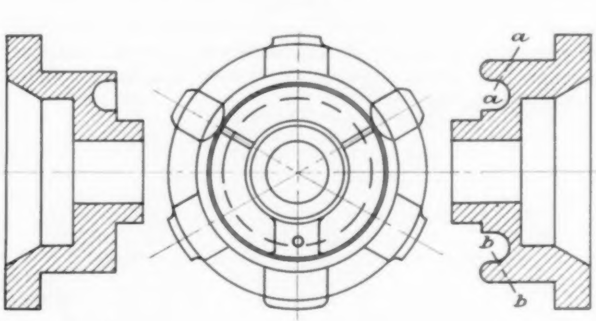

FIG. 9

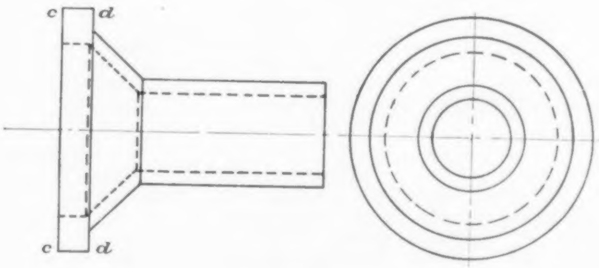

FIG. 10

6 Use as large fillets as possible and avoid the use of reentrant angles. The reasons for rounded corners and large fillets are (1) easier molding, (2) less scrap from shrinkage and cracks, and (3) less danger of cutting away of sand by flowing iron.

7 Where possible, avoid use of dry-sand cores, thus eliminating core-making expense and producing a cleaner casting.

8 Use ram-up cores in preference to set cores where practicable.

9 Parting lines should be as near even as possible.

10 Designs should provide ample draft for easy molding.

11 Try to avoid all deep pockets and small recesses that would complicate drawing the pattern or lifting the cope.

12 Sufficient finish allowance should be given when castings are to be machined, and the amount of such finish should be indicated. For small parts $^{1}/_{16}$-in. finish is satisfactory, with larger parts requiring a proportionately greater allowance. In determining the necessary amount of finish, factors to be considered are (a) size

of casting, (*b*) whether a heavy-sectioned compact casting or a large light-sectioned casting, the latter having of course greater tendency to warp, (*c*) whether part will be made in sufficiently large production quantities to justify the making of straightening dies, (*d*) the fact that many finishing operations on malleable castings can be performed in a coining press which practically eliminates finish allowance in the case of these particular operations.

13 Locating points should be held to one side of the parting to eliminate trouble in machining.

14 Dimensions which have no finish allowance and are to be held to very close limits should be considered as the proper place from which to start development of tooling fixtures.

15 When castings are to be machined, the blueprints sent to the patternmaker should always show machine-shop locating points. If these are not shown, the patternmaker will either not consider these points or may assume them to be other than those which will be used in machining the part.

16 For economical production, dimensions of castings should not be held to closer tolerance limits than is necessary.

17 If there is an opportunity to choose between a single large light-weight intricate casting and an assembly of two or more smaller ones, the latter is preferable.

To illustrate some of these points, several instances are given:

Item 1. A 20-in.-diameter, 70-lb. casting. (See Fig. 5.) This is a redesign of a shop truck wheel, showing in *B* a spoke arrangement eliminating the probability of cracks and high foundry loss inherent in the diametrically opposed straight spokes shown in *A*.

Item 2. A 15-in.-diameter, 11-lb. casting. (See Fig. 6.) Design *B* affords greater uniformity of section than design *A*, particularly when its section is considered in relation to the lighter section of spokes of the hand-brake wheel. This permits more uniform cooling of metal, thereby reducing possibility of shrinkage cracks.

Item 5. An 8-in.-diameter, 4-lb. casting. (See Fig. 7.) Part *B* illustrates the addition of a small amount of stock at points where heavy bosses join the thin flange, thus making it possible to attach a sufficiently heavy gate or feeder to produce a sound casting. This part is a spare-wheel carrier plate.

Item 7. A 5-lb. casting. (See Fig. 8.) Part *B* illustrates the elimination of the unnecessary core shown in the hatch-batten cleat *A*, also simplifying the molding.

Item 11. A 4-in.-diameter, $3^{3}/_{4}$-lb. casting. (See Fig. 9.) By removing the metal projecting into the cope above *a–a* and *b–b*, the lifting of the cope is greatly simplified or a ram-up core is eliminated. This is a differential-case casting.

Item 13. A $4^{1}/_{2}$-in.-diameter, 3-lb. casting. (See Fig. 10.) Locating points should if possible be held on one side of the parting to eliminate trouble in machining. In the case of this transmission-drive pinion-bearing retainer, the parting should be at *c–c* rather than at *d–d*.

In outlining factors that may be advantageously considered when designing parts to be cast in malleable iron, the writer wishes to discourage no one in the specification of this material by reason of any feeling that the part under consideration is one that will not adapt itself to a design in accordance with recommendations which have been listed. Malleable-iron foundrymen are as resourceful as any and will produce excellent castings for parts where it may be impossible to follow much of the recommended practice in design. The purpose has therefore been to cover certain factors which, when possible for the designer to consider them, will aid in the production of the most satisfactory castings from the standpoint of quality, service, and economy.

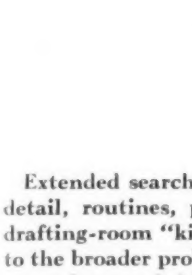
Machine-Design Management

By J. L. ALDEN,[1] CHICAGO, ILL.

Extended search reveals many papers on drawing-room detail, routines, printed forms used in drafting rooms, drafting-room "kinks," etc., but almost nothing relating to the broader problems of management which the design supervisor and his superiors must face. The present paper is a discussion of design-management practices, and is an attempt to record such of these practices as concern the Hawthorne Machine-Design Division of the Western Electric Company, Inc. The author's views are influenced largely by the past and present problems confronting him. Many of these, doubtless, are peculiar to the Western Electric Company.



THE TERM "management" implies control of expenditures, personnel, and technical practices, and, as used in this paper, it must be interpreted in the light of the ultimate purpose of machine-design organizations: namely, to design the best possible machine for the least possible design cost. The "best possible machine" is one in which that economic balance is reached between first cost, operating cost, maintenance cost, etc., which results in the lowest overall cost of the manufactured product consistent with the required quality level of that product. Proper management is the brand of control which achieves these things by orderly constructive thinking and planning.

How can such a brand of management be displayed in connection with machine-design work? To answer this question, management requirements of a design organization will be discussed.

There is no more important duty of management than the selection of capable supervisory personnel. Any machine-design management system, no matter how well chosen, will not be successful unless the men administering it have the proper managerial and technical qualifications. While the higher ranking executives lay down the broad policies of control, the execution of these policies is in the hands of the immediate supervisors, who, if poorly selected, can nullify the best efforts of their superiors. A large part of the successful administration of a sizable machine-design organization depends upon the character of the engineering executive in charge. In the Western Electric Company, this man is ranked as a development engineer. The payroll under his control is as large as the total payroll of many substantial businesses. The annual construction cost of machinery built, in normal times, from his designs is several millions of dollars. Therefore it is obvious that the first requirement for such a division chief is that he be an orderly thinker with sound business sense. Engineering ability and experience are necessary, but it is absolutely essential that he have the ability satisfactorily to take care of the business phases of his job. The division chief who is too close to detail, who is more interested in the size of the shaft than in the relation between payroll and output, lacks the necessary management viewpoint. Since this man must execute the management's policies it is essential that he think in terms of management rather than in terms of machinery and design. With the proper viewpoint at the head of the design organization, changes in policies and methods or even drastic reorganizations are effected with the minimum of trouble. The general supervisor of a large group must necessarily guide his organization by the use of reports and statistical data. It is not possible for him to be in close touch with detail or personally to judge the work of individual designers. He must make decisions based on the reports of others and must evaluate these reports in the light of his knowledge of the individuals reporting. He must, therefore, be continually checking, cross-checking, questioning, and employing that sense of skepticism which is necessary for all supervisors remote from the details of their jobs.

The first-line supervisors, department chiefs, and squad leaders must be skilled designers and engineers, and must be well equipped to lead, direct, train, and discipline their men. The source of supply from which design-department heads are drawn is ordinarily the design organization itself. However, the author believes that, before promotion in the design division, a candidate should be transferred to other development work for a period of training. It is well to have, as a design supervisor, a man who at some time or other has been a customer of the design division and is thus able to look at his organization with less prejudice and self-satisfaction, and is less likely to overlook and excuse faults in his group.

Work should flow through the design division with the minimum of delay or expense caused by lost motion, "red tape," divided authority, personnel peculiarities, etc. This means that the groups handling the various phases of the work must be so set up and supervised that there will be little or no overlapping of function, complete responsibility of each group for its work, and harmonious relations insisted upon and maintained throughout the organization.

Supervisors should not be forced to neglect important phases of their work on account of having to handle too many people. Responsibility for each phase of the work must be clearly centered in some individual. Office routines should be as few and as simple as possible without sacrifice of financial control, work scheduling, and necessary supervisory checks. It must not be forgotten that the primary purpose of a machine-design division is to design machinery and not to support an elaborate and cumbersome clerical and accounting system. The control routine put into effect should assist, at least, in evaluating the kind of a job the individual designers, draftsmen, engineers, and clerical people are doing, as well as develop the overall efficiency of the organization.

---

[1] Assistant Superintendent of Manufacturing Development, Western Electric Company, Inc., Hawthorne Station. Mem. A.S.M.E. Mr. Alden was graduated from the University of Illinois in 1914 and from then to 1916 was employed as an engineer in the fan department of the Oneida Steel Pulley Company, Oneida, New York. From 1916 to 1920, except for the period of the war, he was connected with the jute mills of the Ludlow Manufacturing Associates at Ludlow, Massachusetts, in various operating capacities and was finally sent to Calcutta, India, as Assistant Manager of the Mills Department. For the next five years he was Chief Engineer of the American Insulating Machinery Company, Philadelphia, Pennsylvania. In 1926 he was employed by the Western Electric Company as Commercial Contract Engineer. Since 1929 he has occupied his present position.

Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The foregoing statements are axiomatic and apply to all organizations, but the specific methods adopted must, of course, be selected to suit the nature of the work. For instance, some design organizations may find it desirable to maintain a separate group to handle all detailing, while others may keep the designer on the job until it has been completely detailed. As a matter of fact, both methods are used at Hawthorne. The system should never become so firmly established that flexibility is lost or that changes are difficult to effect.

The control of the technical phases of machine designing must insure that new designs are based upon correct engineering fundamentals, and that the machinery built therefrom will be reasonable in first cost and economical to maintain. Fads and prejudices must be avoided as far as possible, yet the designers' initiative and ingenuity must not be stifled. Advantage should be taken of contemporaneous design developments in the same or allied fields, and when a satisfactory mechanism or unit can be purchased at a reasonable price it should be bought rather than designed. A comprehensive system of design and drawing standards and suggested practices should be compiled and maintained, so that similar jobs will be done at different times in the same way. The accumulated experience of the office will thus be readily available to younger designers, and the man in the shop will always see like information presented upon different drawings in the same way.

The financial control of any machine-design organization should be both comprehensive and definite. A machine-design group may be managed in such a way that good equipment, economical to build and operate, is produced with a reasonable design cost; or it may be managed in such a way that not only are the design costs high, but, what is far more serious, the costs of equipment built in accordance with the designs furnished by such organizations are higher than they should be, and costly and embarrassing delays in equipment deliveries are sometimes traceable to work done in the drawing rooms.

It is essential, therefore, that some method be provided whereby the operating efficiency of the entire organization can be gaged. If there is not too much variation in the types of equipment designed, the work may be divided into relatively small output units such as the drawing sheet or the detail, and a careful record maintained of the average cost per unit over an appreciable period of time. This provides an efficiency measuring stick, which, while not entirely adequate, is perfectly definite, is independent of human judgment, and is not easily tampered with. It probably is more satisfactory, for the set of conditions outlined, than systems depending upon an arbitrary evaluation, by some individual or group, of the work done.

In addition to this, it is essential that the cost of each individual design job be accurately known. These costs and supporting data should be so maintained that they are readily available to facilitate the preparation of reasonably accurate design-cost estimates. Such cost estimates, supplemented by the necessity for securing proper approvals before money is expended for machine-design work, provide partial insurance against the designing and building of "sour jobs;" in other words, equipment which has no sound economic foundation is sometimes complicated and expensive, and should never be built. Detailed information should also be available at all times in connection with the costs of routine and supervision, the costs of those phases of engineering development work which are particularly related to design; and finally, the cost of drawing changes and changes to manufactured equipment caused by drawing inaccuracies should be definitely known.

The different factors mentioned can be integrated to provide a composite picture of the financial side of the organization which, embodied in suitable reports, will convey to the management a definite idea concerning the kind of job the design organization is doing.

The proper solution of the many personnel problems arising in connection with the management of a design organization constitutes no small part of the duties of the design supervisor. Adequate personnel records should at all times be maintained for the use of the supervisors, and so that the management, when endeavoring to fill a specific position requiring certain qualifications, may quickly find qualified prospects from the information available in the personnel file. Before hiring new people the design supervisor should carefully consider the amount of design work on hand and the amount which will become available within a reasonable period. This information should influence the policy followed when new people are hired, as it will help to avoid the expensive practice of hiring new people, breaking them into their new duties, and then laying them off in a few months because of lack of work. Very complete and carefully compiled work-load charts, work schedules, and other data should be maintained at all times so that approaching periods of reduced design activity may be detected and suitable adjustments made. Such records are also essential to enable the force to be increased at the beginning of rush periods before the design organization becomes so loaded with work that extensive overtime programs, etc., are necessary.

It is, perhaps, easier for a design force to become stagnant and ingrown than for any other group of technical men of equal ability. Broadening contacts are often absent, habits of thought become fixed, and an attitude of self-sufficiency is developed which is a bar to the progress not only of the organization but of the individual as well. It is a responsibility of management to avoid the growth of such a situation. Men for all technical jobs must be carefully selected and must be given opportunity for training. Training, both technical and non-technical, is doubly necessary for designers and draftsmen. Their progress must be watched, and selected individuals must be given opportunities to develop and to display such ability as they may have along other than design lines. Latent ability of this nature is difficult to recognize in a drafting organization unless the management makes a deliberate effort to seek it out. In the main, the work is not spectacular and the individual has not the chance to display his talents to supervisors with desirable vacancies to fill in other divisions. It is because so many employers of draftsmen have failed to recognize their responsibility to the men on the board that drafting has acquired the name of being a "blind alley" job. Because drafting has this reputation, the best of the young engineering graduates of the type the drafting room needs most are reluctant to enter this field. The effect of this reluctance is twofold. First, it deprives the design organization of valuable men, and, second, the men who avoid this field miss a type of training which they cannot afford to be without.

In order to attract the highest type of personnel the job must be recognized as being entitled to the same respect as other engineering work commands. It must offer definite opportunity for advancement. Alert and energetic designers who give promise of supervisory ability should be transferred to other divisions for upgrading and further opportunity. As soon as it becomes recognized that good men are adequately rewarded it is no longer difficult to get young engineers into the drafting room. After these men are recruited it is necessary that a definite effort be made to train them. The number of good machine designers now working on the board is wofully small. Many can design mechanisms which will function properly, and many are clever at designing intricate mechanical movements. However, the designer who can, with only nominal supervision, lay out a machine which is good enough for the job, but not too good, which can be easily built and easily maintained, which is safe and easy to operate and control, is a rare individual indeed, and most of the men who can do these things successfully are soon advanced to supervisory positions. Therefore, there is the necessity of constantly developing new men, and this must be recognized as being one of the most important jobs of a design supervisor. It is not felt that a formal or organized course of instruction is either necessary or desirable. It is believed that the best way to develop engineers is by personal attention, advice, criticism, and correction. The division chief must pay personal attention to this work because it will be found that many department chiefs are reluctant to spend the necessary time on instruction of their men. It is necessary that all department chiefs recognize that the building up of a group of energetic, self-reliant, capable designers relieves the supervisor of much of the tedious and disagreeable parts of his work.

It is the function of the management to determine how designers and draftsmen shall be given the required training in shop practices. It is not thought that a formal course is particularly effective. It will be found that plenty of shop contact will be reflected in a higher grade of design, particularly if that shop contact is acquired in correcting shop difficulties encountered during the construction of a machine. Whenever possible, the designer should be required to contact not only with the shop foreman, but with the machinist at the bench on all machining or erecting troubles. The draftsman should be encouraged to become personally acquainted with shop mechanics. Supervisors should be enjoined to make a definite effort to use shop difficulties as examples in the training of their people.

Management Methods Used by a Large Company

As the "proof of the pudding is in the eating," the operation of any set of theories or suggested practices can best be illustrated by actual example. A brief description will therefore be given of the machine-design organization located at the Hawthorne plant of the Western Electric Company, together with an outline of the control policies, systems, and routines used in directing and guiding its activities. It should be clearly understood that no attempt is being made to present this organization as an example of a perfectly controlled and perfectly functioning unit. There are admittedly faulty features in the management and operation of all industrial organizations, and the Hawthorne Machine-Design Division is no exception. However, the controlling and guiding policies used represent an attempt to secure efficiency in a design organization by the application of orderly thinking and sound business principles supplemented by common sense, and engineers and supervisors are requested to read this description with that thought in mind.

General Organization

The Engineer of Manufacture organization, of which the Hawthorne Machine-Design Division is a part, is responsible for all engineering activities conducted by the manufacturing department of the Western Electric Company. One of the most important of these activities, the development of equipment, processes, etc., to improve the quality or reduce the manufacturing cost of company products, is handled by the development branches of the Engineer of Manufacture. The skeleton chart, Fig. 1, shows the relation between these organizations and the Machine-Design Division. In order to avoid needless repetition, only part of the organizations have been shown on the chart.

Economic studies and development work done in connection with specific projects involving mechanical equipment are handled by specialized groups of development engineers, as shown on the chart. When one of these engineering groups has investigated a specific project sufficiently to decide that machine equipment of special design should be provided, a brief description is prepared outlining the machine requirements, operating features, etc. It is sometimes necessary to have preliminary designs worked up by the Machine-Design Division before a specification covering the final design can be written. The specification and a request for the necessary machine drawings are then forwarded to the Machine-Design Division. If doubt exists concerning the feasibility of certain machine constructions or operations, a rude model to demonstrate their performance is made and experimentally operated.

Fig. 1 Chart Showing Relation Between Engineer of Manufacture and Machine-Design Division

The special equipment designed for Western Electric manufacturing operations is of a diversified character, ranging from small and intricate mechanisms such as automatic assembling machinery for small telephone apparatus piece parts, to heavy machinery such as hydraulic extrusion presses, telephone-cable stranding machines, copper-wire drawing machines, etc. Western Electric machinery is designed to operate under conditions ranging from ordinary to most adverse with the minimum of attention and maintenance. The great diversity of manufacturing operations performed, and the large number of kinds of products made in rather limited quantities, means that in relatively few cases does the number of machines of a given type exceed four to six. Since none of the machinery designed is for sale, and since most of it is built in the shops of the Western Electric Company, it will be recognized immediately that some of the problems with which the Hawthorne design organization is confronted are not parallel to those of other companies. It should be borne in mind, of course, that standard purchased equipment is utilized wherever possible.

The Hawthorne machine-design organization also handles considerable work related to machine designing, such as the preparation of specifications from which special machinery is constructed by outside firms, special engineering studies and laboratory work for other company organizations, the handling of all safety activities in connection with machine equipment coming under the jurisdiction of the Hawthorne Engineer of Manufacture, etc. This work, while interesting, is beyond the scope of the present paper, and will not be dealt with here.

Divisional Organization

Fig. 2 illustrates, in chart form, the set-up of the Hawthorne Machine-Design Division. (See also Fig. 3.) The division is composed, essentially, of four separate machine-design departments, a machine-design engineering and checking department, a safety investigation and coordination department, and a clerical and tracing department. Each one of the machine-design departments contains an average of 20 machine designers and draftsmen. The work in each machine-design department is in charge of a department head assisted by one or more squad leaders who are in immediate charge of the different design projects. To a certain extent, each design department specializes in certain classes of design work. This has proved to be a profitable practice, as design work in connection with essentially similar mechanisms is handled by people who are proficient in that particular kind of work. The designers, including the squad leader, generally stay with each design project until it is completed, doing their share of the detail work, as well as minor layouts, etc.

Design and Clerical Routine

The design and clerical routine to be described is graphically shown in Fig. 4. When the Machine-Design Division receives a machinery specification and request for drawings from one of the development organizations, the development engineer in charge of machine design assigns the work to the design department best able to handle it. The design-department head analyzes the specification, and with the squad leader who is expected to carry on the design work, discusses the matter with the development engineer in charge of the project from whom he receives an economic picture of the job. An estimate of the drawing cost is next prepared by the design supervisor and the squad leader, and forwarded to the development engineer on the design estimate and authorization form shown in Fig. 5. The development engineer then obtains the required approvals for design expenditure and returns the approved form to the Machine-Design Division, so that design work may be started.

Upon receipt of the approved authorization an order number is assigned to the job, a record taken, and a folder is prepared by the clerical organization. This folder consists of a copy of the design authorization, a copy of the specification, any other correspondence pertaining to the job, and a time sheet used for cost-recording purposes, and upon which the job or order number is shown. A daily log, in which are recorded items of importance decided upon in discussions between the development engineer and members of the Machine-Design Division, is also included. The job folder is forwarded through the department head to the squad leader in immediate charge of the project as his authorization to start the design. As soon as the work has progressed sufficiently to permit a fairly accurate estimate of the time required to complete the drawings, the information is furnished to the clerical department, which submits the completion date to all interested organizations, and also uses the information for the compilation of work-load charts, etc., to be described later. As design work proceeds, consulting-engineering service is furnished by the engineering and checking department when required, as later described in connection with the technical control of design work. Close contact is maintained at all times with the development engineer responsible for the project in order to insure that floor-space requirements, operating conditions and requirements, etc., have been adequately taken care of.

Drawings of special machines to be built in appreciable numbers, or unusually intricate designs from which only one or two machines will be built, are sent to the checking section for examination. Drawings of the simpler machines are given a rather rough check by the designers, especially if the work is urgent. Checking routines will be outlined in a subsequent paragraph under "Technical Control of Design Work." Upon completion of the drawings, the development engineer in charge of the project, and the development engineer in charge of machine design approve all assembly drawings. The delivery form shown in Fig. 6 is prepared, on which is listed the job number, drawing number, sheet number, and issue number of all drawings that are to be sent to the Machine Ordering Department for manufacturing purposes. This form is approved by the design-department head and is forwarded with the drawings and job folder, to the blueprint-section order clerk.

Upon receipt of tracings and requests for blueprints, the order clerk originates a "record card" of organizations which are to be kept up to date on subsequent issues of blueprints. Next a requisition for blueprints is originated and sent to the blueprinting department with the tracings. Upon receipt of prints from the blueprinting department, the blueprint clerk checks the

TECHNICAL CONTROL OF DESIGN WORK

The technical phases of the machine designing done at Hawthorne are controlled by the design executive and supervisory force, assisted by the machine-design engineering and checking department. The engineering department is composed of a checking section, and engineering section containing mechanical engineers, electrical engineers, a section chief, and a standards engineer with the rank of section chief, reporting to the department head.

As checking routine is substantially similar in all design offices, Western Electric checking methods will not be dealt with to any extent. However, particular care is taken to insure that standard practices are carried out with respect to materials, the use of commercial units, electrical features, etc. Where economically justified, it is by all means desirable to have drawings examined by the checking organization, as the experience gained by the individual checker in handling a large volume of work from a considerable number of designers tends to develop in him a varied fund of information, orderly methods of thought and action, and balanced judgment to a greater extent than is possible on design work. Also, the advantages of an independent check in eliminating both dimensional inaccuracies and errors of technique and judgment are well known. Full cooperation is given the design departments so that the experience mentioned will be readily available and frequently applied through consultation while machine designs are still in the layout stage. By these means the checking section contributes quite largely to the quality of the work turned out by the division and to economies in the construction of special machinery.

It is obvious that careful work by the detailer will keep down to a minimum the number of errors on detail drawings, and consequently the work the checker must do and the number of mistakes allowed to slip through. The checker, when examining detail drawings, records the number of errors he finds. Based upon this information, a simple bar chart having a bar for each month showing the average "percentage of accuracy" for that month is maintained for each man in the division who turns out detail drawings. Planographed copies of the entire chart series with numbers substituted for the names of individuals are distributed to the designers and draftsmen periodically, and those who have an undue number of mistakes per sheet are interviewed personally. By this means a check is kept upon the operating efficiency of those members of the organization who turn out detail drawings, and more accurate work is done. This practice has resulted in a substantial reduction of both drawing and machine-building costs.

In an effort to reduce, by proper design, the cost of equipment built from Hawthorne designs, all drawings turned out by the design departments are carefully and critically examined by the head of the checking section in an endeavor to eliminate complicated or expensive constructions from the different designs. This inspection does not constitute either a functional or dimensional check, but is handled solely from a cost-reduction standpoint. The results of this work have been gratifying, as periodic investigations of the work done indicate that cheaper constructions are quite frequently recommended and accepted by the design supervisor.

Engineering analysis of new and untried machine designs is one of the most important functions of the engineering department, as such analyses furnish assurance to the management that the new machinery turned out is in substantial conformity to correct engineering principles, and that no element or mechanism has been used which can be determined to be defective by an analysis based on conditions known at the time the machine is designed. These analyses are sometimes quite extensive and embrace an independent check of the designers' estimate of the performance of electrical mechanisms, as well as the forces caused by acceleration and retardation, the loads upon cam rollers, Geneva mechanisms, gear and bearing reactions, etc. They also include kinematic studies of linkage systems, etc., to insure that the combination of elements shown upon the drawing will produce the required motions, timing, etc. Information is supplied to the design organizations concerning material properties, safe stresses, methods of processing and fabricating, sources of supply, commercial stocks available, correct specifications, etc.—in short, anything pertaining to materials of machine construction that will help to get the best possible material for a given purpose and predict its action in service. Considerable time is saved which would otherwise be spent by each designer in trying to secure this information from various sources, not to mention the lack of uniformity that would result from the latter practice.

The Engineering Section furnishes consulting service on lubricants and lubrication problems to the several machine-design organizations, analyzes machine designs from a lubrication standpoint while still on the drawing board, and writes lubrication specifications for all special machinery and some purchased machinery. These lubrication specifications are used by the operating and maintenance organizations, and are an important item in the keeping of machinery maintenance costs at the lowest possible figure. A page of a typical lubrication specification is shown in Fig. 7.

LUBRICATION OF THE NO. 27 PROTECTOR
BLOCK TESTING MACHINE - C-201795

1. GENERAL

1.1 The No. 27 Protector Block Testing Machine, C-201795, shall be lubricated as hereinafter specified.

1.2 The parts to be given lubrication service are the motors, speed reducers, air compressor, shaft bearings, gears, chain, feed-bar slides, packing mechanism, and miscellaneous bearings. (See Lubrication Chart on Page 4.)

1.3 The following lubricants, or substitutes approved by the Machine Design Organization, shall be used:

	R.M. No.
Cup Grease	644429
Engine Oil	645281
Light Grease	647656
Motor Oil (Medium)	645420

2. MOTORS (Items 1)

Engine Oil shall be applied to three motors once a week in accordance with Lubrication Specification 20,019.

3. SPEED REDUCERS (Item 2)

3.1 Cup Grease shall be applied once a week to fittings on nine speed reducers.

3.2 The grease shall be cleaned out and replaced with fresh grease once every three months.

3.3 When a new speed reducer is installed, or an old one overhauled, it shall be operated for a period of three weeks, after which the grease shall be cleaned out and the parts washed with Solvent No. 1 (R.M. 646703). The speed reducer shall then be refilled with fresh grease.

FIG. 7 PAGE FROM TYPICAL LUBRICATION SPECIFICATION

The standards section takes care of work in connection with design and drafting standards and allied matters. The section chief functions as chairman of a standards committee which meets about once a month and discusses all suggestions received by as well as originated in the division, relative to changes and additions to drawing standards. Where changes seem desirable new or revised standard sheets are prepared under the supervision of the standards engineer, and submitted to the department heads and development engineer in charge of machine design for further action.

Any specialized line of manufacture requires certain classes of equipment which, through the process of development over a period of time, become characteristic of that line of manufacture and are particularly suited to the class of work they perform. Sketches and short descriptions of such characteristic Western Electric mechanisms are shown in the standards book. Their purpose is to acquaint machine-design employees with the work that has been done, and to furnish a reference to satisfactory mechanisms which may be either adopted in principle or used outright in new designs. By this means, at least a part of the accumulated experience of the organizations is made available to its newer people.

The standards book contains the usual information about drafting conventions, standard mechanisms, machine elements to be incorporated wherever possible, dimensional limit systems, etc.; it also incorporates information concerning welding practices, cost comparisons of various alternative machine constructions, electrical data, and other things useful to the designer.

The standards section handles all outside contacts related to commercial machine elements, materials, etc., maintains up-to-date catalog files, and handles all telephone calls requesting engineering information from outside parties. The information secured as a result of these interviews and telephone conversations is so filed that it is available for future reference, thereby saving much of the machine designers' time when information is needed concerning commercial units, etc.

The choice of the proper machine elements, materials, and mechanisms to incorporate in Western Electric special machine designs is based not only upon experience, but also upon research, which quite often involves fairly extensive laboratory tests which are conducted by members of the engineering section at the request and with the collaboration of the design supervisors. This is true not only of special machine elements and mechanisms such as distributors, transfer devices, cam-driven mechanisms, etc., but is also carried out with respect to commercial machine elements such as clutches, couplings, lubrication devices, speed reducers, etc. As a result of these tests, new machine elements are developed and information is obtained by means of which savings are effected, as well as a reduction of the shop troubles encountered when proving in new machines.

FINANCIAL AND CLERICAL CONTROL

Some of the more important general-accounting and budgetary practices related to the work of the Hawthorne machine-design division are outlined herewith.

Operating expenses of the design division are broken down into three classes; namely, productive expense, non-productive expense, and other direct expense. The machine-design division is classed as a productive-expense organization, and all of the designers, draftsmen, checkers, and tracers in the division are classed as productive-expense employees. Supervisory, engineering, and clerical people are classed as non-productive expense employees. Other direct expense is that expense incurred by the division for supplies, traveling, conducting experimental tests, work in the laboratory, etc.

A budget is provided for each of these three classes of expense, and preparations are made as early as September to determine the budgetary requirements for the following year. Estimates for proposed expenditures are based upon: A survey of the probable amount of design work which the development engineers will require during the following year; a survey of the cost of machines which it is planned to build during the same period, and a careful consideration of past performances. This information enables a reasonably accurate estimate to be made of the average number of designers and draftsmen that will be required by the machine-design division during the coming year. The size of the non-productive force is governed mainly by the size of the productive organization, and by the anticipated work load, etc. On the same basis of calculation, the budget required for other direct expense is determined.

The non-productive drafting expense and other direct expense is recovered through loadings applied against productive drafting labor. The designers, draftsmen, checkers, and tracers, as productive—expense employees, charge their time to definite job or order numbers. Included in the charges against the jobs are the salaries of the productive-expense employees, plus a loading rate, or overhead, which consists of the non-productive salary expense and the other direct expense, as well as a portion of the works service charges.

FIG. 9 NOTIFICATION FORM FOR CHECKING PROGRESS OF WORK

Financial and clerical control activities within the machine-design division, together with their related accounting practices, are handled mainly by the clerical and tracing department. A reasonably accurate idea of the operating efficiency of the organization is secured by detailed and periodic checks of the cost per unit of divisional output. The drawing sheet has been chosen as the design-output unit, and unit costs are kept comparable from year to year by periodic checks of the number of details shown per sheet. The cost of all design layout work, checking, etc. is included in these unit costs. This method of measuring efficiency works out rather well for an organization like the Hawthorne group where the engineering problems encountered over a period of time are quite similar. It has the added advantage of requiring the minimum of clerical and supervisory effort.

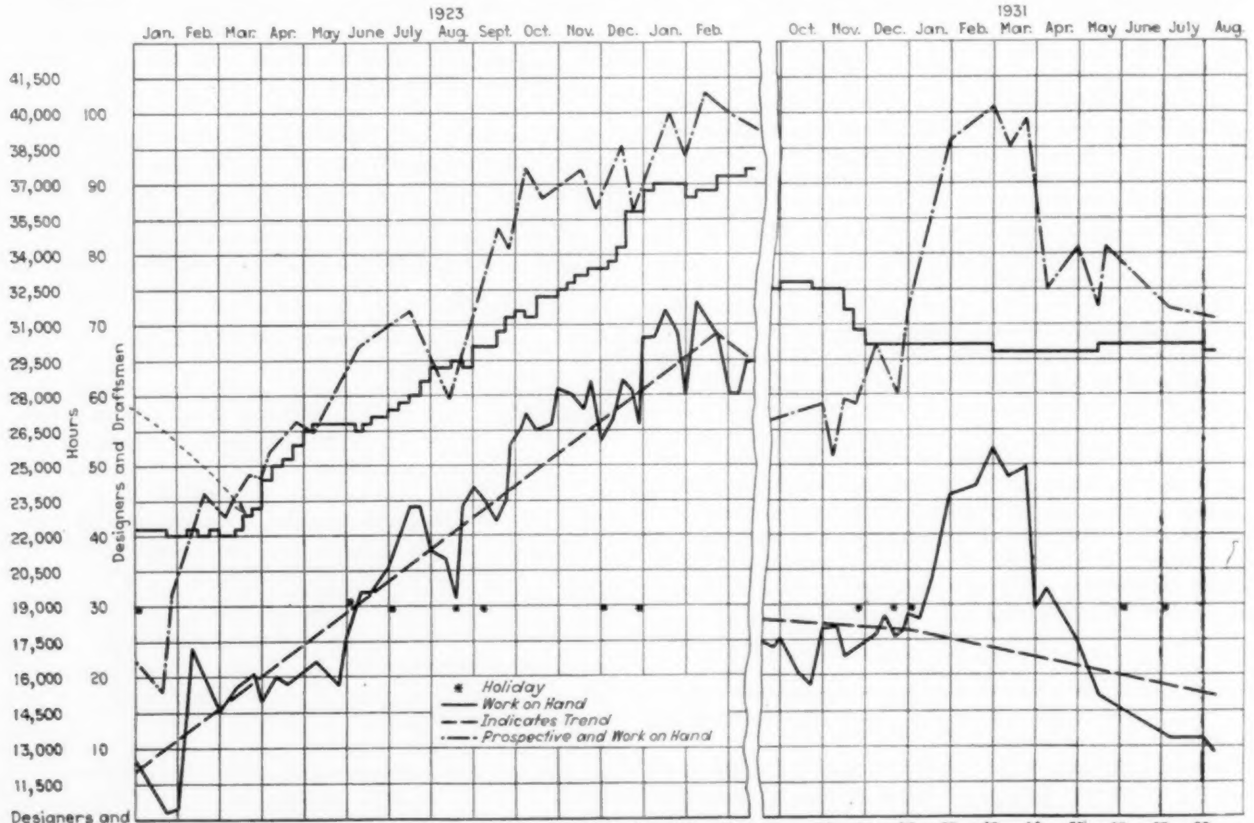
Cost records of each individual design job are also maintained for cost-control purposes, so that information may be given to interested organizations to aid in the preparation of new cost estimates, and to furnish material from which monthly and special cost reports are compiled. All time spent by the designer or draftsman is posted to the cost sheet, Fig. 8, which is issued for each job. The time clerk carefully watches the charges accumulating against each design project, and when such charges reach 80 per cent of the estimated drawing cost, the notification from Fig. 9 is sent to the design-department supervisor, who immediately checks the progress of the work, and determines whether or not an increase in the estimate will be necessary. If more money is needed to complete the design, additional approvals covering the increase are immediately obtained on the form shown in Fig. 5, which is reissued to cover the increase.

At the completion of each new-design job a detailed report of the charges incurred is submitted to the design supervisor and the development engineer in charge of machine design for their information and possible analysis. Monthly reports showing the cost status of each design project are submitted to the management. Special reports, principally in chart form, showing design expense broken down into proper classifications, non-productive payroll, unit costs, budgets, expenditures, etc., are frequently prepared by the clerical organization for the information of the supervisors and management, especially at the beginning of fiscal periods. Experience has shown that these reports are a great aid in properly controlling design activities.

Personnel Control

Not every person has the qualifications necessary to design machinery successfully. In addition to engineering training, the machine designer should possess orderly ways of thought, and have a large fund of the common sense necessary successfully to determine that middle course between conflicting factors which constitutes such a large proportion of machine-design work. When hiring new people a prospective employee is shown existing equipment similar to that he will be expected to design; he is interviewed by several people and every effort is made to ascertain his inclinations, capabilities, and probable future value to the company. The performance of each employee is under the constant observation of his supervisors, and periodic checks are conducted by the Engineer of Manufacture personnel organization.

In an earlier paragraph it was stated that in order to encourage young men to enter design work it is necessary to offer opportunities for advancement. The organization of the Engineer of Manufacture force at Hawthorne is so constituted that there are



Designers and Draftsmen	40	41	44	53	56	57	62	64	71	74	78	86	90	91	75	67	67	67	67	66	66	67	67	66

NOTE: The Amount of Work on Hand for 1931 is not Comparable with 1923 Due to Transfer of Design Work to Other Plants Placed in Operation since 1923

Fig. 10 Long-Time-Trend Chart

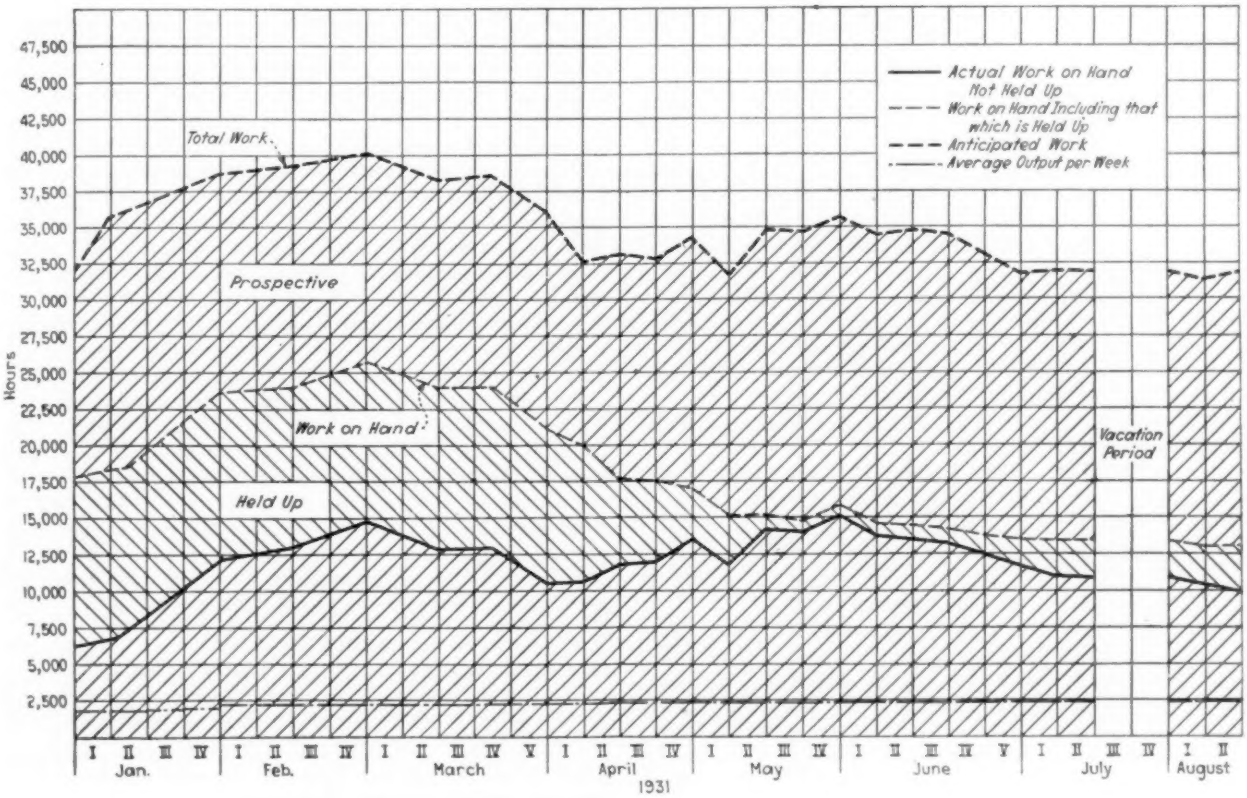

FIG. 11 CHART SHOWING BREAKDOWN OF WORK IN THE MACHINE-DESIGN DIVISION

many places where former designers and draftsmen can be absorbed. Therefore, a practice has been established in the Hawthorne machine-design division of taking in superior types of young men, training them in machine-design practices, and, after three or four years of productive work, transferring them for further training and upgrading to other development divisions. The advantages are twofold. In the first place, the machine-design division is able to attract a higher type of man, and, in the second place, the development divisions gain men by transfer who have had good design training and experience. An incidental benefit to the design division is that when former machine designers feed work into the division, it is generally found to be better conceived and more fully completed than when such work originates with men with non-design training.

Among the important duties of any executive or supervisory staff is that of regulating the size of the organization with respect to its work load. Information upon which control of the size of the Hawthorne machine-design personnel is based is gathered from at least four sources, namely; a long-time-trend chart, Fig. 10; a breakdown chart, Fig. 11, giving more detailed information concerning the work load at given times; a graphic schedule, Fig. 12, showing the work ahead of each designer and draftsman in the division, arranged by departments; and by consultation with the individual development engineers who have equipment designed at Hawthorne.

The long-time-trend chart, Fig. 10, which was started several years ago, has:

A curve showing, in man-hours, the work on hand for which actual orders have been received in the machine-design division.

A curve showing, in man-hours, the sum of work on hand and prospective design work which is quite certain to be released in the near future.

FIG. 12 SCHEDULE SHEET OF WORK TO BE DONE

A curve showing the number of designers and draftsmen in the division.

A line showing the general trend of the work-on-hand curve.

Tabulated figures showing the number of designers and draftsmen, tracers, and administrative and clerical people on the roll at the end of each month.

This chart is brought up to date each month by the machine-design clerical department from divisional personnel records, and an inspection of the others, memoranda, etc., received in the division. It not only presents a most interesting visual record of machine-design activity over a period of years, but is also a valuable aid in determining the general policy to be followed with respect to the size of the force to be maintained in the machine-design division. It should be noted that the curves showing work on hand and the number of designers and draftsmen are substantially parallel throughout their length, indicating that, in general, the working force is adjusted to follow machine-design business conditions quite closely.

The breakdown chart, Fig. 11, presents curves showing in man-hour units: (1) The total amount of prospective design work, (2) work on hand, (3) that portion of the work on hand which has been held up for one reason or another by different development engineers, and (4) a curve showing the average output per week of the productive machine-design force.

This chart is made to a fairly large scale and shows curve fluctuations in much more detail than the long-time-trend chart. It is brought up to date by the machine-design clerical department every third day during the periods of reduced design activity when there may be a possibility of a shortage of work. During busy periods such frequent revisions are, of course, not necessary, and the chart is brought up to date each week.

The graphic schedule of work per designer, Fig. 12, is arranged by departments, and shows the number of weeks' work ahead of each productive person in the division, together with a brief description of the equipment to be designed and whether it is work on hand or prospective work. This chart is reissued each month with minor pencil revisions at such shorter periods as appear advisable. It is frequently used by the design supervisory force at conferences, and is always referred to when adjusting the personnel or the work load between the machine-design departments, so that each department will have the proper amount of work ahead. This distribution of design work and men between departments minimizes the possibility of design jobs, being delayed because of an overload in one department, when another department might be able to handle the job much sooner. When it becomes necessary to schedule rush design work ahead of work already in the division, this chart aids in selecting the job to be deferred.

While this chart is used principally as an aid to the design supervisor in scheduling his work, it is also useful in connection with the other charts in determining the size of the design personnel, as it presents a detailed picture of the different types of work in the division at a given time and also provides information concerning drawing-checking activities that the other charts do not cover.

When deciding upon the proper design personnel to be maintained, the long-time-trend chart is critically examined in an endeavor to visualize the design activity outlook for the next few months. Supporting facts concerning the probable amount of future machine-design activity are gathered by means of consultations with the different development engineers, and by considering budgetary matters, etc. The breakdown chart and graphic schedule are then used to determine the machine-design personnel required efficiently to take care of what may be termed the seasonal fluctuations of machine-design work. The number of man-hours of work ahead shown on the breakdown chart, excluding that portion of the work on hand which has been held up by different development engineers, are carefully plotted and an arbitrary low deadline set. This deadline is not a fixed quantity, but is set differently each time, depending upon those consultations, analyses, etc. mentioned before. Should the available number of man-hours of work fall below this deadline, arrangements are immediately made to adjust the productive working force.

During rush periods an examination of the different charts sometimes shows the work curves steadily rising; in other words, the inflow of work to the machine-design organization is greater than its output. When this condition reaches a point where design work is retarded and reasonably prompt drawing deliveries cannot be made, the usual design-activity forecast is made. If this forecast indicates that the inflow of work to the design organization is likely to be maintained or increased during the not-far-distant future, action is started toward increasing the personnel.

The particular methods exemplified in the control of the Hawthorne design organization probably cannot be used in their entirety by organizations widely different in size, type of work handled, etc. though they are believed to be fundamentally sound and adaptable, with suitable modifications, to either large or small design groups. It is possible, too, that they are already in use, at least partially, by other design offices. However, in view of the dearth of design-management literature, it is hoped that this paper will promote a beneficial exchange of ideas.

Discussion

E. G. Scott.[2] There are not many companies so fortunately situated with regard to their machine design division as the Western Electric. Most companies that maintain an engineering office for design work pertaining only to their own product do not have a big enough organization to subdivide the functions so clearly drawn up in the paper. Usually the head of the department has to supervise, as well as furnish, detail working information for work of a wide and varying character, and this applies to many large industries that are non-technical in their nature.

The experience of the writer has been largely with industries whose basic business has not been engineering. He has experienced most of the things mentioned in this paper and believes that the author has outlined a comprehensive and workable scheme for the management of a large design office. It shows an arrangement toward which one might strive if the organization was large enough to justify it.

However, even in much smaller organizations they have to go through the same motions. One individual may perform many of the separate functions. While it may not be necessary to make a written record of everything, someone has to make at least a mental note of them all.

The writer has tried many schemes to keep track of jobs during the process of development. We have now worked out one quite similar to that of the author. We have a job folder in which are filed the original or a copy of correspondence bearing on a particular job, engineers' calculations, pencil sketches, and a blueprint of all drawings through the process of development. It is helpful when working up new jobs to have a complete record of what was done in past years on similar jobs.

The system of indexing, in use for a number of years, is simple and infinitely expansible. In handling the new construction work and maintenance work for four organizations, it is desirable to keep these separate, and yet the information collected must be easily locatable for any one or all of the four. The writer has organized his index as follows:

The key numbers 1000, 1100, 1200, and 1300 designate the four organizations. Each is divided into departments, such as the administrative, productive, and non-productive departments, and they in turn are subdivided so that every major operation lends itself to classification. The key number has a prefix of the last two numerals in the year. The key number appears on each document, whether it is filed with related papers or not.

In using the system, the key number representing each of the four units ends with two numbers for the department. The productive departments are symbolized by numbers from 00 to 34, the non-productive by 35 to 67, and the administrative by 68 to 93. To further coordinate the papers relating to a particular job, a specification might have the letter number S-31-1027-1 or a bill of material would receive BM-31-1017-1, etc.

The author relates how the Western Electric has solved problems similar to those that have been bothering the writer for many years. One especially troublesome one is the promotion of draftsmen. In industries where engineering is quite remote from the main business, promotion to other departments is not as simple as with an industry such as the Western Electric, but even in these something can be done for the advancement of the draftsmen by transfers to other departments.

The keeping of cost records of engineering reports is quite important. It is easy to ask for reports on certain projects without realizing what such reports cost. When the report is completed, the one asking for it should be advised of the cost. If the department heads have this information, they will use more care in making requests of the engineering department. Of course, it is understood that the engineering department should give an estimate of the cost of the work before starting, but untrained people do not always believe these estimates. The engineering department has the dual responsibility of promoting progress and at the same time of not unduly running up the engineering expense.

F. O. Hoagland.[3] It is difficult to keep a force as large as the one described occupied efficiently. It is interesting to follow the author's description of the duties of the division chief, in continually checking and cross-examining, seeing that standard machinery is procured in the open market when available, that records are kept of past experiences, that designs are standardized, and that costs are kept within reason.

He probably finds that the checking section is the "neck of the bottle" and that in order to rush work through it is often necessary to short-cut it. The writer has found that it works out to advantage to have the group that prepares the designs and layouts and details also to check each other's work, and to have the detail drawings go through the standards engineers in order to check standard parts, means for lubrication, tolerances and allowances for various classes of fits, with the chief designer or a responsible engineer checking for general and functional designs.

The author's budgeting and averaging of the costs of designs per drawing turned out reminds of the mail-order house practice of weighing the first-class mail each morning and thereby determining the dollars represented.

He makes a strong point of the training of men. How about apprentices? Should not the advantage of actual shop training be emphasized? Nor has he overlooked the importance of giving the men opportunities for advancement.

The author's charts show in a comprehensive way the general organization, the distribution of duties and responsibilities, the work on hand, and the men available. It is hoped that he is successful in keeping these charts up to date, as too frequently it is found that this matter is apt to lag, the usefulness of the charts being thereby considerably reduced.

The writer regrets to note that even in the author's line the amount of work and the men employed fluctuate considerably, and if charts could in some way be laid out to eliminate this factor, it certainly would be very desirable.

R. E. W. Harrison.[4] Having regard to the large part played by economics in the determination of managerial policy, it is surprising how little literature there is available on this subject for the guidance of those confronted with similar problems. Most of the executives handling assignments of this nature have developed a technique which is almost entirely the result of their own progressive experience, but to the best of the writer's knowledge, this paper represents the first effort of its kind to place on record the policies and practices of one of the larger engineering corporations.

While the author would probably be the last person to suggest that any scheme of control could be taken and applied in blanket form to another business, there are without doubt many valuable ideas in the paper which can be readily adapted to almost any existing engineering department, even though only a relatively small number of men be employed.

As a result of many years' contact with work of this nature, the writer can confirm that the budget and appropriation method of handling engineering design assignments is the only businesslike way of insuring control over costs, and while experience proves that it is almost impossible to estimate with accuracy the cost of solving a new engineering problem, particularly from the design standpoint, it has been shown that the wise course to follow is to make the appropriations in steps and to bring the whole matter up for review when the financial limit of each step has been reached.

In these days of rapidly changing economic situations, it has not been unknown for a design to become economically unattractive during the period of its development. Hence, step-by-step appropriation brings the management and the designer into closer contact and insures that degree of control which will obviate the spending of money on an unprofitable project.

Relatively few concerns keep accurate cost records of their designs, and it is the writer's belief that this is due, more than anything else, to lack of appreciation of the value of accurate cost records as a basis for estimates of the expense involved in future work.

Too much stress cannot be laid upon the importance of the overall-cost-reducing virtues of a well-organized and up-to-the-minute engineering standards department. This department, when properly run, not only automatically reduces the cost of manufacture, but also tones up the quality of all designs produced by the engineering department as a whole. The writer's experience also indicates that it is just as important to carefully plan the work schedule in the machine-design department as in the works-production department. The management, in consultation with the sales and engineering department executives, should call for a date of completion, as only in this way can the engineer in charge so dispose his forces that they most accurately interpret the business policy of the company.

It would seem that there is too little appreciation of the fact that the drafting room provides a good training ground for potential executives and that a period of not less than two years in this department should be regarded as an essential part of the training of every man destined for a major executive position. The assignment during this period should not be that of a looker-on or even a supervisor, but as a man who is expected to produce and who will be expected also to put up an outstanding performance if he is to be regarded as potential executive material.

It is a regrettable fact that many outstanding designers make poor executives. The trouble would appear to be largely psychological and in a measure can be traced to the type of training which a man must receive to become a first-class designer. As in most things, a compromise is the most effective expedient, and it is usually up to the executive head of the department to supply the economic balance and background and to keep sufficiently closely in touch with the progress of the work to insure that after laying down the principles on which the design is to be made, he also can exercise control over those features which involve manufacturing costs, potential life, and overall efficiency of performance.

Still another unfortunate aspect to this matter is the fact that the generally better remuneration earned by men in executive positions induces some good designers to make every effort to abandon this end of the work in the belief that they can do better for themselves in an executive position. The remedy is obviously a better appreciation by the management of the fact that good design is the starting point of all successful engineering enterprises.

With regard to training the draftsmen in workshop practice, experience shows that no man can become a really efficient designer unless conversant with resources at the disposal of the manufacturing end of the business. It sometimes happens that the most brilliant designs are wrecked in the economic sea because they cannot be economically translated into simple manufacturing procedure.

In this connection much benefit can be accrued from providing facilities for the designers and draftsmen to contact not only with their own manufacturing divisions, but with the user as well. Nothing has quite so completely constructive an effect on a designer as to have to service the machine which is his own creation or to talk over its merits and demerits with a busy production superintendent who has had to live with it for a year or more. While it sometimes happens that the solutions for the defects put forward by the operating end of the business are not all in accordance with the accepted principles of applied mechanics and good design generally, these complaints and suggestions serve a very useful purpose in keeping before the designer's mind a vivid picture of the difficulties which he can create by inattention to the service and operation angles of the design.

In so far as actual drawing-office control of the work schedule is concerned, the writer has found that a very complete picture can be obtained by keeping a master record of each job in a loose-leaf folder. This record is in the form of a chart, at the head of which is the designation of the work, order numbers, dates, promises and estimated time, etc. The chart is ruled vertically into days and weeks, and by utilizing the services of a clerk to make a daily record, indicating the time put in on the job by the designer, detailer, and checker, a very effective running balance can be maintained. Such a picture enables the supervisor to give a reasonably accurate estimate of the time required to deliver the drawings and an absolutely reliable statement of the time already charged to this particular piece of work. Also, it has the merit of being cheap to maintain, and furthermore gives that detailed control which is so necessary to insure the 100 per cent interpretation of the management's requirements.

F. D. Newbury.[5] The writer wishes to discuss some aspects of the design problem that are related to the form of organization of the design department. While discussing organization, there is no wish to overemphasize its importance. It is not as important, for example, as quality of personnel nor as important as skill in administration. The success of any organization is the net result of all three of the factors—form of organization, quality of personnel, and skill in administration; but good organization permits the other two factors to function most effectively.

[5] General Manager, Machinery Engineering, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

The design work connected with the design of any machine or factory equipment may be divided into several parts as follows:

(1) The functional design of the apparatus, the determination of the correct proportions and arrangement of elements to accomplish the desired results—as, for example, the design of the "steam path" of a turbine to perform satisfactorily as a heat engine or the design of the magnetic and electrical circuits of a motor or generator.

(2) The mechanical design of the structure of the machine or apparatus, consisting usually of the combinations of well-known mechanical elements. In the case of the steam turbine, this part of the design problem is the problem of designing a turbine that will function acceptably as a mechanical machine.

(3) The translation of the design into working drawings suitable for use in the factory.

These strictly design operations are, in the most highly technical industries, backed up by a research organization, investigating principles of operation, design methods, and materials.

In connection with all of these research and design activities, each merges more or less into the next, and the best form of organization and administration is the one that provides for the closest cooperation between these various groups interested in the design of the same product.

It is generally agreed that the functional design work requires specialized engineers—electrical engineers of various kinds, steam turbine engineers, pump engineers, etc.

It does not follow, however, that all of these engineers are necessarily of high quality and long experience. This functional design operation includes original work of the highest type and greatest difficulty, but it also includes, in a large company, a great deal of strictly routine "slide-rule" work that requires no more original thinking or ability than does detail drafting.

The mechanical design of the structure requires mechanical engineers, who may be engineers highly trained in mechanics and mathematics and capable of analyzing stress and vibration conditions encountered in high-speed machinery; or this phase of design may require men skilled in kinematics and in the design of machine elements. Usually, the general layout and structural design is drawn up on a paper as a part of this portion of the design operation.

In this second division of the work, also, we are concerned with men of a wide range of talent and education; some must be highly trained in theory, others must be ingenious in devising new mechanical arrangements and others may be merely skilled draftsmen.

In the third or detail drafting division of design work there is the relatively simple job of making suitable drawings of detail parts in accordance with the general layout drawing. This work requires well-trained men who are naturally accurate.

The difficulties and differences of opinion and practice in engineering design departments are encountered largely in the second division of design work concerned with the mechanical structural design. In this division "desk design" and "drafting-table design" overlap considerably, and it is difficult to effectively conduct this part of the design job if the form of organization draws a sharp line between engineers who work at desks and designers who work on the board.

There is a natural step-by-step progression in the design organization from detail draftsman to layout or design draftsman, to mechanical engineer or specialized design engineer, and if the form of organization recognizes and provides for all of these positions in one design group, there will be little difficulty in giving each draftsman and engineer the work he is best able to do, and advancing men as their abilities increase. There need be no blind alleys. On the other hand, if there is a sharp division, arising from the form of organization, between designers who work on the drafting board and engineers who work at desks, there will be difficulty in keeping high-grade engineers and designers, who should do their designing on the drafting board, in the drafting organization.

In the form of organization in which the functional design and the structural or machine-design problems are handled by different major groups, as in the organization described by the author, and also in organizations in which the "functional" type of designing is largely absent, the design department or division becomes entirely a "drafting department," and designer and draftsman become synonomous titles. In design organizations, in which the functional type of designing is combined with the others, more closely related to drafting, so that all grades of specialized engineers, designers, and detail draftsmen are associated together under a single engineer-executive, the problems of administration are greatly reduced. This statement is based on considerable practical experience with both types of organization.

Fig. 13 Order Route Chart of Westinghouse Company Power Engineering Department

To illustrate this difference in type of design organization, the writer wishes to compare the organization described in this paper with that of the Power Engineering Department of the Westinghouse Company. This department is responsible for the electrical and mechanical design and drafting connected with heavy rotating electrical machinery. It is divided into a number of self-contained design divisions, each completely responsible for the design and drafting of a definite class of machinery and small enough to be administered by one engineer-executive.[6] This comparison can be most readily made by comparing the author's graphical chart (Fig. 4) with the accompanying chart (Fig. 13) showing the travel of an order, for the production of a new machine, through the design department. The essential point is the division of responsibility, in the author's organization, among three major groups (development department, machine-design department, and machine-design engineering and checking department), and the concentration of complete design responsibility (in the power engineering department) in one relatively small design division.

Author's Closure

Mr. Hoagland's questions regarding training of men strike at a recognized weakness of design personnel. The Western Electric Company maintains an apprentice course for toolmakers, development machinists, machine-building machinists, tool designers, and machine designers. The machine-design apprentices receive the same fundamental shop training as do the shop apprentices, and it has been our experience that, in general, these young men make very satisfactory designers. It is difficult, of course, in a large organization to provide the close contact between shop and drafting room that is possible in a small company. Nevertheless, we make a definite effort to keep our men in as close touch with the shop as possible. This is accomplished by requiring the designer to correct shop difficulties which arise during the construction of the machines and to contact with the foremen and machinists on the job. It cannot be said, however, that we have completely solved the problem of educating designers in shop practice.

A greater amount of system and routine is necessary in a large drafting room than in a small one. Nevertheless, it is essential that the system be as flexible as possible. Therefore, we make every effort not to take our departmental routines too seriously, and we depart from them just as often as our judgment dictates that such departure is advisable. For example, certain jobs are carefully checked by the regular checkers. On other jobs, the designer checks the work of his detailers. On still others, the designer details his own work, which is sometimes checked and sometimes not. Moreover, at times of reduced load and activity we completely discard some portions of our system with the expectation of resuming these portions whenever the need of the work requires. We feel very strongly that a large design group may easily become overorganized, and therefore take more than ordinary precautions to avoid substituting system and routine for responsibility of personal supervision.

It is because of the foregoing facts that the author believes that the differences between the organization described in the paper and that illustrated by Mr. Newbury are not as great as appears on the surface. In the first place, the Hawthorne Machine Design Division designs nothing but machinery used within the Western Electric Company for the manufacture of telephone apparatus. It designs no machinery for sale. Moreover, the various development groups shown in the organization chart of Fig. 1 are closely associated with the design division. Because of this close association and because the machinery designed is built and installed in the Western Electric Company's plants, the machine designers are in close touch with operating requirements and the practical phases of their jobs. It is certainly a fact that the Hawthorne machine designers are designers rather than draftsmen and that they have full opportunity to exercise all of the ingenuity they possess. From Mr. Newbury's comments, it appears probable that the author's chart, Fig. 1, gives a false picture of functional rigidity which does not actually exist. To be effective, of course, any design group must adapt itself to the conditions surrounding its job. The Hawthorne design division functions smoothly and fits in well with the general scheme of organization of the Western Electric Company, although it is recognized that to meet a different set of conditions, a radical change in type of organization might be necessary.

---

[6] This organization is described in "Improving Drafting Management," by F. D. Newbury, presented before A.S.M.E., Cleveland, Ohio, April 13 to 17, 1931.

MSP-54-10

Oxygen Machine Cutting in Great Britain

By C. G. BAINBRIDGE,[1] LONDON, ENGLAND

Cutting of metal by the oxygen flame has been practiced commercially for more than 25 years by means of hand-guided blowpipes. The hand cutter is largely used for scrap cutting and by concerns whose work involves the use or manipulation of steel plate, forgings, or sections. The work produced by the hand cutter is rough and inaccurate. The paper describes the use of the machine designed to hold the cutter rigidly and that propels the cutter by a simple feed motion at a uniform speed. Great progress has been made in the past 10 years in the development of these machines, and they now are considered as reliable, quick, and accurate shop tools. The paper describes the various machines and their uses, and gives instances of their application to difficult work, with the resulting reduction in costs.

MOST of us remember the laboratory experiment in which a piece of iron or steel wire or strip is heated in a bunsen flame and then passed through a stream of oxygen; the metal is rapidly oxidized and disappears in a shower of sparks. What has happened is that a chemical action has taken place between the iron or steel and the oxygen, forming a magnetic oxide of iron (Fe_3O_4), the sparks being not pieces of molten metal, but particles of red-hot oxide. The bunsen burner merely supplies the necessary heat to bring the iron or steel to the ignition temperature. The process is therefore one of oxidation of the iron or steel.

It is a comparatively simple matter to calculate that 1.17 cu ft of oxygen is required for the complete combustion of 1 cu in. of iron under ideal conditions, assuming the metal to be 100 per cent pure iron and the gas 100 per cent pure oxygen.

In practice, steel is generally the material to be cut, and the oxygen is generally not more than 99.5 per cent pure. Moreover, complete combustion does not always take place, as some of the particles of the iron in the path of the cut are loosened and blown out by the force of the oxygen stream; in other words, we do not always get pure magnetic iron oxide, but probably something between Fe_2O_2 and Fe_3O_4.

In the laboratory experiment the bunsen burner heated the metal before it reached the oxygen jet. In commercial practice this heating flame is furnished by the same blowpipe that carries the oxygen jet. The heating flame consists of a mixture of oxygen and fuel gas, such as acetylene, coal gas, or hydrogen. Some blowpipes are fitted with two oxygen connections—one for the heating flame and one for the cutting jet. Other types have only one oxygen connection in addition to the fuel gas, the oxygen being diverted inside the blowpipe in order to supply both heating flame and cutting jet.

The heating flame of course takes no active part in the actual cutting operation, the heat provided by it being relatively small compared with the heat evolved by the combustion of the metal. It is necessary, however, to maintain the heating flame while cutting in order to compensate for heat losses by radiation and conduction.

In practice, the heating jet or jets must surround the cutting jet. The first blowpipes or cutters had the jets arranged as at *A*, in Fig. 1. In this arrangement, as the cutting jet follows the heating jet, only straight-line cuts could be made satisfactorily. For shape cutting, the cutting jet has to make abrupt changes of direction; therefore, present-day cutter nozzles are usually arranged as at *B* or *C*, where it will be seen that no matter in what direction the cutting jet is moved it is traveling over material that already has been heated by the heating jet.

Oxygen cutting has been applied commercially for more than 25 years by means of hand-guided blowpipes. The hand cutter is largely used for scrap cutting and by concerns whose work involves the use or manipulation of steel plate, forgings, or sections; free-hand cutting is very crude, and when the cut is to be used for production jobs, it is usual to improvise suitable guides, trammels, or templets, with which to steady the cutter.

There can be no doubt that the hand cutter saves a tremendous amount of time and considerably simplifies the roughing out of large or intricate shapes that would be impossible to shear and for the production of which the only alternative would be drilling.

The work produced by the hand cutter is, however, at its best very rough and inaccurate. It is difficult to obtain uniformity over a number of cuts, and a considerable amount of machining is necessary in order to obtain a clean cut.

It is obviously a very short step from a guided hand cutter to a simple machine that will hold the cutter rigidly and that will by means of a simple feed motion propel the cutter at a uniform speed. The first machines introduced were, in fact, merely devices for holding a hand cutter. Some users, seeing the good results that would be obtained if the cutter were mechanically driven and guided, converted old lathes and planing machines into oxygen cutting machines.

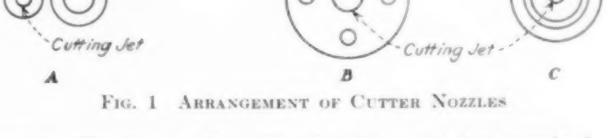

FIG. 1 ARRANGEMENT OF CUTTER NOZZLES

The past 10 years or so has witnessed great progress in the development of these machines, and now there are machines on the market for a very wide range of applications of oxygen cutting. These machines may be definitely considered as reliable, quick, and accurate shop tools. Indeed, the large machines especially designed for profile cutting are machine tools in every sense of the term.

Owing to the regular feed and the steady travel of the cutter, the cut surface is so smooth and accurate that often no further machining is necessary. If, however, the use to which the article is to be put necessitates a machined surface, the amount of metal

Contributed by the Machine Shop Practice Division and presented at the Semi-Annual Meeting, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

left on for machining can be reduced to a minimum; $^1/_{32}$ to $^1/_{16}$ in. is ample for jobs in good-quality material up to about 4 in. thick, and $^1/_8$ in. on material up to about 8 in. thick. On material thicker than this it is advisable to leave a little more metal for machining to size, as there is often the risk of slight drag, causing the bottom of the cut to be out of register with the top; also, it is more difficult to control expansion and contraction. Again, as articles of this thickness probably will be cut from forgings, it is as well to allow for slight defects in the forging.

Reference to the illustrations will indicate some present-day commercial applications of the process.

One of the most frequently applied uses of oxygen cutting is for gapping crankshafts and for cutting out complete crank webs. (See Fig. 2.) The crankshaft shown here is for an air compressor; the thickness of the cut part is about 7 in., and the time for cutting out the shape shown is about 4 min, only $^1/_8$ in. over the diameter of the crank journal being left for machining off. The smoothness of the cut can be judged from the middle throw which has been cut.

Separate crank webs are usually cut from slab forgings, if fairly thick, or from forged steel bar when practicable. Fig. 3 shows a machine shaping a crank web from a forged slab about 10 in. thick. Fig. 4 shows a machine cutting crank webs from a forged bar about 5 in. thick.

Firms that produce large forgings and that have installed an oxygen cutting machine now find it convenient in many cases to eliminate expensive intricate forging, which cannot be conveniently or accurately done under the hammer, leaving the intricate shaping to be done by the oxygen cutting machines.

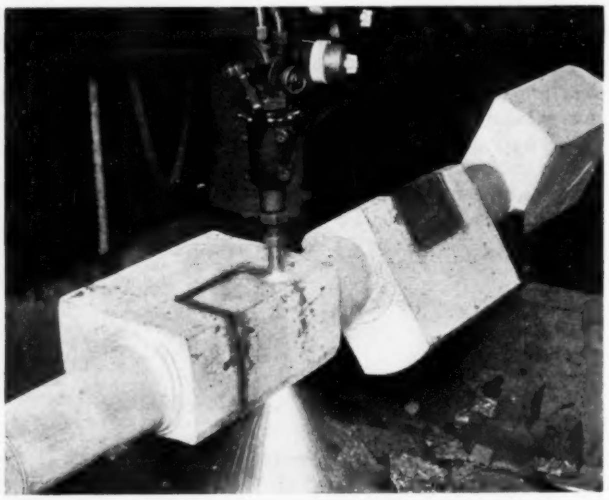

FIG. 2 OXYGEN CUTTING OF CRANKSHAFT WEBS

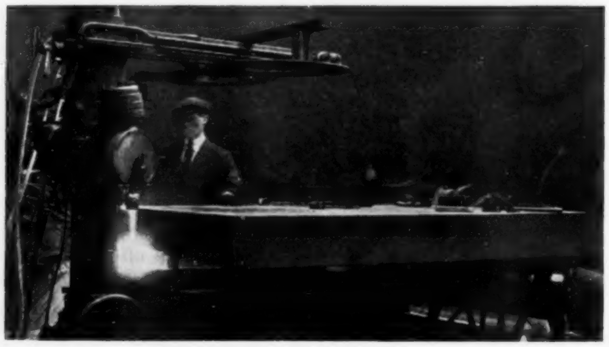

FIG. 3 MACHINE CUTTING CRANKSHAFT WEBS FROM FORGED SLAB

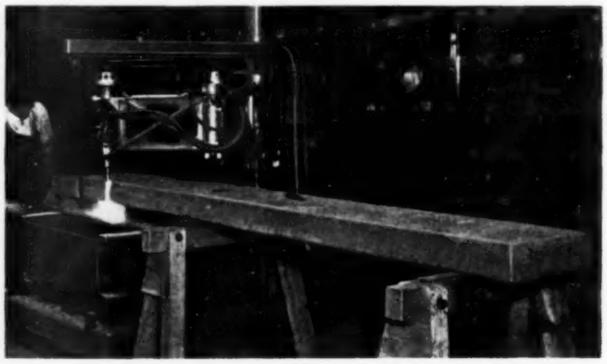

FIG. 4 MACHINE CUTTING CRANKSHAFT WEBS FROM FORGED BAR

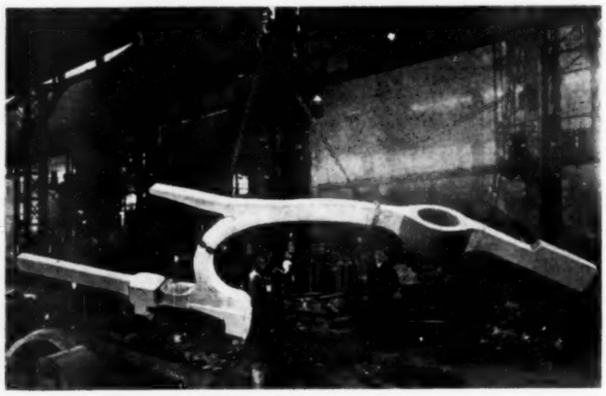

FIG. 5 INTRICATE SHAPING DONE BY OXYGEN CUTTING MACHINE

A remarkable instance of this class of work is shown in Fig. 5. The forging shown is a complete stern frame for a ship. The steel varies in thickness from 12 in. to 14 in., and the total length of cutting on the job was about 13 ft. The oxygen cutting machine used on this job is seen in the background.

EFFECT OF OXYGEN CUTTING ON MATERIAL

The usual question asked by those unacquainted with the process is, "Does oxygen cutting affect the steel?" The answer is that, generally speaking, it does not. That is to say, oxygen cutting has no detrimental effect on the material provided it is a steel not adversely affected by the application of heat. This means that all carbon steels containing carbon up to 0.3 per cent can be quite easily cut and the surface of the cut will be readily machinable after cutting.

The general effect of oxygen cutting is to change normal ferrite and pearlite condition to sorbitic pearlite with ferrite envelopes at the cut edge. This results in a slight hardening at the cut surface, the total increase in Brinell hardness on mild steel being 30 to 40 points. There is also an increase of carbon near the surface of the cut, but this carbon change usually penetrates only for little more than half the total depth of hardening effect.

This is a structure and effect similar to that produced by water quenching and tempering steel of the same composition. On ordinary mild steels of 20 to 30 tons tensile, 0.18 to 0.25 carbon, the change of structure does not extend inward from the cut surface for more than $^1/_8$ in., and generally only for $^3/_{32}$ in. This applies to material up to 3 or 4 in. thick, but the depth of effect varies with the material's thickness and may extend nearly $^1/_4$ in. on material 6 in. thick. The depth given, of $^1/_8$ and $^1/_4$ in., re-

resents the point where the steel becomes normal in structure and hardness; i.e., the hardness diminishes from a maximum at the cut surface to this point.

This change of structure is largely due to the chilling effect of the comparatively cold mass of metal at the back of the cut surface. Cuts made on metal that has been preheated show only a superficial film of toughened metal.

The depth of effect will be increased if, because of vibration of the machine or dirty or damaged jets, the cut surface is rough.

If the article is normalized after cutting, all traces of cutting effect will be removed, but unless the use of the article makes machining unnecessary, there is no reason why jobs cut from steel containing up to 0.3 per cent carbon should not be put into service exactly as produced.

Above the 0.3 per cent carbon the increase in carbon and surface hardening may possibly cause a little inconvenience from the machining point of view; therefore, it is recommended that carbon steels of more than 0.3 per cent carbon content be preheated to about 500 C (visible red in daylight) before cutting. Alternatively, normalizing may be carried out after cutting with thicker material containing 0.4 per cent carbon. There may possibly be some chances of the oxygen-cut surfaces developing small cracks, etc., so that material of this composition always should be preheated before cutting in order to eliminate the possibility.

This cracking does not necessarily occur, but would largely depend on the shape and dimensions of the article being cut. The cracking is probably brought about in the following manner: The heating of the steel causes the cut face to expand, and this expansion is resisted by the colder metal at the back of the face. The metal at the cut face tends to be compressed by this resistance, and during cooling the compressed metal endeavors to resume its original length, but cannot without stressing the metal beyond the yield point.

The stress may be so severe as to crack material, such as high-carbon steel, that has not sufficient ductility to accommodate itself to any concentration of stress. The preheating precautions are not required for carbon steels of carbon content below 0.4 per cent or for parts that are not subjected to severe stresses in service.

Alloy steels, such as nickel, nickel-chrome, nickel-chrome-molybdenum, and high-carbon steels, should be preheated before oxygen cutting to avoid hardness of the cut faces and internal stresses that may lead to cracking.

It is important to mention that great advantages can be obtained by employing oxygen for cutting manganese steel. As is well known, manganese steel cannot be machined by the ordinary mechanical methods available to the engineer. Oxygen cutting has no such detrimental effect on steel, and perfectly smooth accurate cuts are obtainable, with no hardening of the cut surface.

Fourteen tests carried out to ascertain the effect of oxygen cutting on the tensile strength of mild steel gave the following average results:

	Oxygen cutting	Machine-tool shaping
Yield, tons per sq in.	17.50	16.50
Tensile strength, tons per sq in.	25.95	24.40
Elongation, per cent in 8 in.	21.95	23.2
Reduction of area, per cent.	59.0	58.8

It will be seen that, with oxygen cutting, ductility is not affected to any great extent, while the yield point and tensile strength are slightly increased. This is probably due to the slight toughening effect of the cutting on the surface of the metal.

In order to further investigate the effect of oxygen cutting on the ductility of the material, some bend tests were made in the following manner: A piece of mild steel 2 in. thick was cut into a strip about $^{5}/_{8}$ in. wide with oxygen cuts on both sides of the strip; the strip was then bent around a pin $^{3}/_{4}$ in. in diameter so that the cut surfaces were in tension and compression, respectively. No signs of cracking occurred until the piece had been bent through almost 180 deg.

It should not be overlooked that oxygen cutting depends on the accurate direction of a jet of gas through the depth of the metal, and that characteristically this jet will tend to take the path of least resistance. Cavities and porous spots, laminations, or slag inclusions will therefore almost certainly cause defects in the cutting due to diversion of the oxygen stream. Only good quality steel should be used, and forgings should be free from any of these defects.

Equipment for Oxygen Machine Cutting

There are several different types of oxygen shape-cutting machines on the market, but they may be divided into two classes—those that employ a templet representing the shape to be cut and those that cut the required shape direct from a drawing; some machines also embody a combination of the two systems.

The machines that cut direct from a drawing are undoubtedly very convenient and useful where only a few shapes have to be cut; for instance for repair work, where it may be necessary to cut a replacement shape, only a sketch of the original article being available. In this case, unless a high degree of accuracy is required, it would hardly be necessary to make a templet. (See Fig. 6.)

Machines employing templets are generally most suitable for quantity production when uniformity and accuracy are desired.

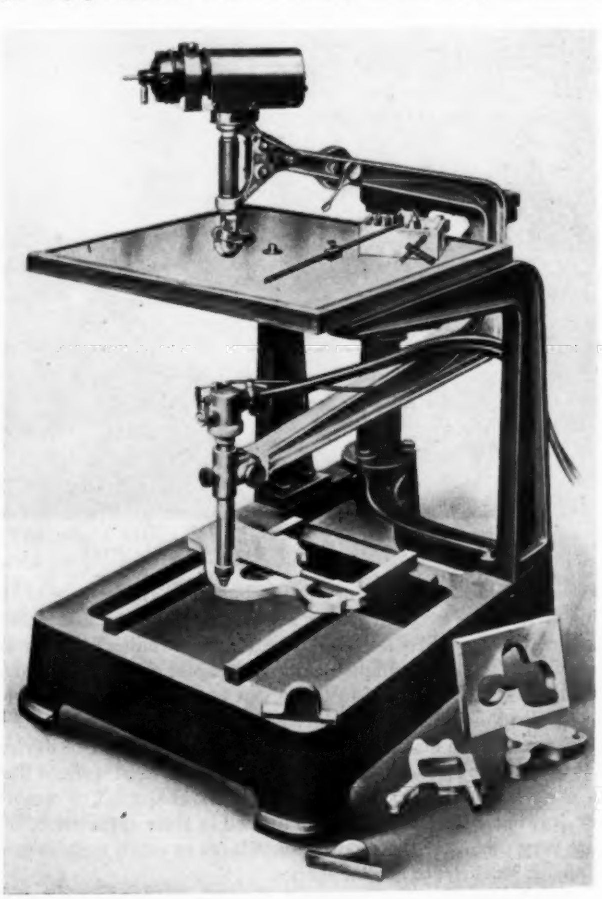

Fig. 6 Small Model of Direct Profiling Machine

Machines of this type are usually automatic, the templet-tracing device being arranged to follow the templet shape either magnetically or mechanically by gripping rollers. (See Fig. 7.) It should not be assumed that an automatic oxygen shape-cutting machine working from a templet is suitable only for quantity production; the process can be used to considerable advantage for the production of small quantities of irregular shapes. It is often asserted that the cost of making the templet is out of proportion to the job when only small quantities are required. This is probably true if the article required is only in thin plate, but as the thickness of plate increases, so the cost of making a templet decreases when compared with the cost of producing the required article by other methods. Obviously on material 1 in. thick and upward the saving by oxygen cutting is considerable, even including the time taken to make the templet.

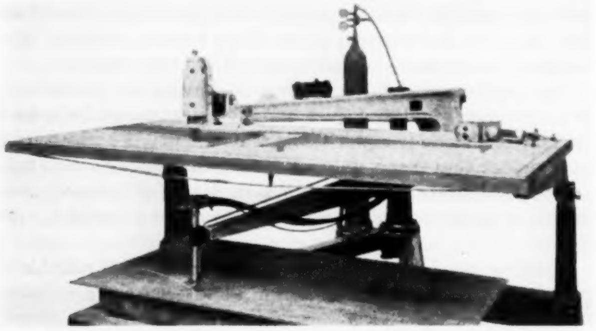

FIG. 7 DIRECT PROFILING MACHINE, SHOWING AUTOMATIC HEAD

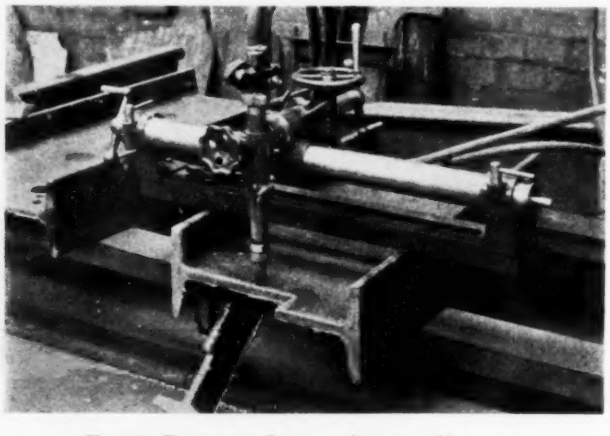

FIG. 8 PORTABLE OXYGEN CUTTING MACHINE

The templet has the advantage that it can be stored and used at any subsequent time for further production. In the case of the metal templets necessary with a very popular type of machine in Great Britain there is no deterioration due to climatic or storing conditions, wear is negligible, and the templet can be adjusted so that a very fine degree of accuracy can be obtained. Such templets also take up very little space.

Some of these machines employ mechanical guides and devices by means of which shapes that are a combination of straight lines and circles can be cut automatically without the aid of templet or drawing. Such machines are limited in their application, but are very useful for the production of large or small quantities of flanges, brackets, or similar shapes.

Apart from the vast potential applications of the automatic shape-cutting machine, there are many less obvious applications of the process which have become established in a large number of industries.

For instance, oxygen cutting in connection with constructional steel work is developing rapidly. Apart from the problem of shaping plates, gussets, brackets, cleats, reams, column bottoms, and other items, the process can be used for shaping steel joists and other sections used in this class of work.

There are several machines suitable for this purpose, some of them portable (see Fig. 8), enabling cutting to be done on site or in the stock-yard, while others are shop tools equivalent to the hacksaw, which can perform a variety of operations, such as parting off, beveling, notching, etc., after the joist has been brought into the shop. Such machines also are suitable for cutting up bar and strip plate stock. Further than this, holes now can be cut by means of a special oxygen cutting machine.

Of special interest to railway companies is a machine that has recently been introduced for parting off rails. Such a machine is extremely portable and weighs very little more than a hand cutter, but of course the cut has all the finish of a machine cut. As previously mentioned, oxygen cutting will deal with manganese steel just as easily as ordinary mild or carbon steel, and this is a decided advantage when cutting rails. Whereas it is almost impossible to drill or saw manganese rails on the track, an oxygen hole-cutting or parting-off machine will do the work easily and quickly.

There are also many machines on the market for straight and circle cutting, the variation being chiefly in the capacity of the machine. Such machines are extremely useful to shipbuilders, tank and boiler makers, etc., especially where cuts have to be made in plates that would be too big to go on the usual automatic machines. Such machines will generally cut bevel edges, so that if the article is being cut for welding it can be passed direct to the welders from the cutting machine.

Oxygen cutting machines are not subject to the strains and excessive wear of the mechanical tool, and should therefore have a fairly long life if properly attended to. Compared with the extraordinary saving that often can be made by employing this process in place of other methods, the cost of the equipment is very low. According to size an oxygen shape-cutting machine will cost between £75 and £1500 ($275 and $5500),[2] the cheaper machines being suitable for the small workshop, while the higher priced ones are machine tools fitted with every possible refinement and capable of producing a complete locomotive sideframe at one setting.

Portable appliances, such as those described for constructional and railway work, do not cost more than £30 or £40 ($110 or $147), while appliances for hole cutting and parting off rails are at the bottom of the price scale at £12 to £15 ($44 to $55).

It is usual in the case of oxygen cutting machines which are installed in the workshop as permanent production units, to convey the oxygen at suitable pressure by pipe lines and cylinders located outside the workshop in a convenient position for the replenishment of supplies. Other gases such as acetylene or coal gas also can be piped to the machine from storage, so that there need be none of the inconvenience or risk of having cylinders or acetylene generators located in the machine shop.

SPEED AND QUALITY OF CUT

As mentioned before, the chief features that make oxygen machine cutting so totally different from hand cutting are the rigidly held cutter and the uniform rate of travel, resulting in a remarkably smooth and accurate cut, which is, moreover, produced at a much faster speed than hand cutting.

---

[2] In converting the pound sterling into the American dollar, the exchange rate of £1 = $3.67, prevailing on May 12, 1932, has been taken. The shilling is taken as equivalent to $18^1/_2$ cents and the penny as $1^1/_2$ cents.

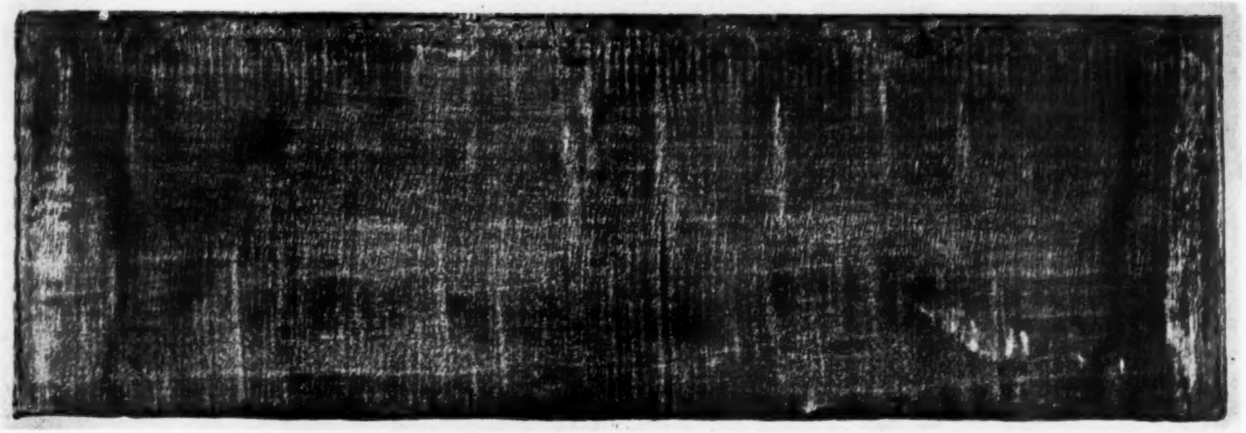

FIG. 9 FACE OF CUT MADE AT NORMAL SPEED

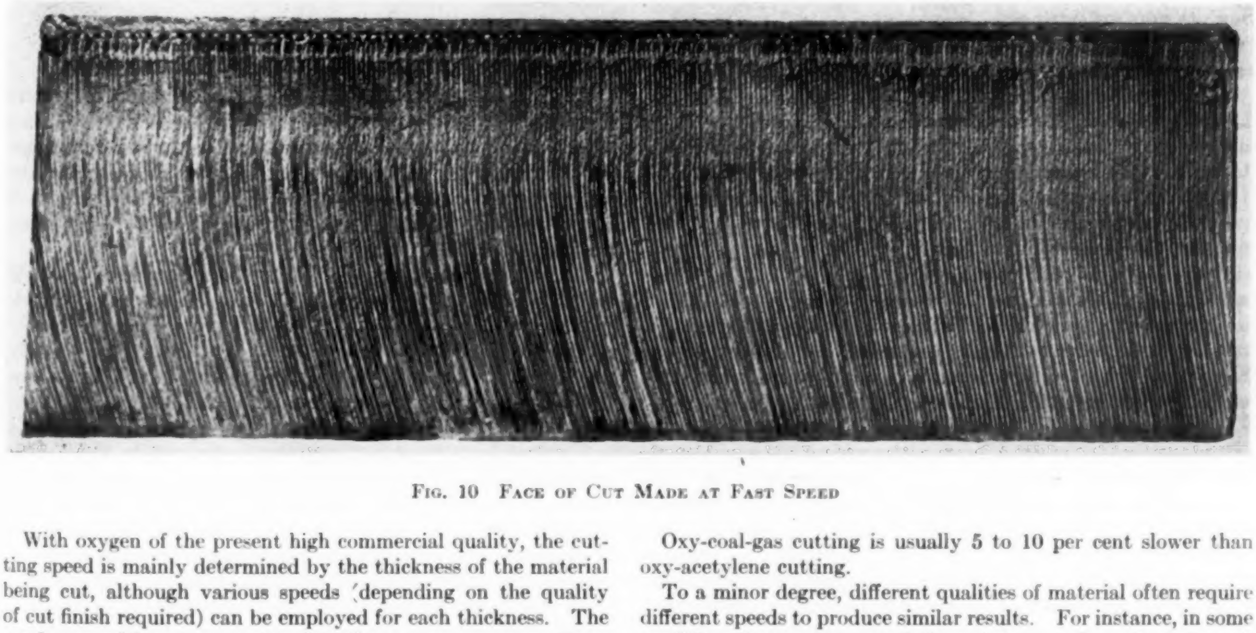

FIG. 10 FACE OF CUT MADE AT FAST SPEED

With oxygen of the present high commercial quality, the cutting speed is mainly determined by the thickness of the material being cut, although various speeds (depending on the quality of cut finish required) can be employed for each thickness. The cutting speed is not proportional to the oxygen pressure; 10 or 15 per cent increase in oxygen pressure may allow the speed to be increased 40 or 50 per cent on thin material, but on thick material it may be necessary to increase the pressure 30 per cent to obtain a 20 per cent increase in speed.

If the article is to be machined after cutting, a roughing cut can be made at a fairly fast speed, but if the article is to be used as produced, a good smooth finish is generally desired, in which case it is advisable to use a slower speed. Straight and large circular cuts always can be made at a faster speed than profile cuts, as shape cutting to a templet often involves abrupt changes in direction and a fast speed will cause the cut to drag, so that the bottom of the cut may not register quite accurately with the top. Fig. 9 shows the face of a cut made at normal speed and Fig. 10 at fast speed. The following table shows typical oxy-acetylene cutting speeds:

	Thickness of steel, in.																
	$^1/_2$	1	$1^1/_2$	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Normal speed, ft per hour.......	60	46	40	35	26	23	22	21	21	20	20	19	18	16	15	14	14
Fast speed, ft per hour.......	90	65	55	50	40	35	30	25	—	—	—	—	—	—	—	—	—

Oxy-coal-gas cutting is usually 5 to 10 per cent slower than oxy-acetylene cutting.

To a minor degree, different qualities of material often require different speeds to produce similar results. For instance, in some qualities of manganese steel the cutting speed can be increased to almost double the speed required for cutting mild steel in order to produce results similar to those usually obtained on mild steel of the same thickness.

The speed attainable in oxygen machine cutting facilitates increased production in comparison with other shaping methods, such as sawing, slotting, or shaping. This applies especially to large shapes which are often drilled out of plates, afterward being smoothed up to the required size by slotting or milling.

To give an example, concerning locomotive sideframes, one firm using an oxygen cutting machine is now able to produce a complete locomotive sideframe in 6 hours, compared with 30 hours by the previously used mechanical shaping methods. This example is for ordinary frames $1^1/_4$ in. thick; when bar frames about 4 in. thick are being dealt with, the saving is increased proportionally.

FUEL GAS

An oxygen cutting machine requires to be supplied with two gases, oxygen and a fuel gas. The function of the fuel gas is to provide the necessary heat value in the flame which is used for

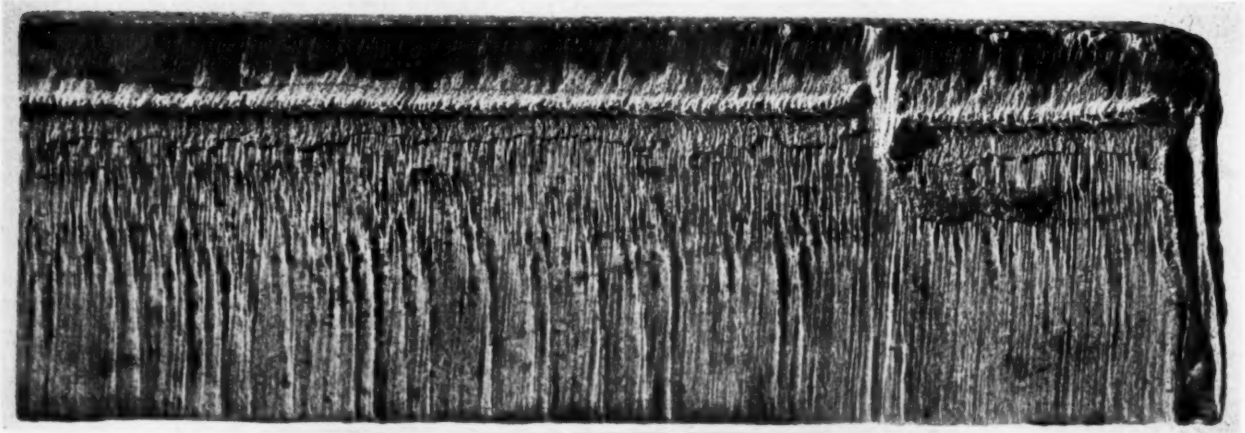

Fig. 11 Bad Cutting as Result of Cutter Nozzles or Jets in Poor Condition

preheating prior to commencing the cut and for maintaining the requisite heat for cutting.

Three fuel gases are, as a rule, commercially available—namely, acetylene, coal gas, and hydrogen; and the question not unnaturally arises, which is the best to use? No hard-and-fast ruling can be made on this point, as the choice of a suitable fuel gas will probably be decided by the conditions under which the machine is to be used.

From the point of view of convenience, coal gas is often preferred, as not only is coal gas usually available in an engineering shop, but it provides sufficient heat for the process consistent with economy and a fair cutting speed. The oxy-coal-gas flame is not easily mishandled, and is therefore specially suitable for use by comparatively inexperienced operators. It is especially suitable for use when cutting thin material, say between $^1/_8$ and 3 in., and its limit of usefulness is generally considered to be reached on material 8 in. thick.

A popular alternative to coal gas is acetylene; this has the advantage that it enables a faster cutting speed to be employed, while the oxygen consumption is generally somewhat less. The flame may be a little more difficult for an inexperienced operator to adjust, and there is a risk in such cases of burning the metal, especially on thin material.

Acetylene is available in two forms: that produced by a generator on the spot and that compressed in cylinders. Generated acetylene is cheaper, but a disadvantage is that a generator is not very suitable for intermittent operation, and this not infrequently leads to a considerable waste of gas. The acetylene generator cannot be housed inside a factory building, and an outside shed or other covering is usually necessary. Water supplies and drainage and means for disposal of carbide sludge also must be available. Compressed acetylene has the advantage that there is no mess and there is no waste when not in use. If sufficient supplies are kept in hand, it is always ready when required, and so is suitable for intermittent operation.

Acetylene is suitable for cutting all thicknesses up to 18 in., but if not skilfully employed, is likely to produce too much heat for very thin plate.

Hydrogen is an excellent fuel gas for cutting, is similar to coal gas in its application, and has the advantage that it is equally suitable for cutting thin or thick sections. Its employment usually is prohibited by the fact that it is only available compressed in cylinders, and its freightage makes it expensive unless it is employed near a compressing station. It is not so easily obtainable as coal gas or acetylene.

Tests have proved that, provided the flame is properly regulated, no difference in depth or intensity of effect on the cut metal is noticeable whatever fuel gas is employed.

Cost of Cutting

The power required to drive a mechanically operated machine is usually supplied by a motor of $^1/_8$ to $^1/_4$ hp, so that the running costs are extremely small, the maintenance being correspondingly low. Therefore, the main factors entering into the cost of cutting are the oxygen, fuel gas, and operator's time. Of these the gases form the largest item; the operator's time usually costs much less than the gases.

Assuming oxygen to be available at the cutting machine at the rate of 25 shillings ($4.58) per 1000 cu ft and the proportionate quantity of fuel gas at about one-quarter of this amount, and the operator's time to be 1 shilling 6 pence (27 cents) per hour, the average cost of cutting per inch thickness per foot run of material varies from $1^1/_2$ pence ($2^1/_4$ cents) on thin material (say 1 in. thick) to $3^1/_2$ pence ($5^1/_4$) cents on material about 14 in. thick.

The first foot of cutting is generally assumed to cost a little more than this, as the time and the gas involved in preheating the metal immediately prior to cutting have to be considered. As the thickness of the material increases, this preheating cost becomes a considerable item when compared with the cost of cutting per foot run. Whereas the cost of preheating on material 1 in. thick could almost be neglected, the preheating cost on material about 14 in. thick may amount to as much as 6 pence (9 cents).

The foregoing figures are of course averages taken over a number of cuts under varying conditions; and variations in the cost of gases, operator's time, etc., will affect them to a slight extent. These figures of course refer only to running costs; idle time, depreciation of machine, setting up costs, etc., must be added to obtain a real cost figure.

It is not usually necessary to clamp down material that is being cut with oxygen; the material has only to be laid on the cutting table supports. Therefore the time taken to shift the material between cuts is reduced to a minimum.

Rigid clamping of work to be cut might result in buckling and distortion due to expansion of the metal while cutting, but there is no reason why this expansion should not be controlled by means of suitable stops.

Apart from the low cost of the actual cutting operation, considerable economy in material can be effected. Many jobs are so shaped that by careful planning one can be cut within the other; in fact, it often is possible to make arrangements so that part of the cut on one shape suffices for part of the next shape to be cut.

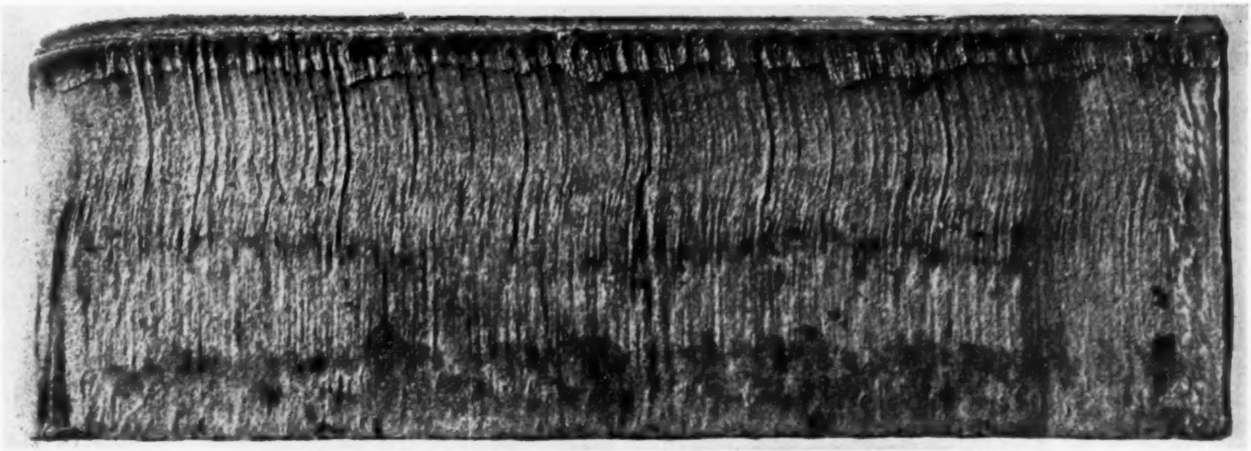

Fig. 12 Bad Cutting as Result of Cutter Nozzles or Jets in Poor Condition

Apart from this method of working one job in with another, it will be found that the scrap left over from one job can be utilized for the production of smaller shapes. For instance, the pieces cut from the crankshaft shown in Fig. 2 are found very useful for toolroom blocks. Of course, the only material that really is scrap and unrecoverable is that discharged from the small kerf left by the cutting jet, and the width of this varies from about $^1/_{10}$ in. in thin material, say $^1/_2$ in. thick, to about $^1/_4$ in. on 8-in. and 10-in. material.

Practical Considerations

In the same way that a mechanical tool will not give good service unless it is maintained in good condition, with sharp tools and operated intelligently, so it is necessary to exercise the same care with an oxygen cutting machine. The best oxygen cutting machine in existence will not produce good smooth cuts unless the cutter nozzles or jets are kept in good condition, free from burrs or particles of dirt or oxide, which will tend to partially obstruct or divert the gas stream. Some idea of the bad results caused by dirty jets will be gained from Figs. 11 and 12.

There has been a tendency, largely due to earlier experience gained with the hand cutter used as a scrapping tool, to regard the oxygen cutting machine as nothing more than a roughing process, with consequent carelessness in fixing the machine suitably. Fortunately, the true value of the process as an accurate and reliable production method is now realized, but even now it is necessary to point out that machines should not be placed in positions where they are subject to floor tremors or vibration caused by the operation of nearby hammers, punches, presses, or guillotines (shears). The vibration will be evident in the cut, and the operator will find it impossible to produce the smooth clean cuts that are characteristic of good machine cutting.

The manufacturers of oxygen cutting machines have now done a considerable amount of experimental and research work in connection with the correct oxygen pressures and cutting speeds suitable for various thicknesses of material and charts, and these and other details necessary for the operation of the machine are supplied by the makers. Provided the operator reads his instruction book and carries out the instructions, there is no reason why he should not be able to produce good cuts right from the start. The only item that is left to the operator's judgment is the adjustment of the cutter to produce the correct heating flame, but here again charts usually are provided, and a little practice soon enables the operator to judge the correct flame for any particular class of work.

Cutting must start from an edge, and when cutting a quantity of shapes from a piece of steel plate, this is quite easy. The first cut being started from the edge of the plate, subsequent cuts are started from the hole left by the previous cut. If it is necessary to cut a hole within a shape or a piece of plate, such as the hole in a flange or spring buckle or a manhole in a piece of boiler plate, it is necessary to drill the hole for starting. A hole $^3/_8$ in. or $^1/_2$ in. in diameter is usual, but the larger the hole the easier it is to start; $^3/_8$ in. is suitable for material 1 in. thick, but anything from $^1/_2$ in. to $^3/_4$ in. would be desirable on material over 6 in. thick.

Blowing through or piercing the plate by means of the cutter itself is sometimes done, but this is recommended only up to 1 in. thick. Greater thicknesses than this can be pierced with the hand cutter, but it is not recommended that this be done with the machine, owing to the risk of burning the nozzles through particles of molten metal or slag being blown upward; moreover, some of the slag is likely to adhere to the nozzle, thus diverting the oxygen stream and causing bad cuts. Starting on round surfaces, such as the edges of forged slabs or round bar, sometimes causes difficulty. To minimize this difficulty a piece of iron welding wire should be applied to the point where the cut is to be started. If this is done, with the heating flame alight, the wire will melt and a blob of metal will adhere to the material, quickly forming an incandescent spot, which will start burning readily when the cutting oxygen is turned on.

Industrial Applications

The remarkable result obtainable with the oxygen cutting process has led to its adoption as a recognized production stage in most of the industries employing steel plate or forgings in the course of manufacture of their products.

The ability of the cutting machine to produce intricate shapes from steel plate or slabs of almost any thickness has induced many manufacturers to dispense with forgings, with a corresponding decrease in overhead charges, machining, and waste-material costs. Moreover, steel plate or slab forgings are useful stock, and factories not possessing their own forge are able to produce special jobs at short notice with the oxygen cutting machine.

As an instance of this class of work, a firm employing an oxygen cutting machine now produces a brake arm in 10 min that previously took a smith and striker $2^1/_2$ hours at 2 shillings 6 pence (46 cents) per hour to forge, and after that the forging had to be machined. The oxygen-cut article is not machined, and the scrap metal can be used, whereas previously the articles were cut off from the solid bar and bored out, leaving no usable metal.

In another instance concerning the cutting of two mast rings out of material over 9 in. thick, the rings were $4^{1}/_{2}$ ft over the lugs, and it is believed that the wage cost in forging would have been about £36 ($132), whereas the oxygen cutting cost was about 70 shillings ($12.83).

Apart from the possibility for some classes of work of substituting forgings by oxygen cutting, parts which are better forged can often be produced more economically by leaving intricate shaping to the cutting machine. The ship stern frame shown in Fig. 5 is an instance of this class of work.

Some firms are cutting blanks to profile prior to shape forging, notably for locomotive components.

One of the greatest fields of development for the oxygen cutting process, in conjunction with oxyacetylene or electric welding, is the fabrication of parts to substitute castings; a cutting machine is indispensable to firms undertaking this class of work.

Fabricated parts compared with castings have many advantages; for instance, no blowholes or sponginess of metal are encountered. More reliable finished parts are obtained, pattern-shop charges are eliminated, and the necessity of carrying heavy stocks is obviated, on account of the fact that any part can be manufactured at short notice. The designer is not restricted by limitations of casting, steel fabrication affording him considerable latitude and scope. Changes in design, alterations, and additions can be made at any time; generally speaking, fabricated parts are lighter than corresponding castings; the reduction in weight lessens transport and freightage costs, while the danger of breakages occurring in transit abroad is considerably reduced.

A printing-machine manufacturer who is now fabricating his machines entirely with steel claims that owing to the additional strength and rigidity of the machine it would now stand up to a much higher speed than hitherto obtainable.

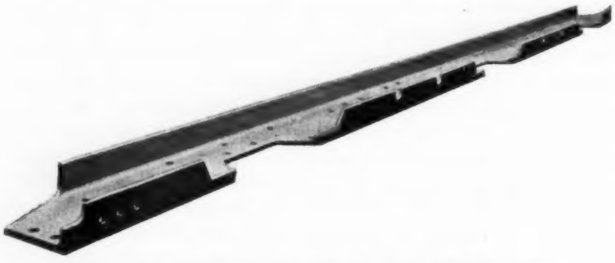

Fig. 13 Side Frame Cut on Universal Machine

Electrical-equipment manufacturers have adopted fabrication to a very large extent. Some of the parts that they now are fabricating are a-c machine sideplates, stator and alternator frames, wrapper plates, rings for armature end shields, rotor end plates, foundation plates, switch covers, switch cubicles, and bearing housings.

A particularly noteworthy job recently executed is the cover for a large oil-immersed circuit-breaker switch, measuring over 5 ft in diameter, weighing about 1 ton, and tested to a pressure of 500 lb per sq in.

Apart from the savings resulting from the substitution of castings and forgings by oxygen cutting, there are many instances where oxygen machine cutting replaces operations previously carried out by drilling, sawing, and shaping, with considerable reduction in production time and cost. The instance of locomotive frames given previously is a case in point. The ability to cut plain or intricate profiles with equal facility enables many jobs to be done that otherwise could not be undertaken. Another instance can be given of a firm cutting slots in large-diameter steel pipes, with a tube thickness of $1^{1}/_{4}$ in. The cost by oxygen cutting works out at $2^{1}/_{4}$ pence ($3^{1}/_{3}$ cents) per slot, whereas the cost previously was 2 shillings 3 pence (41 cents).

The railway companies and railway-equipment manufacturers oxygen-cut large quantities of spring buckles. These are generally cut from bar, and what was originally a fairly expensive forging, which had to be machined, is now produced by the oxygen cutting machine and taken direct to the smith's shop to have the spring leaves fitted. This is some indication of the consistent accuracy that is obtainable by oxygen cutting.

Many machines are in use for cutting for die work, forgers and stampers finding it a great advantage to be able to rough out the centers of their stripping dies by this method.

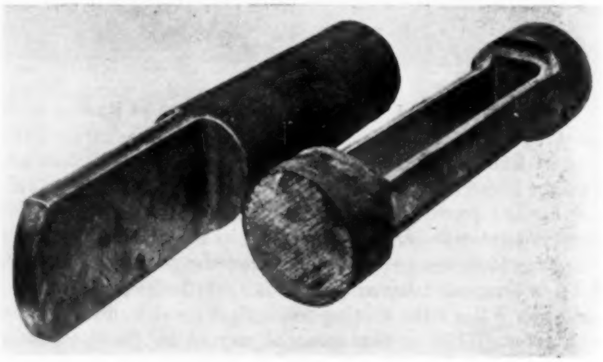

Fig. 14 Round Bar as Shaped for Turnbuckles, Yoke Ends, Eyes, Forks, Etc.

The use of oxygen machine cutting is not limited to cutting from flat steel plate or forgings; it is quite common practice to employ the process for shaping brackets, links, and similar parts on stock angle, tee, and channel sections. (See Fig. 13.) Round bar also can be employed with advantage for many jobs, such as lifting eyes, turnbuckles, connectors, etc.; a square end can be cut on a round shaft much quicker than it would be forged. (See Fig. 14.)

In many engine shops it is common practice to employ the process for cutting out the ends or jaws of connecting rods after they have been forged. On this class of work there may be considerable variation of thickness throughout the cut.

Ship repairers owning oxygen cutting machines have used them very effectively on urgent ship repairs. During the winter gales a cargo boat put into a South Coast yard with damaged steering gear. To have obtained from the Midlands the large forgings that were required would have meant several days' delay, but the oxygen cutting machine was brought into service and the parts were produced in about two days.

Another job recently recorded was the cutting out of certain sections of a three-throw crankshaft; the sections had faulty shaft extremities. The crankshaft weighed 8 tons and was in three sections, the shaft and pin diameter was 14 in., and the web thickness was 9 in. Three cuts through the 14-in.-diameter shaft were made at various places, each cut taking 7 min, whereas $2^{1}/_{2}$ hours would be required for sawing.

To remove the pieces of shaft remaining in the web, cores were cut out, leaving shells approximately $^{3}/_{8}$ in. thick, which could easily be withdrawn, leaving the web undamaged.

MSP-54-11

Researches on Steels and Forgings for Greater Density, Machinability, and Durability

By FRED W. CEDERLEAF[1] AND W. E. SANDERS,[2] MUNCIE, IND.

F. W. CEDERLEAF

In this paper the authors give details of a research carried out in an endeavor to find means of improving the machinability of gear blanks upset from bar steel, as well as the durability of the finished gears after heat treatment. The investigation shows that a steel of coarse grain upsets into a denser product than one of finer grain, and that this denser material is more readily machined, and with much less resultant tool wear. Specifications are given for the steel finally adopted and also details of its heat treatment, as well as figures from dynamometer tests which indicate a longer life for the wearing surfaces of the teeth on the gears made therefrom, and a marked decrease in pitting and granulation.

W. E. SANDERS

THE purpose of this paper is to deal with the improved machinability and durability obtained by the greater working or compressing of steel in the process of forging; and also to study the various steel characteristics affecting the development of greater density in forgings. The result of this working or compressing is referred to as density, but in the sense of greater compression rather than that of specific gravity.

The steels used in these experiments, other than those specifically mentioned, were S.A.E. 2320, 4615, 5140, 1315, 3140, 3240, 2515, and 2520.

I—THE THEORY OF POROSITY IN DEEP-ETCHED FORGINGS

Nearly every one having to deal with steels and forgings has at some time or other cut pieces in two, polished the faces and etched them, and after etching has found a number of tiny cavities or voids occurring at various places, sometimes more prominent at the center or core and sometimes near the surface. The location, nature, and extent of these voids or cavities, as brought out by the etch test, determine the degree of density of any forging. The authors' theory is, substantially, that in forging it is possible to produce internal slipping or tearing of the fibers in the steel.[3,4,5,6,7] This slipping, or tearing, is indicated by the voids or cavities brought out by acid etching. Some previous papers on the subject attribute the general porosity in etched forging sections entirely to the quality of the steel, this quality being determined by the amount and nature of the non-metallic substances present.[8] With this the authors cannot quite agree, although they recognize that sulphur and other impurities existing in the steel to too great an extent will make the grain appear coarse or open. In addition to this, however, they are endeavoring to bring out the fact that the largest percentage of openness or coarseness is due to torn fibers; also, that there are some steels of the same analysis, containing approximately the same amount of non-metallic impurities, which after proper forging do not show this porosity.

Fig. 1 represents an etched forging section in which it is believed that non-metallic substances are entirely responsible for the appearance. On the other hand, Fig. 2 is a typical example in which it is thought that forging has played an important part in developing the open etched condition. Fig. 3 exhibits the same characteristics observed in Fig. 2 at ten times higher magnification.

Having observed a large number of etched forgings in which the porosity or density was almost negligible in some and quite pronounced in others, the authors were inclined to associate these conditions with the variables in machinability in the machine shop.

About this time, in machining a number of 3.50 per cent

---

[1] Works Manager, Muncie Products Division of General Motors Corporation, Muncie, Ind. Mr. Cederleaf was born in Jonkoping, Sweden, in 1889, and came to the United States at the age of three. He was graduated from the Central High School of Detroit, Mich., after which he completed the mechanical-engineering course at the Central Tech of the same city. He then served an apprenticeship in tool and die making and designing at the Burroughs Adding Machine Co., of Detroit, after which he successively held the following positions: Asst. Supt., Boston Pressed Metal Co., Worcester, Mass.; Works Mgr., Ziegler Mfg. Co., Alexandria, Ind., and Metal Specialty Co., Cincinnati, Ohio; Ch. Engr., Sparks-Withington Co., Jackson, Mich., and Supt. of Tool Division, Olds Motor Works, Division of General Motors Corp., Lansing, Mich. He is a member of the S.A.E. and A.S.S.T.

[2] Plant and Metallurgical Engineer, Muncie Products Division of General Motors Corporation, Muncie, Ind. Mr. Sanders received his education at Muncie High School, later taking courses in electrical, heat, and railway engineering. He then entered the employ of the T. W. Warner Co., Muncie, Ind., as chief electrician. In 1919 he became electrical engineer for the Muncie Products Division and was put in charge of construction under the Tarrytown (N. Y.) Engineering Division. In 1921 he was appointed chief electrician of the new plant, and in 1923 was made plant engineer, with the duties of process engineering. In April, 1931, he was promoted to his present position. He is a member of the A.S.T.M., A.E.S., and the A.S.S.T.

Contributed by the Machine Shop Practice Division and presented at the Semi-Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27–July 1, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

nickel (S.A.E. 2315) gears, it was noticed that some of them, after being drilled and broached, showed a very smooth finish in the hole, broaching with considerably more ease than others that had been forged and annealed at the same time. Some of the gears tore badly in the drilling. The broach, being hydraulically actuated, pulled very unevenly, showing that greater energy was required to force it through, and the holes were torn and very rough, as shown in Fig. 4.

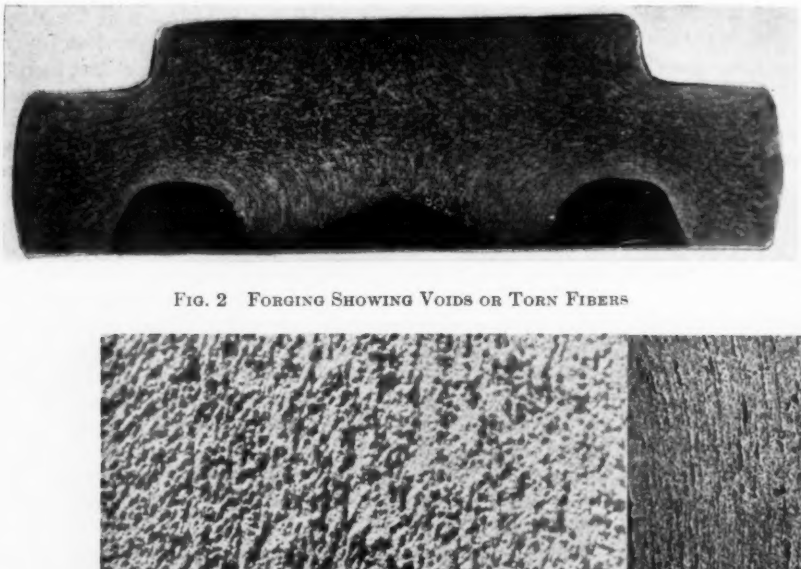

Fig. 2 Forging Showing Voids or Torn Fibers

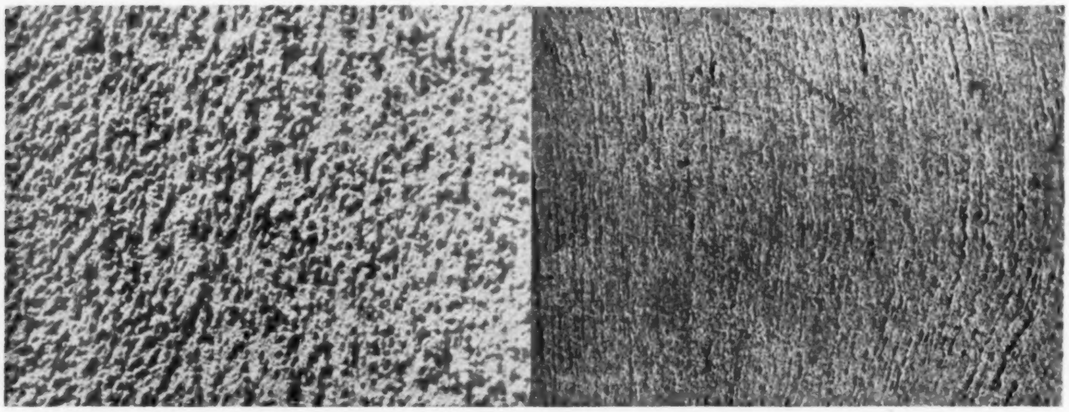

Fig. 3 Improved Structure by Greater Compression

Characteristics Observed in Fig. 2 at 10×

Improved Structure by Greater Compression

After studying these forgings, it was found that some of them had round corners while others had square ones. This indicated a difference in the filling of the die at the time the pieces had been forged. It was then found that by machining a round-cornered, or unfilled, piece a torn condition in the hole was produced, but when machining a square-cornered, or filled, piece a very smooth surface was obtained. The same procedure was repeated several times with both filled and unfilled forgings, and the same results were obtained. This suggested a study of forge-shop conditions.

II—Forging Practice and Its Relation to Density

Investigating conditions in the forge shop, it was found that a higher and more uniform temperature, namely, 2150 F, must be maintained, and that this temperature must not vary more than 100 F; the dies must be properly designed so that in no operation would a flash be created which would minimize the compressing of the metal by the dies in the subsequent operations; and the flash must be longitudinal with the heading tool, or there must be a flash pocket to prevent the metal from flowing between the dies so that the compression would not be on the flash but on the forging.

After correcting the dies and forging temperatures, a marked improvement was found in machinability. The next thing was to determine whether, by filling the dies and controlling the flash, maximum machinability had been attained, and whether anything further could be accomplished by compression of the metal. It was also desired to learn the actual effect of the forging temperature on machinability. As far as could be determined, the only effect accomplished by proper heating for forging was that of permitting satisfactory flow of the metal to fill the die.

To determine further whether still greater compression would improve machinability, pieces were upset, reheated, and struck several blows by a board hammer. These pieces were then used for machinability tests. Like pieces were also upset, reheated, and struck several blows by the hammer; the flashes were then ground off and the pieces reheated and again put under the hammer, and the same operation repeated the third time. In each of these tests it was found that the repeated hammering or compressing of the metal improved its machinability. The pieces which had been repeatedly heated and hammered showed upon etching that the original cavities had not been entirely closed.

However, there was an evidence of adhesion at the cavity surfaces, but not of cohesion. This confirms Emil Gathmann's statement[9] to the effect that rolling of an unsound ingot can never result in more than intermittent adhesion of the metal at the piped or blowhole portion, and cohesion, not adhesion, is necessary for strength and reliability in any portion. It has been shown that it is only possible to effect reasonable adhesion of the original cavities produced in the first forging by further hammering and compression. The next thought was to study the characteristics of the steel prior to forging that might produce more ductile fibers, thus promoting flow of the metal without tearing.

This suggested experiments having as their object a coarsening of the structure of the forging bars prior to heating for forging. It was decided to accomplish this by annealing at high temperatures. A bar of 0.50 carbon, 1.00 chromium steel was selected which had a medium-fine structure in the rolled condition. Forgings were made from one end of this bar, after which the remainder was cut into lengths suitable for making the same kind of forgings. These pieces were then annealed by furnace cooling after soaking for one hour at 1650 F. Half of these forging lengths were then upset into forgings like those which had been produced from the original bar. The remaining pieces were then reannealed by furnace cooling from 1750 F after soaking one hour, and were then upset into the same kind of forgings. Microscopic specimens, prepared from the bars in each group before forging, showed the structure to be coarsened considerably after each anneal.

The three groups of the forgings were then cut and etched. Typical examples of each group are shown in Fig. 5, *A* representing the structure of the forging made from the untreated bar; *B*, after the first anneal; and *C*, after the double anneal. It will be observed from this figure that there is a progressive decrease in the amount of torn fibers from *A* through to *C*, and a like increase in the continuity of the flow lines. The increased density of forgings *B* and *C* made it necessary to etch them 10 minutes longer to bring out the flow lines. This experiment is significant in that it suggested that a coarse structure has more ductile fibers, leading to further research on steels which are inherently coarse-grained.

III—Relation of McQuaid-Ehn Grain Size in Steel to Density in Forgings

It is desirable at this point to explain the meaning of inherent grain size, or, as it is commonly spoken of, the McQuaid-Ehn grain size. This is the grain size which is developed in steel when it is subjected to carburizing at 1700 F for a minimum of eight hours and allowed to cool slowly. This procedure brings out a carbide network in the case outlining the grain boundaries, which, when examined under the microscope at 100 magnification, shows the number of grains per unit area. This number, or the size of the grains at the specified magnification, is compared with certain standard charts prepared for the purpose of rating the grain size of any particular lot of steel. An example of one of these charts is shown in Fig. 6. For instance, if a sample is carburized as stated above and if upon examination it is found to look very much like photomicrograph No. 3 in Fig. 6, this steel would then be given a McQuaid-Ehn grain-size rating of No. 3.

In view of the previous statements in regard to the higher

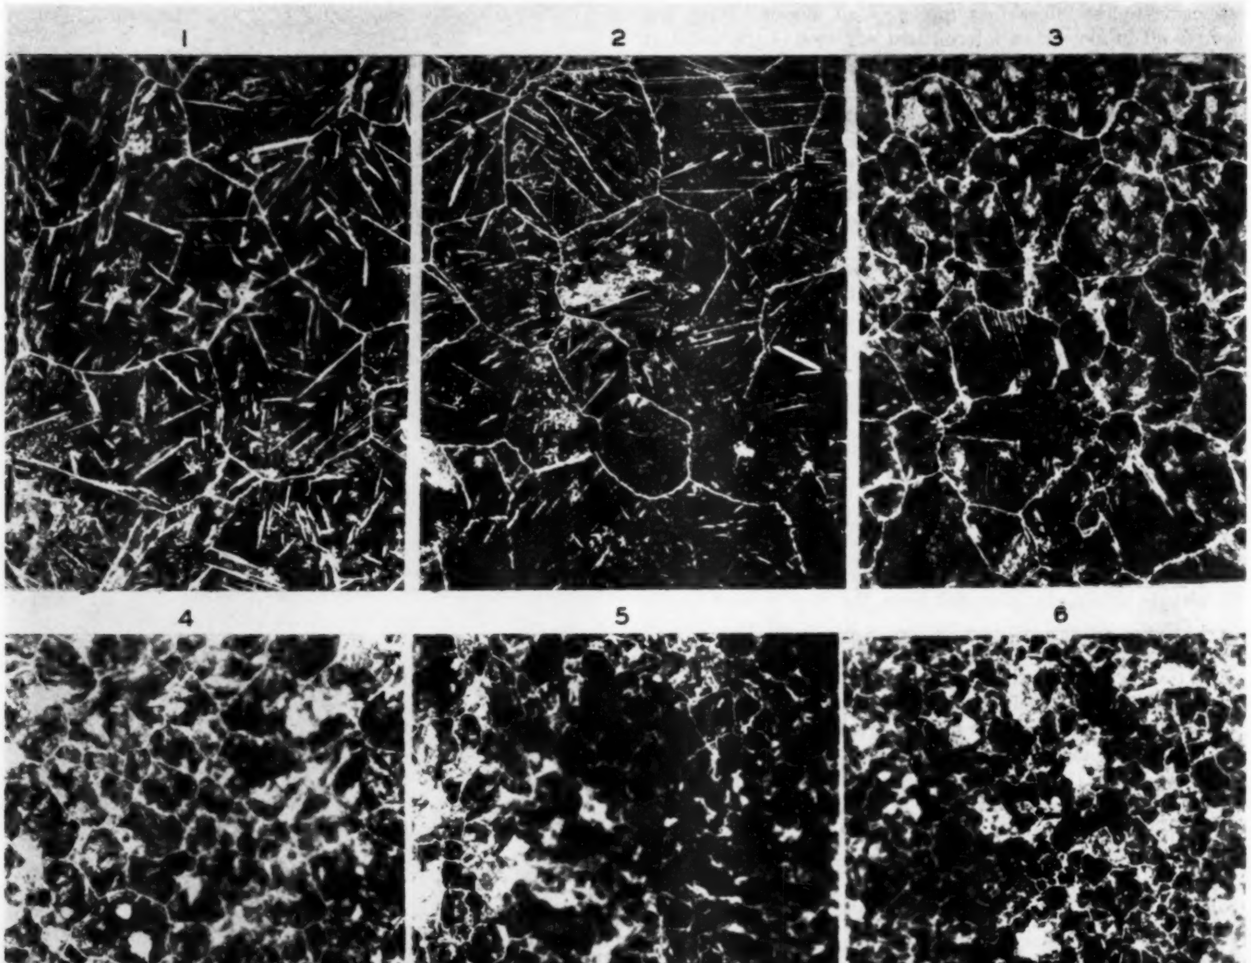

Fig. 6 The McQuaid-Ehn Grain-Size Chart (×100)

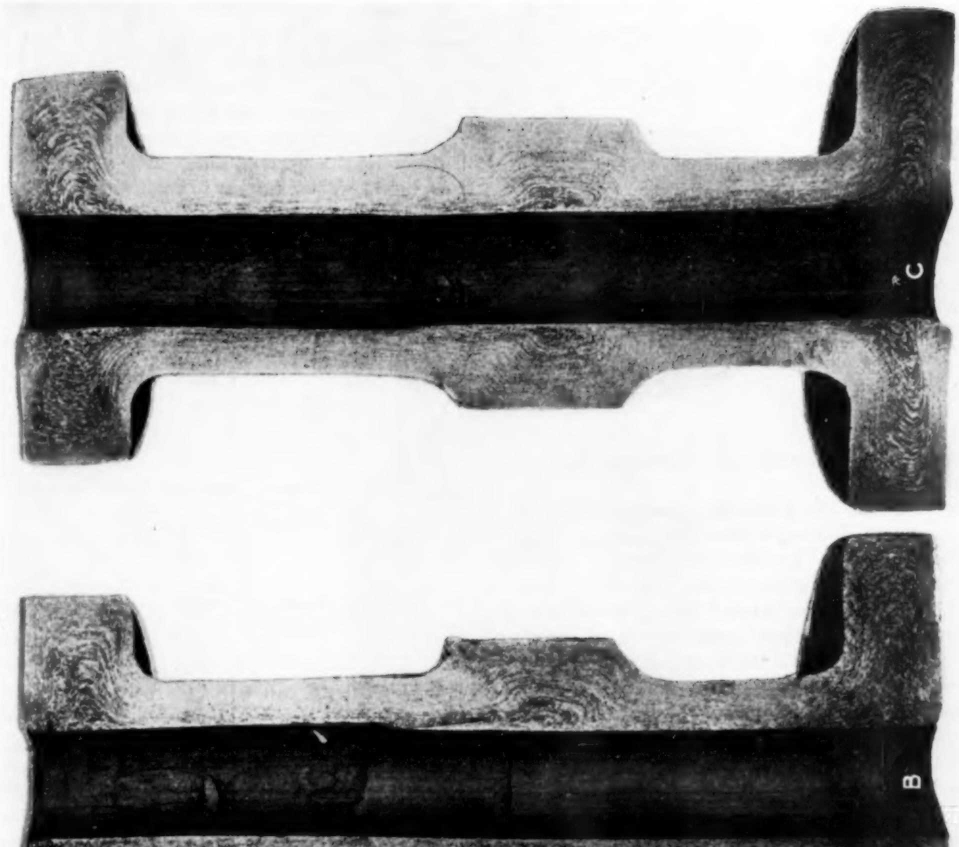

FIG. 7 EFFECT OF GRAIN SIZE IN FORGINGS

ductility of the coarser structures as produced by high annealing, it was thought advisable to investigate a variety of steels having different McQuaid-Ehn grain sizes. This was done on the assumption that the coarser-grained steels would exhibit forging properties different from those of finer-grained steels. Arrangements were made at this time with the steel companies to furnish a few bars having McQuaid-Ehn grain-size ratings from 4 to 9. These tests were made to determine the effect, if any, of the grain size of steel on upsetting. The bars were heated to 2100 F and different-sized upsets were made on the end of the bar in ratios of $1^1/_2$ to 1, in $^1/_2$-in. steps, up to 7 to 1. It was noted in these tests that the coarse-grained steels were more ductile and did not tear in upsetting, while the finer-grained steels tore and became more porous. At this time two forgings were received from different gear makers. These were cut in two and etched. One of them showed a very dense structure, while the other had porous sections with torn fibers. The one having a dense structure was rated a coarse grain, and the other a fine grain. Grain-size tests were made on different heats of steel in stock, and it was found that these varied from 4 to 8. The bars of coarse-grained steel were upset and again checked, all showing dense structures. This research proved that the fibers were more ductile in the coarse-grained steel than in the fine-grained, and that these more ductile fibers afford greater density in the forging.

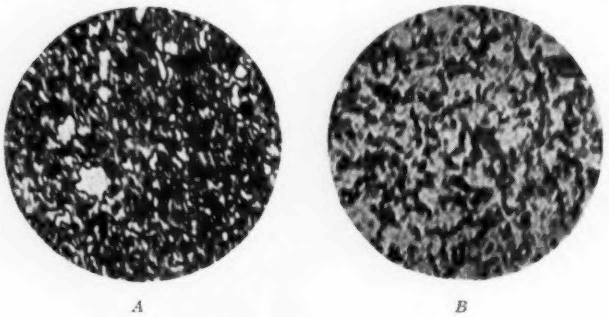

Fig. 8 Photomicrographs of Filled and Unfilled Forgings

A good illustration of the difference in upsetting fine- and coarse-grained steel can be seen in Fig. 7. Here bars of three different grain sizes, namely, 4, 6, and 7, were upset into cluster-gear forgings. *A*, representing the No. 7 grain size, shows tearing in the piercing of the hole as well as tearing of the fibers in the upsets; *B*, representing the No. 6 grain size, denotes less tearing in the hole, with less tearing of the fibers and slightly greater density; while *C*, representing the No. 4 grain size, shows a clean, well-pierced hole with very little, if any, tearing of fibers and much greater density.

It will be noted from these photographs that the ductility of the fibers of the coarse-grained steel not only makes it possible to obtain greater density of the metal in upsetting, but also permits piercing of smaller holes of greater depths or lengths.

A larger quantity of steel of the coarse-grained variety, namely, 4 to 6, was then obtained, from which forgings for test gears were made. For test this steel was cast into 23-in. ingots. It was noticed that the forgings were materially improved, but there was still some evidence of torn fibers. It was then that the authors began to consider the ingot size from a different angle, recognizing the fact that a smaller-sized ingot, with fewer fibers over a given area to be controlled or made ductile, might lead to further improvement. To substantiate this hypothesis, arrangements were made to have a test run on steel of the coarse-grained variety, namely, 4 to 6, cast in different-sized ingots. The ingot molds were all of the Gathmann type: big-end up, fluted molds, with hot tops.

One heat of steel of the 4-to-6-grain size was cast into 12-, 17-, 19-, 20-, and 21-in. ingots. Another heat was made and cast in 23-, 26-, and 28-in. ingots. Bars were rolled from each of these ingots and tests made much the same as described heretofore on the upsets used for showing the effect of grain size, with the exception that greater steps were taken between upsets. The best results were obtained with a No. 4 grain size and a 19-in. ingot. Then, further to confirm this test, a large number of gear sets were forged from steel having a No. 4 grain size which had been cast in 19-in. ingots, the object being to use some of these forgings for etch testing and others later for annealing, machining, hardening, and dynamometer tests for durability.

Being fully aware of the more or less prevalent idea that fine-grained steels have practically the same values as coarse-grained steels for the yield point, tensile strength, and elongation, but that fine-grained steels are tougher, have higher impact values, less distortion in heat treatment, and wider hardening ranges, the authors naturally proceeded with this research on

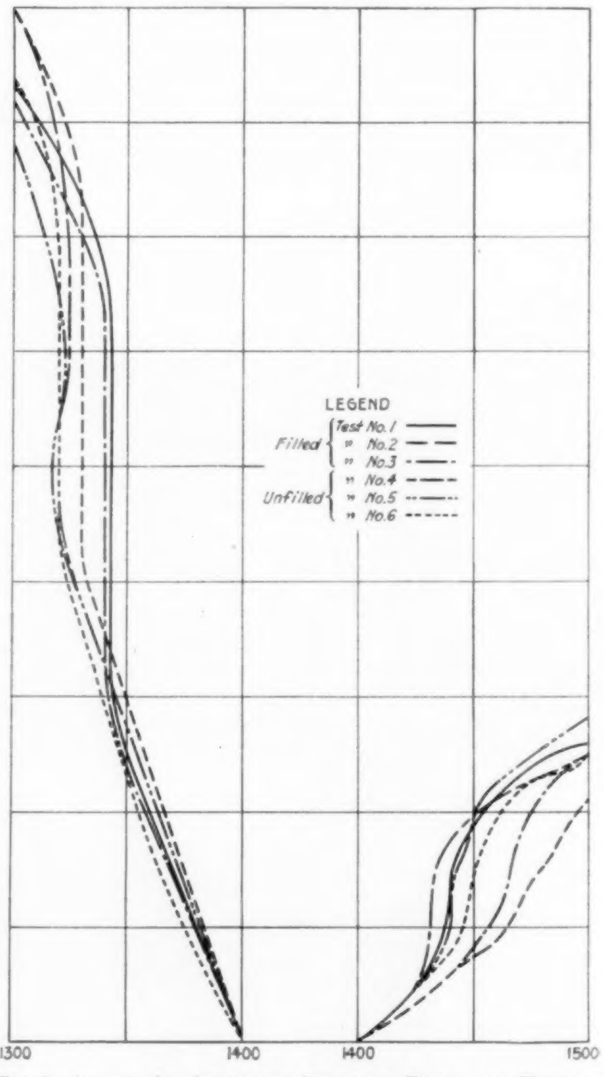

Fig. 9 Ac_3 and Ar_3 Annealing Curves of Filled and Unfilled Forgings

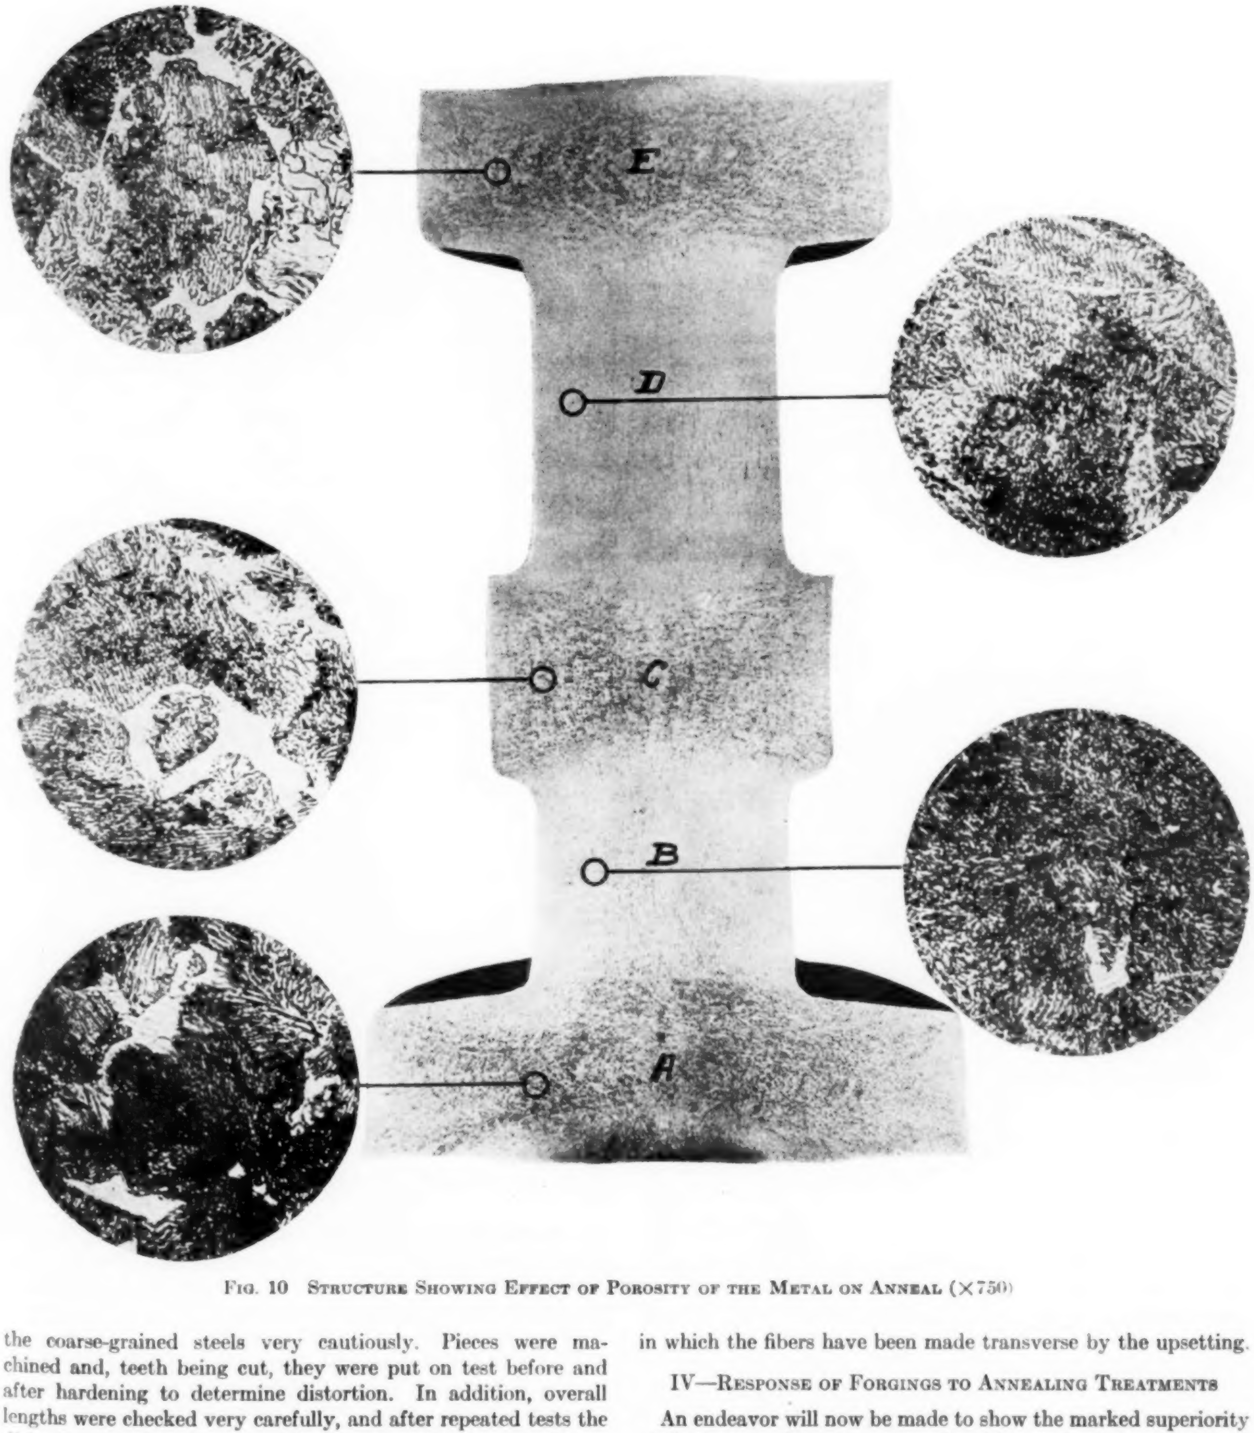

FIG. 10 STRUCTURE SHOWING EFFECT OF POROSITY OF THE METAL ON ANNEAL (×750)

the coarse-grained steels very cautiously. Pieces were machined and, teeth being cut, they were put on test before and after hardening to determine distortion. In addition, overall lengths were checked very carefully, and after repeated tests the distortion was found to be of little consequence because it was uniform and could be allowed for in the cutting. While the same thing is true of the fine-grained steel, the authors have found greater uniformity in the distortion of the coarse-grained metal. It was observed when the metal was properly compressed the impacts were no lower on the coarse-grained than on the fine-grained steels. In one particular test, in which gears made from steel of three different grain sizes were heated and quenched on the same fixture, the impacts were found to be the same. This of course refers to actual tooth impacts of the gear in which the fibers have been made transverse by the upsetting.

IV—RESPONSE OF FORGINGS TO ANNEALING TREATMENTS

An endeavor will now be made to show the marked superiority of the improved forgings over the old type in their response to standardized annealing treatments.

Referring to Fig. 4, one of each of these gears of the filled and unfilled type was cut up for microscopic analysis. The photomicrographs, Fig. 8, show the difference in the microstructure of the two forgings after the same annealing treatment, *A* representing the unfilled forging and *B* the filled forging. Observing this difference, the authors become interested in determining the actual effect of the annealing treatment upon the spongy material. Tests were made on filled and unfilled gear forgings in a

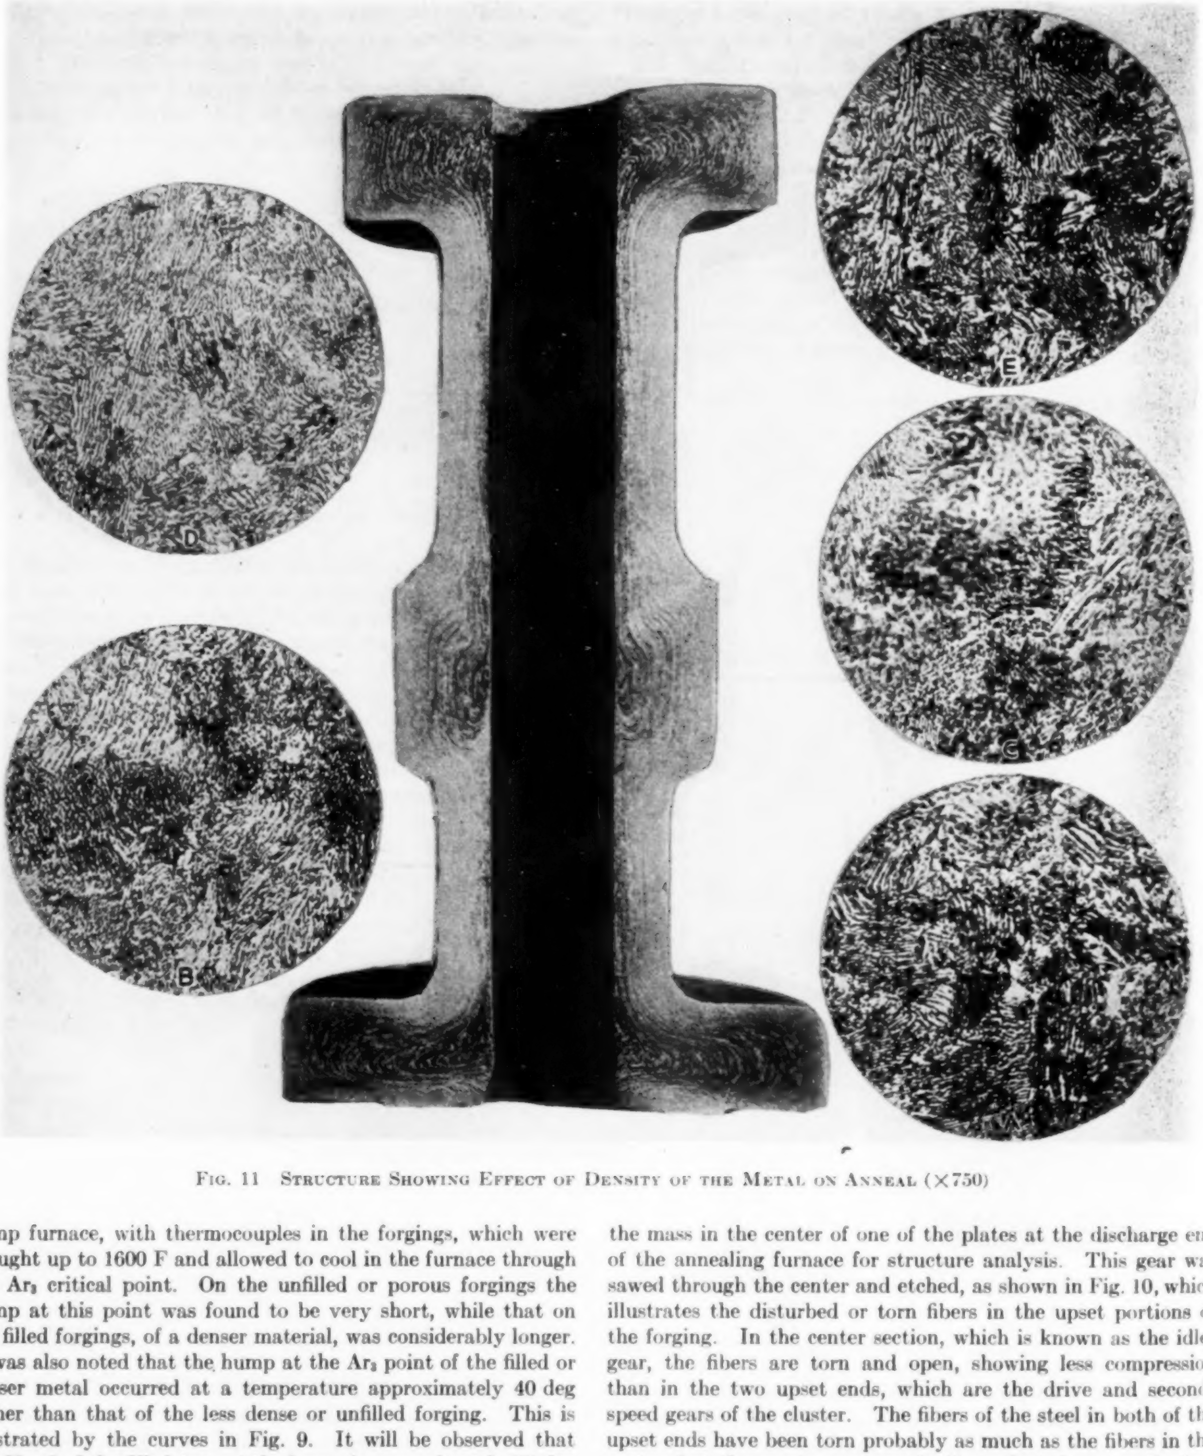

FIG. 11 STRUCTURE SHOWING EFFECT OF DENSITY OF THE METAL ON ANNEAL (×750)

hump furnace, with thermocouples in the forgings, which were brought up to 1600 F and allowed to cool in the furnace through the Ar_3 critical point. On the unfilled or porous forgings the hump at this point was found to be very short, while that on the filled forgings, of a denser material, was considerably longer. It was also noted that the hump at the Ar_3 point of the filled or denser metal occurred at a temperature approximately 40 deg higher than that of the less dense or unfilled forging. This is illustrated by the curves in Fig. 9. It will be observed that line No. 2 of the filled type at the hump is approximately 20 deg below lines Nos. 1 and 3, but the duration through the recalescence is as long as in lines Nos. 1 and 3. The explanation for this is that while the forging had the appearance of being filled and well compressed, its density was not as great as that of Nos. 1 and 3.

In additional tests that were made to determine, if possible, the reason why the material was unresponsive to the annealing treatment, a cluster-gear forging was taken from the center of the mass in the center of one of the plates at the discharge end of the annealing furnace for structure analysis. This gear was sawed through the center and etched, as shown in Fig. 10, which illustrates the disturbed or torn fibers in the upset portions of the forging. In the center section, which is known as the idler gear, the fibers are torn and open, showing less compression than in the two upset ends, which are the drive and second-speed gears of the cluster. The fibers of the steel in both of the upset ends have been torn probably as much as the fibers in the center, but the greater compression has effected some adhesion.

Photomicrographs were then taken of the various sections of this cluster gear, as shown in Fig. 10, *A*, *C*, and *E* designating the different upsets, and *B* and *D* the undisturbed portions of the bar. These photomicrographs show clearly the non-uniform response of the less dense or porous sections to the annealing treatment. *A*, *C*, and *E* show a considerable precipitation of free ferrite and some large islands of massive ferrite—a very poor structure for machinability, while *B* and *D* show a fairly uniform structure of lamellar pearlite with very small islands of free ferrite—a more suitable structure for machinability. These structures seem to prove definitely that the sections of the cluster which were disturbed in forging do not readily respond to the anneal, while those which were undisturbed exhibit a homogeneous lamellar pearlite, due, in all probability, to the denser metal prevalent at these locations.

For comparative purposes a similar analysis was then made of one of the improved cluster-gear forgings made from steel having a No. 4 grain-size rating. Fig. 11 shows structural microphotographs taken in positions comparable to those in Fig. 10. These structures are all quite alike, indicating a very uniform response of the entire forging to the annealing treatment. This uniformity is no doubt the result of the denser structure made possible by the present upsetting methods applied to the coarse-grained steel.

V—Improved Machinability Resulting From Denser Forgings

In this research the authors think it has been proved beyond a doubt that these cavities or voids which affect machinability are due to a spongy surface or metal at the cutting edge of the tool; the tool has double duty to perform; first, to close the cavities with adjacent metal so that it has proper backing, and then to cut—see Fig. 12.

After correcting the forging practice, an improvement in machinability of 50 to 400 per cent was found, depending on the operation. Speeds and feeds had been increased 11 to 60 per cent, and tool life increased in like proportion. As an example, figures on the cutting of gear teeth on gear-hobbing machines may be cited showing the number of pieces per shift of hob, the hob having four shifts per grind. The following table compares machining results today with those obtained a year ago on the old-type gears. At that time the steel was purchased without grain-size specification, and no precautions were taken in forging to develop increased density.

	—Pieces per shift of hob—	
Part name	December, 1931	A year ago
M. D. gear	35	27
Idler (15-tooth)	120	65
Idler (19-tooth)	64	58
Second-speed	35	24
Sleeve	14	8 to 10
Low slider	70	60
Cluster (17-tooth)	35	20
Cluster (15-tooth)	90	52
Cluster (20-tooth)	30	20

Note the variation in figures. With the exception of the 15- and 19-tooth gears, all are finished in one cut with 0.060 in. feed per revolution of blank.

In addition to the improved machinability shown, it might be added that the overall tool cost of the plant per job has been reduced from 84 cents to 44 cents within the last year.

To a gear manufacturer there are other things of major importance besides machinability, that is, changes in the fire. If these changes can be controlled and made uniform, the change in cutting can be allowed for and becomes of little consequence. To show how uniform these changes are after settling on steel of a definite grain size and making forgings of improved density, Mr. Stanard, gear supervisor of the company with which the authors are associated, will be quoted:

> Since we have been getting forgings with greater density we have maintained an accuracy of spacing on hobbing machines within 0.0002 in., contour within ±0.00025 in., and when they come out of fire, we can expect to get about 0.0004 to 0.0005 in. change in contour and no apparent change in spacing. All checks were made with teeth marked and starting from the same position and carrying through in the same direction. Gears going to the fire with a concentricity of less than 0.001 in., come back with one of about 0.0015 in.
>
> Those who cut gears perhaps know that a great deal of the deformation of tooth contour is caused by cold working of the metal when the hob loses its keen, sharp edge. In going through the fire the strain is relieved and the portion cold-worked will rise above the remainder of the profile. As the portion around the point of the hob tooth removes the most stock, it is important that the metal being cut shall be dense and not cause undue wear at this point, as this portion forms the flanks of the teeth, their most sensitive area. The flanks are difficult to correct by burnishing or lapping, and are the contact points of the top edge of the mating tooth when two teeth are in contact in each gear. If we can prevent the rapid wear of the hob tooth around the top, the gear will go to be hardened without cold working, and the distortion due to hardening will be uniform.
>
> With the control now maintained on the steel and forgings, it is a simple matter to correct the hob by grinding more or less rake in the cutting face, thus compensating for the regular fire distortion. To say the least, it is very gratifying to a gear man to have his product come back in the shape it went away. This year's production has shown without any chance of dispute that the contours, spacings, and concentricity maintained before the fire, changed as expected. This has proved of infinite value to us.

VI—Improved Durability Resulting From Denser Forgings

Under this heading, reference will be made to some dynamometer tests which were run to determine the difference in durability of gears made from old- and new-type forgings. Enough forgings were made for two complete sets each of gears of the unfilled and the filled type. These were machined, hardened, and assembled for dynamometer tests. The four assembled transmissions were then mounted on a fan dynamometer and 40-hp loads were applied with the transmissions in second gear. They were operated for periods of 15 min each. In the intervals between they were allowed to cool for approximately 15 min while the wearing surfaces of the gears were being examined. The transmissions were torn down periodically and the shafts and bushings examined for wear.

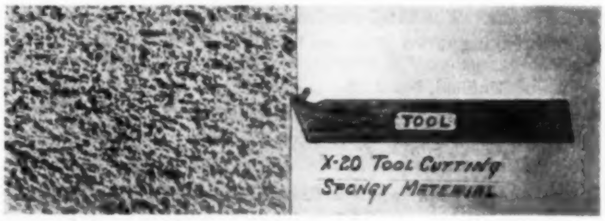

Fig. 12 Illustrating Theory of Effect of Porosity on the Cutting Tool

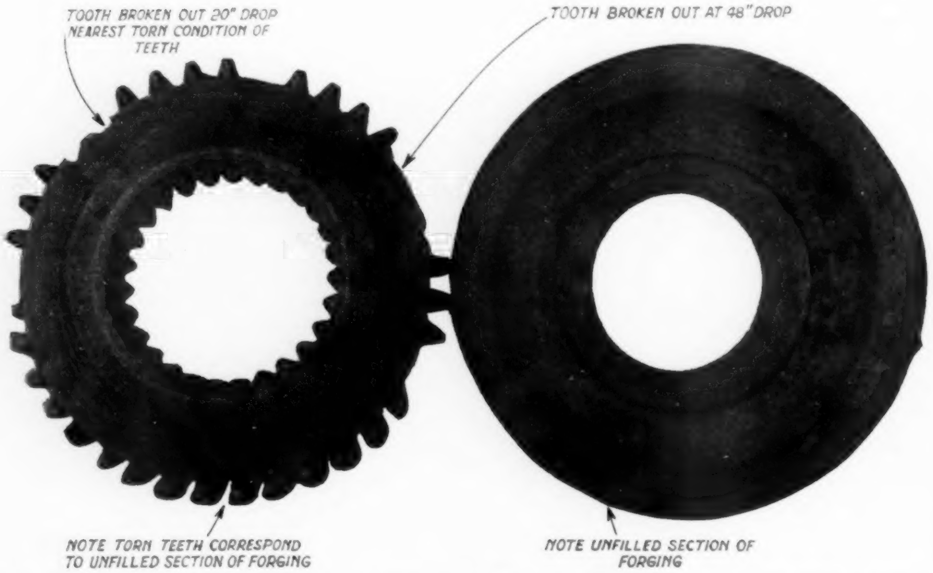
Accurate records were kept of the operating temperatures and air temperatures, as well as of the time required to show granulations, pitting, and, finally, breakdown. Examination of these gears, after they finally broke down, disclosed that the pits on the filled-forging gears were considerably smaller than those on the unfilled ones.

Due to the fact that these tests required a considerable length of time, it was impossible to maintain exactly the same atmospheric temperature throughout the test. Therefore records were kept to permit checking the average temperature rise in the 15-min intervals during which the transmissions were operated. The average temperature rise for each of the four transmissions was as follows:

Unfilled, No. 1	146 F
Unfilled, No. 2	159 F
Filled, No. 1	116 F
Filled, No. 2	126 F



TOOTH BROKEN OUT 20" DROP NEAREST TORN CONDITION OF TEETH
TOOTH BROKEN OUT AT 48" DROP
NOTE TORN TEETH CORRESPOND TO UNFILLED SECTION OF FORGING
NOTE UNFILLED SECTION OF FORGING

Fig. 13 Sliding Gear Broken in Dynamometer Tests and Forging Illustrating Reasons for Failure

It is apparent that the transmissions made from filled forgings operated at a lower temperature difference, and this means that their efficiencies were higher because of smaller frictional losses.

All four transmissions were operated as outlined above until a breakdown prevented further testing. It happened in each case that one or more teeth broke out of the second-speed countershaft gear. The total number of hours each transmission ran before breaking down is shown below:

Unfilled, No. 1	80 hr
Unfilled, No. 2	70 hr
Filled, No. 1	126 hr
Filled, No. 2	128 hr

These hours are equivalent to like numbers in thousands of miles of service. It may be safely concluded from the foregoing tests that the filled-forging gears excelled the unfilled-forging ones on the basis of hours operated before granulations and pitting took place, cooler operation, high efficiency, and longer life.

At this time another discovery was made on the dynamometer which showed that the durability of the metal was affected by its porosity. Among the dynamometer tests that are constantly being made is one which the authors designate as the slip-out test. This test is conducted by having the dynamometer mounted at an angle and duplicating the effect of the transmission in a car being propelled up or down hill. The test has as its object the detection of errors or defects in the transmission which might cause a slip-out in first or second speed on a grade. On one of these tests the horsepower was built up to approximately 300, at which point the transmission broke down. Upon opening the latter it was found, as shown in Fig. 13, that the teeth on one side of the sliding gear had been torn out, while those on the opposite side showed no pitting or wear. After disassembling, it was also noted that the broached internal teeth opposite the missing peripheral teeth had been slightly torn in machining, while those on the opposite side had machined without tearing, and with a good finish. This gear was then submitted to an impact test, and it was found that the tooth nearest the torn section broke out with a 20-in. drop of the hammer, while the tooth on the opposite side broke out with a 48-in. drop.

In operating this test the gear is clamped in a fixture on the base of the testing machine, and an anvil is placed on a tooth of the gear; a 10-lb hammer is then raised with a rope until, coming in contact with a dog set on a vertical rail, it is tripped and allowed to drop upon the anvil. The dog is originally set to trip at 1 in., which height is increased an inch at a time until the gear tooth is broken out.

Investigation of the gear blanks disclosed that the forgings showed less compression or density on one side than on the opposite side. This was caused by the gathering of the metal forming the cone in the first operation being eccentric to the bar, and, in forging, one side failed to fill the die because of this unequal distribution of metal. This is shown in Fig. 13.

VII—Conclusions

Regardless of analysis, the same beneficial results were obtained with all types of steel used.

It has been shown that it is possible to produce denser forgings, in which slipping and tearing of the fibers are eliminated by employing a steel of a specified grain size, accurate forging temperatures, and specially designed dies for controlling the flash to insure greater compression of the forging.

Employing this procedure the authors have been able to produce forgings with a more uniform anneal, thereby effecting improved machinability, i.e., greater feeds and speeds, and longer tool life, resulting in lower tool costs. In addition, these denser forgings have proved highly responsive to the hardening treatment, resulting in uniform distortion, and dynamometer tests run for durability have shown that the life of the gears has been increased more than 50 per cent, with marked decrease in pitting and granulations, the maintenance of smoother surfaces, and quieter operation.

Discussion

S. D. Williams.[10] Much of the authors' work can be explained if we will remember that all steels have what is known as "fiber" to a greater or less degree. The fibrous structure in forged or rolled steels is a deformed structure of the dendrites in which the segregation of impurities is present. Phosphorus is an impurity that is one of the chief causes of the fibrous structure. The desirability of fibrous steel is one of the bitterly disputed subjects. Severely fibrous steel is almost always associated with a steel that shows fine grain in the McQuaid-Ehn test, but the latter does not necessarily imply a fibrous steel.

A steel made fine grained according to the McQuaid-Ehn test, assuming the same ingot size, is usually more fibrous, or rather the fibers are finer and shorter, than a steel that is made inherently coarse grained according to the McQuaid-Ehn test. The fine-grained steel, when given the same heat treatment as the coarse-grained steel, will show approximately the same values for tensile

[10] Timken Steel and Tube Company, Canton, Ohio.

strength and elastic limit, but decidedly superior ductility values in the static test piece taken longitudinally to the direction of rolling. The dynamic test piece machined longitudinally to the direction of rolling and broken across the fiber or grain will show decidedly superior values under impact for the steel made inherently fine grained. When, however, a static test is made transversely to the direction of rolling, the tensile strength and elastic limit are again approximately the same, but the ductility values as shown by the elongation and reduction of area are now decidedly greater in the case of the steel made inherently coarse grained. The transverse impact piece machined transversely and broken parallel to the direction of rolling will show much better resistance to shock in the case of the coarse-grained steel.

In the authors' forging operation on upset gears, the steel is subjected to severe transverse stresses, and there is less tearing on large-grain steel than on fine-grain steel, simply because there are fewer planes of weakness and less chance for a parting of the metal. It is certainly a very interesting fact that this work seems to be the first that has tied up actual density of forgings with the fibrous condition in steel which has been recognized for some time to contain planes of weakness where a slippage or parting of the metal is possible in the upsetting operation.

The authors have proved that a dense forging lends itself more readily to the normalizing cycle, resulting in a more suitable structure for machining than a less dense forging. This, in the writer's opinion, is due to the fact that a dense forging is more fiber-free or has less non-metallic film material between the fibers than a less dense forging, and consequently there is less of an insulating effect to the transfer of heat. In other words, the transformations that take place in the normalizing operation with an evolution of heat occur more uniformly because of the relative absence of insulating non-metallic films between the fibers.

The work of Charpy and others has shown that excessive reduction from ingot to bar lowers the transverse test values of steel, especially the dynamic test values. One of the reasons that a crucible-melted steel performs better than a similar grade of steel cast in a larger ingot is due to the fact that with a smaller ingot a more uniform and quicker freezing occurs with smaller dendritic growth and less non-uniform distribution of carbon, etc. The smaller the ingot, the fewer and also shorter will be the number of fibers in a bar rolled from that ingot. Also, the larger the ingot, the more is the likelihood of the non-metallic particles, carbides, etc. being thrown into the center before freezing occurs. The authors have proved that there is a more dense condition on the surface of hot-rolled steel bars than in the center. The non-metallic material thrown into the center of the slowly cooling large steel ingot causes a pronounced fibrous condition, resulting in planes of weakness where tearing occurs in the upsetting operation. It seems, therefore, that for quality steel our trend should be to work to the smallest commercially practical steel-ingot size in order to get the quickest possible freezing of the ingot. The quicker the freezing that occurs in the ingot, the more uniform will be the fiber condition from skin to center of the bar and the more uniform will be the density of the bar, as the authors understand it, from outside to center of the bar.

Incidentally, it might be mentioned that the direction of the fibers has an intimate relation to the lines of quenching cracks in steel.

Recent researches have shown that the fibrous structure decreases gradually in distinctness as the heating temperature rises above 1100 C, but complete disappearance seems to be almost impossible even though the heating be conducted as high as 1300 C (2372 F). It might be advisable for the authors to conduct further tests on steels that have previously been heated for some time at these high temperatures and see if the diffusion that takes place has some bearing on their results.

Some years ago the English metallurgist, Brearley, made the following statement:

"The relation between the figure obtained on the longitudinal impact piece and the figure obtained in the transverse impact piece is, roughly, a measure of the cleanness of the steel; the transverse figure is never as high as the longitudinal figure, and sometimes it is ten times less. If the steel is for high-class purposes, such as ball races, where the transverse strength of the material is very important, the transverse impact figures should not be less than one-half of the longitudinal."

It would be interesting and probably instructive if the authors in their future work would get some data on the ratio between transverse impact and longitudinal impact and the relation of this ratio to their findings regarding density, machinability, and durability.

R. E. W. Harrison.[11] The authors have accomplished an extremely useful basic manufacturing research, and it is remarkable that this vitally important subject has not hitherto been throughly probed. The conclusions are as basically important in their influence on manufacturing procedure as the introduction of the new carbide cutting materials. The remarkable results obtained from what is nothing more or less than the application of painstaking care in preliminary operations and the admixture of common sense to drop-forging practice indicate the need for the trained analytical machine-shop type of mind in all the operations preceding the actual machining of the forging.

It is an unfortunate fact that many of the manufacturers preparing the raw materials do not appreciate the difficulties that they can create in the machine shop as well as in the performance of the finished product by hit-and-miss methods of chemical analysis, temperature control, die practice, pickling, and in fact all the operations that are necessary before the forging is delivered to the first machine tool.

The most remarkable result obtained from the researches of the authors, apart from the increased efficiency of machine-shop operations, lies in the increased strength of the gear teeth with the possible influence of this factor on the design of transmissions. In these times, when more and more mechanisms are being introduced into automobile transmissions, the question of compactness, which is directly related to strength of materials, is paramount.

The photomicrographs remind the writer of some interesting models made to indicate fiber structure, in which an ingot or slug of laminated colored wax was used and then sectioned. The availability of this method of obtaining a quick picture of fiber placement should not be lost sight of by those responsible for the design of forged structures.

There is an interesting thought in connection with this matter regarding the applications of carbide material-cutting tools to the superior forgings produced by the authors' method, and the writer would like to suggest to the makers of these tools that some research along these lines would probably well repay them, especially having regard to the relatively poor showing hitherto made by all carbide tools on steels as against cast irons.

The pressure of economics compels all process engineers to be constantly on the lookout for practices that reduce the number of operations necessary to fabricate a given piece, and the writer wonders if the authors could state whether their more accurate dies, and forging practice in general, would permit of an increased number of precision-grinding operations directly from the forging without the necessity for the intermediate turning operation.

It is understood that in certain European factories which manufacture anti-friction bearings the most popular sizes are ground direct from the forging, this practice having been made economically possible by the provision of really accurate forgings. It is also understood that the practice is not altogether unknown in one or two of the larger manufacturers of this commodity in the United States.

---

[11] Chief Engineer, Cincinnati Grinders, Inc., Cincinnati, Ohio. Mem. A.S.M.E. Secretary, Machine Shop Practice Division, A.S.M.E.

The writer would also like to inquire if the authors have investigated the merits of the rolling die, and whether they believe this would enable them to obtain the same density of internal structure; also if this type of die could be utilized effectively for the rolling of gear teeth to such proportions that the gashing operation could be eliminated and the gear-cutting machinery employed for finish cutting only. It would seem that this thought might have some merit, inasmuch as it would reduce the tendency to cold working, which the authors have observed when hobs are used that need sharpening.

The writer was privileged to see the results of some of this research work prior to the publication of the paper, and he can testify, both from the point of view of the machine-tool manufacturer and the user of the product, that the results of this improvement in manufacturing technique will be far-reaching indeed. This paper is but another evidence of the value of the well-hammered anvil, a phenomenon with which most engineers have been conversant, but which we all apparently have been slow to apply.

It is suggested that some special means be taken to circulate this paper to all concerns making forgings, either for their own product or for the trade.

Authors' Closure

Mr. Williams may recall the results that the authors obtained by annealing the bar before upsetting, as by annealing before upsetting greater density was obtained. The authors are now working on tests that have been run at high temperatures for diffusion before upsetting.

The authors are unwilling to say much of these tests, but will say that in the 18 tests that have been run very gratifying results have been recorded, and it is the authors' opinion that the work from these results will terminate in still greater accomplishment.

Mr. Harrison may be interested to know that from this work the authors have been able to reduce the weight of the transmission by 12 lb, with greater strength and longer life by dynamometer tests. With this method of forging and material there is less need of the application of carbide material-cutting tools.

All gear-blank forgings are forged with the holes in them. They are taken from the forge shop annealed, broaching the hole as forged without core drilling, and then machined from hole, with some surfaces ground to size without turning.

The authors have investigated the merits of the rolling dies for rolling the teeth in a ring gear. In this case the fibers were torn in the center of the teeth, but the forged ring before rolling showed considerable porosity. It may be accomplished, but it is believed that continued rolling on the surface of the teeth to size would cause porosity in the center of the tooth, as you are pulling metal out of the teeth and using it to compress the metal at the root of the teeth or in the body of the gear.

Life of Tools Machining Free-Cutting Brass

By L. D. Spence[1] and J. A. Hall,[2] Providence, R. I.

L. D. Spence

J. A. Hall

The authors present a considerable amount of data on the life of tools under shop conditions machining free-cutting brass in automatic screw machines. The analysis of this data shows that larger feeds and higher cutting speeds than those used in current practice can be combined with a reasonable tool life. The type of relation existing between cutting speed, feed, and life of tool found by Frederick W. Taylor and others for rough-turning of steel does not fit these tests of forming and drilling free-cutting brass. Within the limits of these tests an increase of the cutting speed is accompanied by greater economy. When machining free-cutting brass with ground circular-form tools, the life of the cutting tool between grinds appears to be nearly independent of the feed and of the cutting speed, and to depend primarily on the linear distance the work moves in contact with the tool. This indicates that the wear is primarily a lapping action, which is influenced more by the amount of movement of the edge of the tool against the work than by the pressure between them. Within the limits of the tests the maximum economy in machining free-cutting brass is secured by using the largest feed that the work and tools will stand and by running the stock at the highest spindle speed available.

This paper gives a summary of data collected on the life of tools during the past five or six years in the screw-machine laboratory of the Brown & Sharpe Mfg. Co. The figures are a by-product of the main work of the laboratory, in which the study of automatic screw machines under extreme operating conditions and the experimental investigation of new developments are made. In carrying out these investigations, each machine was equipped with a counter that recorded the number of pieces completed. Whenever adjustments or replacements were necessary, the information concerning what was done was entered against the counter reading in a log book. Thus a definite basis for the comparison of different designs was secured. In connection with this study of machines it was easy to obtain accurate data on the life of tools between grindings by requiring an entry in the log book, together with the counter reading, each time that a tool was ground.

The tools were ground whenever it was necessary in getting the specified finish in maintaining manufacturing limits and so forth. Undoubtedly much longer time between grindings could have been secured if every effort had been exerted toward securing the greatest possible tool life. Regular shop operating conditions were maintained in the laboratory; so these results can in no way be considered stunt cuts. The results showed considerable variation in the successive records of life of tools between grindings, as might be expected where finish plays a part. However, no figures were included in this study unless there were a sufficient number of grindings to give a reasonable average. While it may be objected that the method does not give scientifically exact results, it should be noted that the machines were operated under shop conditions, and that the results should therefore be close to what may be expected in manufacturing plants.

In all cases the material cut was free-cutting brass rod. Circular-form tools made of high-speed or of carbon tool steels were used in the forming and cutting-off operations. In all cases the cutting lubricant was a commercial mineral-lard oil.

Form Cutting

The data on the life of a considerable number of circular-form tools are given in Table 1. In all cases the forms of these tools had been ground after the hardening operation. The maximum cutting speed is the surface velocity of the work at the outside where the tool starts cutting, while the same figure for the smallest diameter to which the tool cuts gives the minimum. In cases where the feed per revolution was changed during the cut, the weighted average is given. The feeds vary through a rather wide range, as their choice depends on the width of the cut and on the diameter of the work. A heavy, wide cut may cause excessive deflections of small-diameter stock. If an excess of time is available for forming due to the requirements of the turret operations, a feed smaller than the maximum may be used.

The last three columns of Table 1 give calculated data for the average number of pieces per grind. From the work of others in this field, it was at first felt that the most significant figure would be the cutting life of the tool. This was calculated by multiplying the length of time during which the tool was cutting on each piece by the average number of pieces per grind, and is given in the third from the last column. Another figure, which roughly corresponds to the amount of work done, was the total cutting depth, which is entered in the next column. This is the product of the depth of cut per piece times the average number of pieces.

---

[1] In charge of tool designing, Brown & Sharpe Mfg. Co. Mem. A.S.M.E. Following a public-school education, Mr. Spence became a machinist's apprentice at the Brown & Sharpe Mfg. Co., completing the course in 1902. Since that time he has been in charge of various departments at that plant, including both engineering and manufacturing work. For the past 12 years he has been in charge of screw-machine tool design and screw-machine sales.

[2] Professor of Mechanical Engineering, Brown University. Mem. A.S.M.E. James A. Hall was graduated from Brown University with the degree of A.B. in 1908, and received the degree of Sc.B. in M.E. from the same institution. He remained there as a laboratory instructor for four years, and then entered the Engineering Department of the Link-Belt Company in Philadelphia. In 1915 he returned to Brown University as an assistant professor, teaching machine design and industrial management, and is now Professor of Mechanical Engineering. During the past ten years he has held a position with Brown & Sharpe as part-time consulting engineer.

Contributed by the Machine Shop Practice Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The third column gives the linear distance that the surface of the work moved in contact with the tool while being cut. This figure is found by multiplying the average of the maximum and minimum cutting speeds by the cutting time. Where hexagonal or square stock was being formed, the maximum cutting speed and depth of cut were based on the radial distance to the corners. No attempt was made to correct for the reduced distance on the flat sides, as it was felt that the shock of hitting the corners more than balanced the saving in wear while passing the spaces where no metal was removed.

Referring to Table 1, test No. 1 was a wide cut on a piece of small diameter, and this accounts for the very fine feed. A fine finish was required, which probably made it necessary to grind the form tool more frequently than on average work. Nos. 2, 3, and 4 were all on the same piece. The cut was fairly wide, and the maximum tolerance on the diameter over part of the piece was but 0.001 in. A very fine finish had to be maintained as the piece was to be plated. In test No. 2 a high-carbon-steel tool was used, and this was replaced by high-speed steel in No. 3. A ground circular-form tool that had been chromium plated was used in test No. 4.

The limits were not particularly close on Nos. 5 and 6, although a fair finish was required. On job No. 7 the finish was not so important, as the formed surface had a thread cut on it by a die. Nos. 6 and 7 were made from hexagonal bars. Nos. 8 and 9 are the same piece, the first test being run with a carbon-steel tool and the second with high-speed. The stock was square, and a very good finish had to be maintained on the turned surface. On No. 10 the cut was rather narrow, and a liberal tolerance was permitted on the diameter. No. 11 was similar to No. 10, except that less attention was paid to the finish, because the formed surface was later knurled.

Nos. 12 and 13 are alike in that the form tool also acted as a cutting-off tool. The back of the first piece and the front of the next were formed and the cutting off was completed all at the same time. Possibly these two should be considered as cutting-off rather than as forming tools.

In trying to find some correlation between the results, the first thought is that the life of the tool in minutes should have some relation to the cutting speed. Frederick W. Taylor, in his "Art of Cutting Metals," found for rough-turning that the cutting speed and the life of the tool for a given feed varied by the equation $V = K/\sqrt[8]{T}$, where V is the cutting speed, T the time, and K a constant.

Some of the German authorities have urged that the 3d root rather than the 8th should be used. Prof. W. A. Knight, in an article entitled "Cutting Speeds and Feeds," published in *American Machinist* in 1916, applied the results of the researches of Taylor and others to screw-machine work and suggested the use of the 10th root of the time in the foregoing equation. For any desired life of tool, Professor Knight gave, as an approximation based on the work of Taylor and others, the following equation for the relation between feed, depth of cut, and cutting speed: $V = K/\sqrt[3]{(DF^2)}$, where V is the cutting speed, D the depth of cut, F the feed, and K a constant.

A cursory examination shows that the data given in Table 1 cannot be correlated by these equations. For instance, the feeds in tests Nos. 3 and 5 are practically the same, while the cutting speed is twice as great in the latter. The life of the tool was reduced only about a third by the increase in speed, while it should have dropped to less than 15 per cent by any of the suggested relations. Furthermore, nearly doubling the feed between tests Nos. 5 and 7 with practically the same cutting speed resulted in an increased rather than a decreased life of tool. Similar comparison of the other tests shows that those results do not fit into the equations given.

It should be remembered that the equations referred to were all developed from tests of lathe tools rough-turning steel. In the present studies a relatively new material, free-cutting brass rod, was used. Furthermore, the tool movement is radial, a reasonable surface finish must be secured, and manufacturing limits have to be maintained. It is therefore doubtful if any equations for rough-turning with lathe tools can be adapted to this type of form-cutting.

In a further attempt to secure some correlation between the data, the last columns, entitled "Total cutting depth" and "Linear distance of cutting," were calculated. The first of these gives some idea of the total amount of work done between grinds by the tool, while the second gives the linear distance through which the tool cut. If lapping action of the work on the point of the tool is a major factor, the last figure may be of importance, as it really gives the linear distance of rubbing of the point of the tool against the surface of the work.

An examination of the figures for "Linear distance of cutting" raises the question if this lapping action is not the primary consideration in form-cutting of this type of brass. The figures for all of the tests are fairly close together, while they vary widely for cutting time and total cutting depth. For instance, in tests Nos. 1 and 3, where finish was highly important, the values for "Linear distance of cutting" were 31,800 and 32,500, respectively. Where the finish was somewhat less important, the amounts go up, but fall rather close together, while the highest figure of all, 77,100, is for the job where the finish was of the least importance.

In the range of these tests, the average cutting speeds were changed by a more than 5-to-1 ratio from the largest to the smallest value, while the feeds per revolution varied through a 15-to-1 range. Yet the "Linear distance of cutting" for high-speed steel tools came within a $2^1/_2$-to-1 range, and this variation is largely explained by the difference in finish required.

It should be remembered that all of these tools had ground forms. It is quite possible that the same relation would not be found with tools which were finish-formed prior to the hardening operation and polished afterward. The latter type of tool is likely to have a soft film at the surface, and hence is not as resistant to the lapping action.

While the data are not sufficiently extensive to come to any final conclusion, it appears that within the range of these tests variations in cutting speed and in feed per revolution have a negligible effect on the life of the tool between grinds as compared with the "Linear distance of cutting." In other words, when using a ground form tool on free-cutting brass rod, the linear distance through which the edge of the tool contacts with the rod while cutting, appears to be the primary factor in the life of such a tool between grindings.

If the foregoing conclusion is accepted, the maximum production rate and the greatest output between tool grinds will be secured by conforming to the two following rules: First, the maximum possible feed should be used. This is limited by the power of the drive and the ability of the stock to keep from deflecting unduly under the pressure of a partly worn tool. Second, the cutting speed should be as high as possible. There is undoubtedly a limit beyond which increase in speed results in a loss rather than a gain, but it had not been reached in these tests at 600 fpm.

Another conclusion has to do with the relative merits of carbon- and high-speed-steel tools. At the time of the first tests there was still a strong feeling among users of screw machines that carbon steel was preferable for form tools when a fine finish was required on the work. Probably this was due to the fact that high-speed steel tended to deform more in hardening at the high temperature required and the practice of grinding form tools after hardening had not been generally adopted. These tests show definitely that longer life can be expected from high-speed steel even in this field. Chromium plating was tried on one tool without causing appreciable improvement. In this case the tool was plated but once, so that when freshly ground the top did not present a plated surface. Better results might have been secured if the whole tool could have been replated after each grinding, but this would be out of the question from a production standpoint where a single form tool was available.

CUTTING OFF

The action of a cutting-off tool is similar to that of a form tool except that it does not have to leave a smooth surface on the face. On the other hand, there must always be an acute corner at the point where it finished the back of the piece cut off. This may increase the tendency to wear. Furthermore, it is essential that this corner does not throw up a burr if it is cutting to the edge of a drilled hole. Such a burr may be the factor which determines when the tool must be reground.

The record of a number of cutting-off tools is shown in Table 2. The meaning of the column headings is the same as in the form-tool records. Possibly tests Nos. 12 and 13 of Table 1 should be included with the cutting-off group.

In general these tests show higher values than for forming in the "Linear distance of cutting" column. This is as would be expected, since slight wear near the point of the cutting-off tool is not as serious as on the face of a form tool. One result which is out of line is test No. 4, but here there may have been a greater tendency to throw up a burr at the hole due to the high feed.

Taking the group as a whole, the advantages of high-speed steel over carbon steel are not as obvious as in the form-tool series. However, two cases are given where both types of material are used in cutting the same piece, Nos. 4 and 5 and Nos. 9 and 10. In the former there is a decided advantage in the use of high-speed steel, while it is relatively small in the latter.

While the conclusions concerning the life of these tools are not as definite as with the forming group, the data do give a considerable number of cases where high cutting speeds and large feeds have been combined with long tool life.

DRILLING

Table 3 gives the data on a number of cases of drilling. Cutting speed refers to the surface velocity of the outside of the drill. The feed is given in both inches per minute and inches per revolution. The last two columns record the "Cutting time," which is given by the time spent in drilling one piece multiplied by the number of pieces per grind, and the "Total depth," which is the product of the distance drilled in each piece and the number of pieces.

In the tests reported, the feeds per revolution varied from 0.0078 in. to 0.030 in., while the feeds per minute went from a minimum of 36.7 in. to a maximum of 81 in. All of the drills were of high-speed steel. Most of them were standard twist drills designed for brass, except No. 1, which was a combination drill and counterbore, and No. 8, which was a special steep-spiral drill. There was quite an amount of breakage on test No. 4, so that the figures for 4a are inserted, which give the results of six successive grindings on one drill.

One point of interest in these tests is that large feeds can be combined with high cutting speeds and fairly long tool life can still be attained. Another conclusion is purely negative, as the tests show that high speeds are not accompanied by greatly increased wear.

TABLE 3 DRILLING

No.	Drill rpm	Diam, in.	Cutting speed, ft per min	Feed, in. per rev	Feed, in. per min	Average pieces per grind	Data per grind: No. of grinds	Data per grind: Cutting time, min	Data per grind: Total depth, in.
1	2400	$^{9}/_{16}$	350	0.027	64.8	5,750	21	71.8	4,660
2	3600	0.358	338	0.0173	62.3	22,800	21	179.0	11,200
3	2400	0.358	226	0.018	43.2	30,000	38	270.0	14,700
4	2700	0.173	122	0.030	81.0	11,260	70	92.2	8,700
4a	2700	0.173	122	0.030	81.0	13,000	6	106.5	10,100
5	3600	0.358	338	0.020	72.0	30,400	87	210.0	15,150
6	2400	0.406	255	0.022	52.8	7,200	15	77.6	4,100
7	5000	0.181	237	0.0078	39.0	72,500	5	242.0	9,420
8	2400	0.246	156	0.0153	36.7	13,290	6	305.0	11,200

A number of writers have felt that in general the relation between cutting speed and tool life in drilling was practically the same as for rough turning. In test No. 1 the cutting speed is nearly three times that of test No. 4 and the feeds per revolution are nearly alike, yet the cutting time is reduced by less than 25 per cent, while according to the theories advanced it should have dropped over 90 per cent. This and other comparisons indicate that laws for the rough turning of steel do not apply.

While it seems impossible to deduce any law of drill life from the data of these tests, it does seem apparent that when using free-cutting brass, feeds much in excess of average practice can be used, and that high cutting speeds do not result in a rapid increase of wear.

CONCLUSIONS

This paper has given a considerable amount of data on the life of tools used in machining free-cutting brass in automatic screw machines. The analysis of this data shows that larger feeds and higher cutting speeds than those used in average current practice can be combined with a reasonable tool life.

It is found that the type of relation between cutting speed and life of tool determined by Frederick W. Taylor and others for the rough turning of steel does not apply to the forming and drilling of free-cutting brass, but that within the limits of these tests an increase in the cutting speed is accompanied by greater economy.

When machine free-cutting brass with ground circular-form tools, the life of the tool was determined primarily by the "Linear distance of cutting" and appears to be practically independent of the feed and of the cutting speed. The wear of the form tool seems to be due mainly to the lapping action of the work on the tool. This lapping action appears to be influenced much more by the amount of movement of the edge of the tool against the work than by the pressure between them.

The maximum economy in machining free-cutting brass will be secured by using the greatest feed that the work and tools will stand and by running the stock at the highest spindle speed available.

OGP-54-1

Report on Oil-Engine Power Cost for 1930[1]

THIS report presents information covering 94 oil-engine generating plants, containing 283 engines, totaling 161,583 rated brake horsepower. The previous report (1929) covered data on 36 plants, containing 107 engines, totaling 68,775 rated brake horsepower.

The questionnaires for 1930 were sent to over 1000 plants. Owing to the fact that many additions to the mailing list were made late in the investigation, some plants did not receive the questionnaires in time to have the data in their replies included in the main report. Data pertaining to these plants are given in Supplementary Tables VII, VIII, IX, and X.

Engines listed in the report are full-Diesel, vertical type, direct-connected to generators, unless otherwise noted.

Of the 81 plants in the main report, all but one are located in the United States. The one exception is in Mexico. Of the 13 plants listed in the supplementary tables, one is in Mexico, the remainder being in the United States.

Plant Numbers. The system used in former reports of designating plants by numbers has been retained. Numbers identifying plants previously reported correspond to the same plants in this report.

Period Covered. Most of the data submitted refer to the calendar year 1930. Some plants, however, have reported for periods of three and four years, and a few have presented figures for periods of less than one year.

Output Represented. The total *net* output for the 94 plants listed in this report amounts to 309,369,930 kw-hr.

Bases for Costs and Performances. Unit costs referred to in this report were calculated on the basis of net kilowatt-hours. The net kilowatt-hour output is found by subtracting the power used for plant auxiliaries and station lights from the total gross output of the plant.

Figures given for power output per gallon of fuel oil and of lubricating oil were calculated on the basis of the gross outputs of the individual units and plants.

Load and capacity factors were calculated on the basis of the gross outputs.

Formulas defining running engine capacity factor, running plant capacity factor, annual plant load factor, and plant service factor are as follows:

$$\text{Running engine capacity factor, per cent} = \frac{\text{Engine output in gross kw-hr.} \times 100}{\text{Kw. rating} \times \text{number of hours operated}}$$

$$\text{Running plant capacity factor, per cent} = \frac{\text{Plant output in gross kw-hr.} \times 100}{\text{Total rated kw-hr. of individual units}}$$

$$\text{Annual plant load factor per cent (see below)} = \frac{\text{Plant output in gross kw-hr.} \times 100}{\text{Peak load in kw.} \times \text{number of hours in period}}$$

$$\text{Plant service factor per cent} = \frac{\text{Total rated kw-hr. of individual units} \times 100}{\text{Total installed kw.} \times \text{number of hours in period (see below)}}$$

The expression "rated kw-hr." refers to the kilowatt rating of an engine-generator set multiplied by the number of hours operated. For example, if a unit having a rating of 200 kw. was operated 4000 hours, the rated kw-hr. equals 800,000, no matter what the actual output may have been. Thus the denominator of the expression for "Running plant capacity factory" and likewise the numerator for the "Plant service factor" are arrived a by totaling the rated kilowatt-hours of all plant units.

In the strict sense of its definition, the annual plant load factor cannot be correctly applied to data covering any period other than one year. However, the committee extended the application of this to plants operated 8760 hours plus or minus 2 per cent, using the actual number of hours in the denominator in each case.

The formula for "Plant service factor" requires further explanation for special cases. The expression is an index of the actual number of hours of operation as compared to the total number of hours installed for operation. Therefore, when some units have been installed for longer periods than have others in the same plant, account must be taken of the fact in the calculation. For example, assume that a plant is reported for a twelvemonth period, during which time one unit rated at 200 kw., installed before the start of the period, was operated 5000 hours. Six months after the start of the period, a unit rated at 300 kw. was installed, and subsequently operated 2500 hours. The plant service factor in per cent is therefore:

$$\frac{200 \times 5000 + 300 \times 2500}{200 \times 8760 + 300 \times 4380} \times 100$$

Since the 300-kw. unit was not installed during the entire 8760 hours, but only for 4380 hours, this adjustment must be made. In comparing this year's plant service factors with those contained in the previous reports, it should be borne in mind that these adjustments were not always made in the past. The comparative table for the two years' operation (Table II) included in this report contains only those figures that are in accord with the preceding definitions.

Fuel- and Lubricating-Oil Data. This year the committee summarizes the tabulated figures on fuel- and lubricating-oil economy in graphical form in Figs. 1 and 2. In these charts the gross kilowatt-hours per gallon, using plant averages only, are plotted against running plant capacity factors. The type of the plant was judged to be that of the engines generating 95 per cent of the gross output. The following types of plants are illustrated:

Diesel four-stroke cycle, air injection
Diesel four-stroke cycle, mechanical injection
Diesel two-stroke cycle, air injection
Diesel two-stroke cycle mechanical injection, separate scavenging
Diesel two-stroke cycle mechanical injection, crankcase scavenging
Mixed-type full Diesel
Mixed Diesel and semi-Diesel.

A median line was drawn on each chart, the number of points above the line being equal to the number below. High and low boundary lines were drawn to include all but 10 per cent of the full-Diesel plants on the high and low sides, respectively.

Unless it is otherwise noted in the tables, plants received fuel oil in tank cars.

The fuel- and lubricating-oil costs presented this year include costs for the handling of oil from the cars to the tanks. It was the intention of the committee to have these handling charges included in the 1929 report also. However, some operators may not have included these expenses; this year they were all specifically asked to do so.

This year the committee extended its questions on lubricating oil by asking that the number of gallons of new oil used be segregated as follows:

(*a*) Lubricating oil used to replace shrinkage
(*b*) Lubricating oil used to replace oil discarded.

---

[1] Submitted by the Sub-Committee on Oil Engine Power Cost; Oil and Gas Power Division, A.S.M.E., Franz Eder, Chairman, Engineer, Robert W. Hunt Company, New York, N. Y.

Presented at the Fourth National Oil and Gas Power Meeting, Madison, Wis., June 23 to 26, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

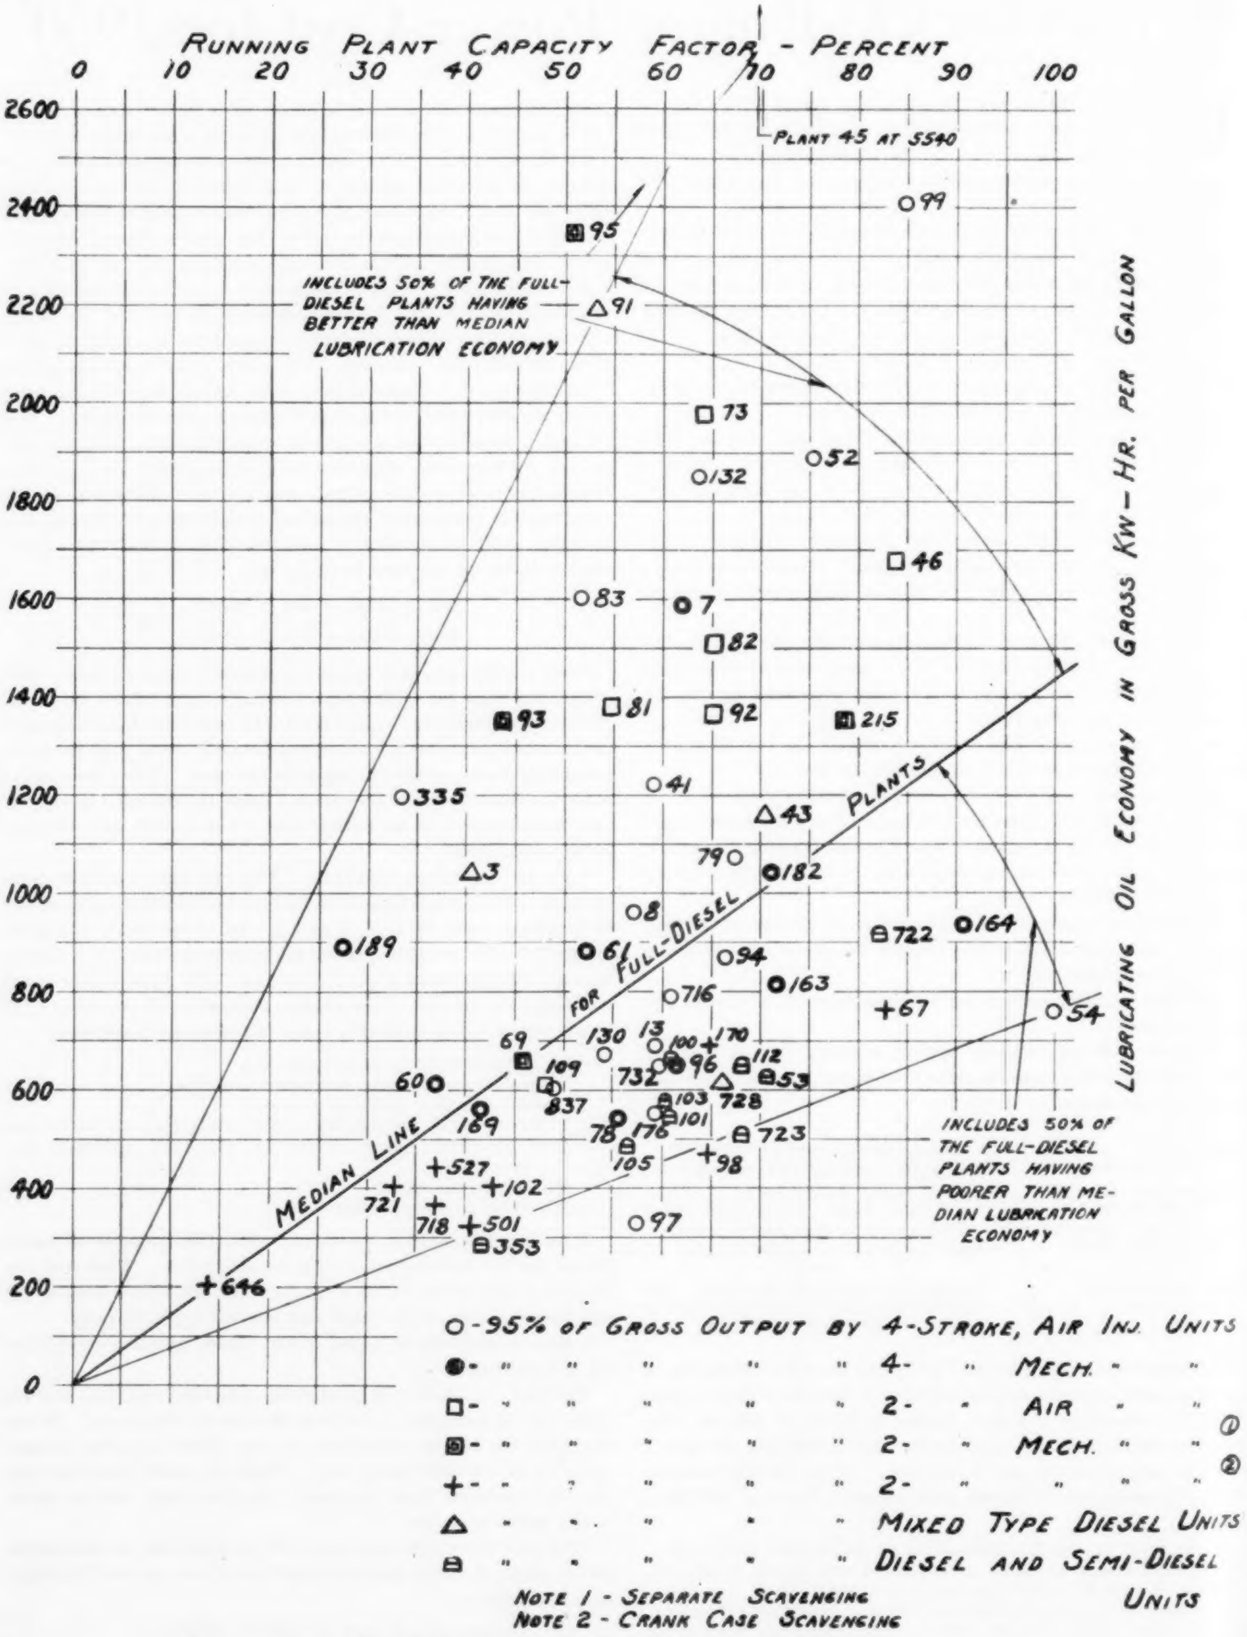

FIG. 1 LUBRICATING-OIL ECONOMY OF OIL-ENGINE PLANTS

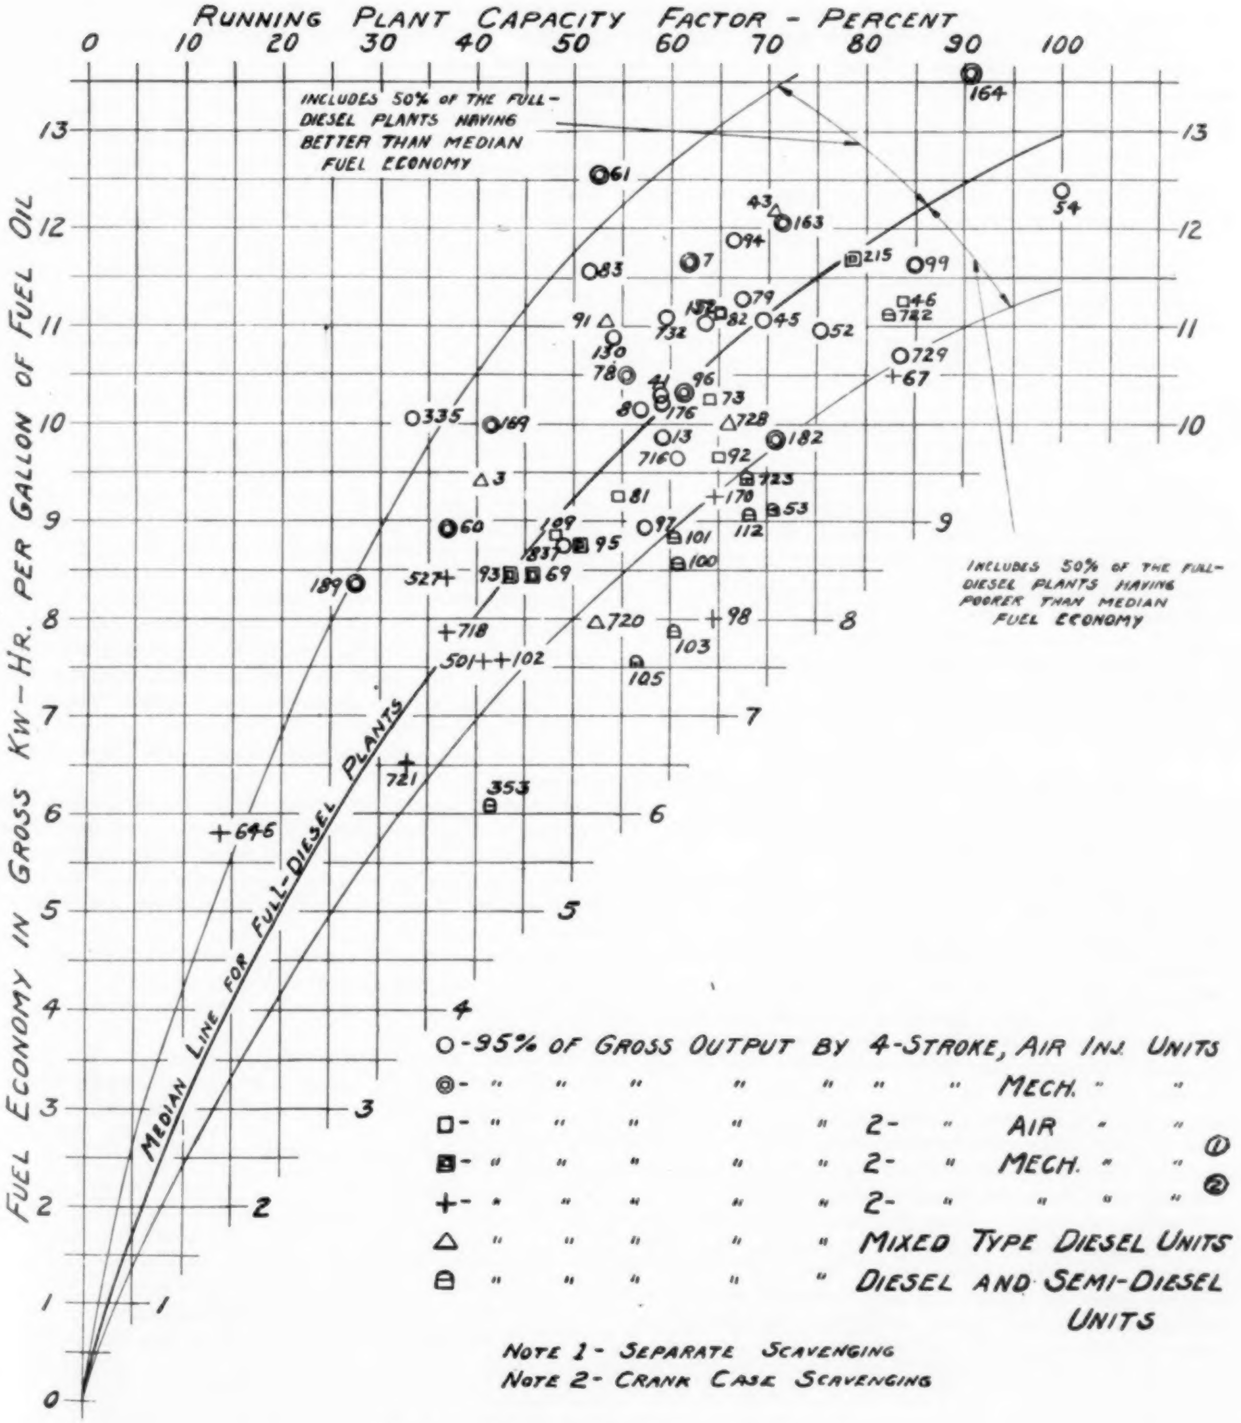

Fig. 2 Fuel-Oil Economy of Oil-Engine Plants

As applied to crankcase oil, this segregation could be easily accomplished; but interpretation was more difficult in the cases of cylinder and compressor oil. Therefore the committee in setting up the tables changed the classification to the following:

(*a*) Gallons of new lubricating oil used
(*b*) Gallons of unfit lubricating oil discarded.

Cooling Water. The various water-cooling systems are indicated by the following symbols:

System A, raw water going to waste after one pass
System B, raw water recirculated after passing over cooling tower or spray pond
System C, soft water continuously recirculated, cooled by raw water going to waste after one pass through heat exchanger
System D, soft water continuously recirculated, cooled by raw water also recirculated after cooling by cooling tower or spray pond
System E, any of the foregoing systems with engine circulating water treated (added as a suffix).

Investment Costs. Last year the committee presented a short table of fixed charges. This year it was considered more informative to present investment costs. Table VI sets forth the actual expenditures for land, buildings, and equipment in whole or part by plants, specifying, where possible, in what years the expenditures were made. It is hoped that in next year's report more complete data can be presented on these items.

The committee invites discussion on the following items which it suggests for the 1931 questionnaire:

Enforced Shutdowns. The committee proposes to ask in future for:

(*a*) Number and total duration of enforced shutdowns due to engine failures
(*b*) Number and total duration of enforced shutdowns for all failures other than engine failures.

Peak Loads. The duration of peak loads has heretofore not been specified. Some operators report instantaneous peaks, others 15-minute peaks, a few hourly peaks, and one operator reported 24-hour peaks. The committee proposes to define peak load as the highest average load sustained for 15 minutes.

Liner Wear. No specification has been previously given for the measurement of liner wear. The committee proposes to stipulate in the future that this measurement be the average of the wear in inches in all the cylinders of the engine, the wear in each cylinder to be found by averaging two measurements, one taken parallel to the crankshaft, the other at 90° to the crankshaft, both taken at the point of greatest wear, which in most cases will be at the top of the piston-ring travel.

Supplies and Repairs. There still exists some confusion as to what is included in the terms "supplies," "repairs," and "miscellaneous." Rather than set up another standard, the committee suggests definitions presented in the "Uniform Classification of Accounts for Electrical Utilities," published by the National Association of Railway and Utilities Commissioners.

Under "Account A707.22" "Production Supplies" are defined as items "used in the power generating plant which are consumed in the operating process, the replacement of which does not constitute a repair or renewal." The principal items are listed as "waste, packing, wipers, gage glasses, gaskets, bolts, screws, nails, dynamo and motor brushes, cans for containing rags and waste, transformer oil and hand oil cans." A definition is given under "Account A707.23" which the committee suggests for "miscellaneous." The items listed are "lighting, heating, and cleaning systems, fire-protection systems, janitor's supplies, ice water, meals and carfares, stationery, telephone and toilet service, care of streets, yards, and sidings."

Investment Cost. There seems to be some uncertainty as to what items belong properly under "land," "buildings," and "equipment." The committee suggests the following divisions:

Land—real estate, clearing, grading, draining, sodding, roads, walks, fences, legal fees.

Buildings—drainage or unwatering, excavation and backfill, piling, concrete work (except equipment foundations), structural steel, walls, floors, roof, doors, windows, skylights, millwork, painting and finishing, heating and ventilating provisions, plumbing and toilet facilities, lighting and building wiring, fire protection, offices, shops, warehouses, and other outbuildings.

Equipment—crane, crane runway, cooling system including pond or tower, oil storage and handling facilities, engines, generators, auxiliaries, and their foundations, lubricating, oil handling, and purifying equipment, air ducts and filters, exhaust mufflers, station piping, switchboards, control and protective equipment, but not including outside electrical structures.

Type of Load. The committee suggests the following definitions:

Complete Power—The plant is run regularly alone when needed, without assistance from any base- or peak-load service.

Base Load—The plant is run at substantially full load whenever its capacity can be used, usually supplemented by a peak-load service. When full or nearly full capacity cannot be used, the plant is shut down.

Peak Load—The plant is run only when the load exceeds the capacity of the regular source of power.

Standby—The plant is run only when the regular source of power is interrupted.

Seasonal—Any of the foregoing types of loads may apply to a "seasonal" plant; i.e., one which is operated normally for annually recurring periods, between which it is shut down.

SUB-COMMITTEE ON OIL ENGINE POWER COST

NOTES: Character of Plant
U - Private Power Company
P - Private Pumping Company
M - Municipal Power Plant
W - Municipal Pumping Plant
I - Industrial Power Plant

Type of Load
C - Complete Power
B - Base Load
S - Standby
P - Peak Load

Numbered Notes
1 - Estimated by Operator.
2 - Estimated by the Committee.
3 - Includes Water Department Labor also.
4 - Includes Steam Plant Labor also.

TABLE II - COMPARATIVE COSTS - 1929 REPORT AND 1930 REPORT (Corrected)

TABLE III INFORMATION COVERING LUBRICATING OIL (Page 3)

Plant Number	Engine Designation	Engine Cycle	Injection System - See Notes	Scavenging System - See Notes	Trunk Piston or Cross Head	Rated B.H.P.	Number of Cylinders	Cylinder Bore - Inches	Stroke - Inches	Rated R.P.M.	Generator Rating - K.W.	Year Engine Started to Work	Engine Hours Operated in Reported Period	Rated Horsepower Hours in Reported Period	Gallons of New Lubricating Oil Used	Gallons of Unfit Lubricating Oil Discarded	Rated H.P. Hrs. per Gallon of New Lubricating Oil	Running Engine Capacity Factor (See Text)	Running Plant Capacity Factor (See Text)	Gross Output - K.W. Hrs.	Gross K.W. Hrs. per Gallon of New Lubricating Oil	Lubricating Oil Treatment - (See Notes)	Average Cost of Lubricating Oil - Cents per Gallon

NOTES:

INJECTION SYSTEM

A - Air
M - Mechanical

SCAVENGING SYSTEM

S - Separate (i.e., Pump or Blower)
CC - Crankcase (for 2-Stroke Cycle Only)

LUBRICATING OIL TREATMENT

CC - Continuous Centrifuging.
BC - "BATCH" Centrifuging
C - Chemically
F - Filtering
S - Settling

NUMBERED NOTES

1. Speeded up and Connected to New Generator since last Report
2. Name Plates are 700 and 1400 K.W.
3. April 4. February 5. October
6. Rated 450 KVA. 7. September
8. Horizontal Engine. 9. December
10. Semi-Diesel Engine
11. Cost includes Import Duty
12. August
13. March - the start of the Period.
14. No. 1 Engine has Plain Rings; No. 2 has Special Rings
15. Installed in Plt. #103 in August, 1930
16. Installed in Plt. #102 in October, 1930
17. Estimated by Operator
